Human milk contains around 200 mmol/L (68 g/L) of lactose, which is normally digested to glucose and galactose by the brush border enzyme lactase prior to absorption. In most populations, enterocyte lactase activity declines throughout childhood. The enzyme is deficient in up to 90% of adult Africans, Asians and South Americans, but only 5% of northern Europeans.

In cases of genetically determined (primary) lactase deficiency, jejunal morphology is normal. 'Secondary' lactase deficiency occurs as a consequence of disorders which damage the jejunal mucosa, such as coeliac disease and viral gastroenteritis. Unhydrolysed lactose enters the colon, where bacterial fermentation produces volatile short-chain fatty acids, hydrogen and carbon dioxide.

Clinical features

In most people, lactase deficiency is completely asymptomatic. However, some complain of colicky pain,

abdominal distension, increased flatus, borborygmi and diarrhoea after ingesting milk or milk products. Irritable bowel syndrome may be suspected but the correct diagnosis is suggested by clinical improvement on lactose withdrawal. The lactose hydrogen breath test is a useful non-invasive confirmatory investigation.

Dietary exclusion of lactose is recommended, although most sufferers are able to tolerate small amounts of milk without symptoms. Addition of commercial lactase preparations to milk has been effective in some studies but is costly.

Intolerance of other sugars

'Osmotic' diarrhoea can be caused by sorbitol, an unabsorbable carbohydrate which is used as an artificial sweetener. Fructose contained within fruit juices may also cause diarrhoea if it is consumed in greater quantities than can be absorbed.

Food allergy

Food allergies are immune-mediated disorders, most commonly due to type I hypersensitivity reactions with production of IgE antibodies, although type IV delayed hypersensitivity reactions are also seen. Up to 20% of the population perceive themselves as suffering from food allergy but only 1–2% of adults and 5–7% of children have genuine food allergies. The most common culprits are peanuts, milk, eggs, soya and shellfish.

Clinical manifestations occur immediately on exposure and range from trivial to life-threatening or even fatal anaphylaxis. The common oral allergy syndrome results from contact with benzoic acid in certain fresh fruit juices, leading to urticaria and angioedema of the lips and oropharynx. This is not, however, an immune-mediated reaction. 'Allergic gastroenteropathy' has features similar to eosinophilic gastroenteritis, while 'gastrointestinal anaphylaxis' consists of nausea, vomiting, diarrhoea and sometimes cardiovascular and respiratory collapse. Fatal reactions to trace amounts of peanuts are well documented.

The diagnosis of food allergy is difficult to prove or refute. Skin prick tests and measurements of antigen-specific IgE antibodies in serum have limited predictive value. Double-blind placebo-controlled food challenges are the gold standard, but are laborious and are not readily available. In many cases, clinical suspicion and trials of elimination diets are used.

Treatment of proven food allergy consists of detailed patient education and awareness, strict elimination of the offending antigen, and, in some cases, antihistamines or sodium cromoglicate. Anaphylaxis should be treated as a medical emergency with resuscitation, airway support and intravenous adrenaline (epinephrine). Teachers and other carers of affected children should be trained to deal with this. Patients should wear an information bracelet and be taught to carry and use a preloaded adrenaline syringe.

Infections of the small intestine

Travellers' diarrhoea, giardiasis and amoebiasis

See pages 310, 368 and 367.

Abdominal tuberculosis

Mycobacterium tuberculosis is a rare cause of abdominal disease in Caucasians but must be considered in people in and from the developing world and in AIDS patients. Gut infection usually results from human *M. tuberculosis*, which is swallowed after coughing. Many patients have no pulmonary symptoms and a normal chest X-ray.

The area most commonly affected is the ileocaecal region. The presentation and radiological findings may be very similar to those of Crohn's disease. Abdominal pain can be acute or of several months' duration, but diarrhoea is less common in tuberculosis than in Crohn's disease. Low-grade fever is common but not invariable. Like Crohn's disease, tuberculosis can affect any part of the gastrointestinal tract, and perianal disease with fistula is recognised. Peritoneal tuberculosis may result in peritonitis with exudative ascites, associated with abdominal pain and fever. Granulomatous hepatitis occurs.

Diagnosis

Abdominal tuberculosis causes an elevated ESR; a raised serum alkaline phosphatase concentration suggests hepatic involvement. Histological confirmation should be sought by endoscopy, laparoscopy or liver biopsy. Caseation of granulomas is not always seen and acid- and alcohol-fast bacteria are often scanty. Culture may be helpful but identification of the organism may take 6 weeks and diagnosis is now possible on biopsy specimens using PCR-based techniques.

Management

When the presentation is very suggestive of abdominal tuberculosis, chemotherapy with four drugs – isoniazid, rifampicin, pyrazinamide and ethambutol (p. 691) – should be commenced, even if bacteriological or histological proof is lacking.

Cryptosporidiosis

Cryptosporidiosis and other protozoal infections, including isosporiasis (*Isospora belli*) and microsporidiosis, are dealt with on pages 369 and 399.

Tumours of the small intestine

The small intestine is rarely affected by neoplasia, and fewer than 5% of all gastrointestinal tumours occur at this site.

Benign tumours

The most common are adenomas, GIST, lipomas and hamartomas. Adenomas are most often found in the periampullary region and are usually asymptomatic, although occult bleeding or obstruction due to intussusception may occur. Transformation to adenocarcinoma is rare. Multiple adenomas are common in the duodenum of patients with familial adenomatous polyposis (FAP), who merit regular endoscopic surveillance. Hamartomatous polyps with almost no malignant potential occur in Peutz–Jeghers syndrome (p. 912).

Malignant tumours

These are rare and include, in decreasing order of frequency, adenocarcinoma, carcinoid tumour, malignant GIST and lymphoma. The majority occur in middle age or later. Kaposi's sarcoma of the small bowel may arise in patients with AIDS.

Adenocarcinomas

Adenocarcinomas occur with increased frequency in patients with FAP, coeliac disease and Peutz–Jeghers syndrome. The non-specific presentation and rarity of these lesions often lead to delay in diagnosis. Barium follow-through examination or small bowel enema studies demonstrate most lesions of this type. Enteroscopy, capsule endoscopy, mesenteric angiography and CT also play a role in investigation. Treatment is by surgical resection.

Neuro-endocrine tumours

Also known as carcinoid tumours, these are derived from enterochromaffin cells and are most common in the appendix. Localised spread and the potential for metastasis to the liver increase with primary lesions over 2 cm in diameter. They also occur in the rectum and in the appendix; those in the appendix are usually benign. Overall, these tumours are less aggressive than carcinomas and their growth is usually slow.

Symptoms depend on the location of the tumour and whether or not it is producing hormones or vasoactive peptides. The term 'carcinoid syndrome' refers to the systemic symptoms that result when secretory products of the neoplastic enterochromaffin cells reach the systemic circulation (Box 22.60). When produced by the primary tumour, they are usually metabolised in the liver and do not reach the systemic circulation. The syndrome is therefore only seen with hepatic metastases.

Management

The treatment is surgical resection. The treatment of carcinoid syndrome is palliative because hepatic metastases have already occurred, although prolonged survival is common. Surgical removal of the primary tumour and hepatic metastases may be of value, as reduction of tumour mass (cytoreductive surgery) improves symptoms. Hepatic artery embolisation is another option, since it can retard growth of hepatic deposits. Octreotide (200 µg 3 times daily by subcutaneous injection) can be used to reduce release of 5-HT, bradykinin and peptide hormones by the tumour. Cytotoxic chemotherapy with streptozotocin and 5-fluorouracil has limited benefits and is reserved as second-line therapy after other therapies have failed.

22.60 Clinical features of neuro-endocrine tumours*

- Small-bowel obstruction due to the tumour mass
- Intestinal ischaemia (due to mesenteric infiltration or vasospasm)
- Hepatic metastases causing pain, hepatomegaly and jaundice
- Flushing and wheezing
- Diarrhoea
- Cardiac involvement (tricuspid regurgitation, pulmonary stenosis, right ventricular endocardial plaques) leading to heart failure
- Facial telangiectasia

*The diagnosis is made by detecting excess levels of the 5-HT metabolite, 5-HIAA, in a 24-hr urine collection and by raised serum chromogranin A levels.

Lymphoma

Non-Hodgkin lymphoma (p. 1043) may involve the gastrointestinal tract as part of more generalised disease or may rarely arise in the gut, the small intestine being most commonly affected. Lymphomas occur with increased frequency in patients with coeliac disease, HIV-AIDS and other immunodeficiency states. Most are of B-cell origin, although lymphoma associated with coeliac disease is derived from T cells (enteropathy-associated T-cell lymphoma).

Colicky abdominal pain, obstruction and weight loss are the presenting features, and perforation is also occasionally seen. Malabsorption is a feature of diffuse bowel involvement and hepatosplenomegaly is rare.

The diagnosis is made by small bowel biopsy, radiological contrast studies and CT. Staging investigations should be performed as for lymphomas occurring elsewhere (p. 1042). Surgical resection, where possible, is the treatment of choice, with radiotherapy and combination chemotherapy reserved for those with advanced disease. The prognosis depends largely on the stage at diagnosis, cell type, patient age and the presence of 'B' symptoms (fever, weight loss, night sweats).

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID), also known as alpha heavy chain disease, is a rare condition occurring mainly in Mediterranean countries, the Middle East, India, Pakistan and North America. It is a variant of B-cell lymphoma of MALT type and often associated with *Campylobacter jejuni* infection. The condition varies in severity from relatively benign to frankly malignant.

The small intestinal mucosa is diffusely affected, especially proximally, by a dense lymphoplasmacytic infiltrate. Enlarged mesenteric lymph nodes are also common. Most patients are young adults, who present with malabsorption, anorexia and fever. Serum electrophoresis confirms the presence of alpha heavy chains (from the F_c portion of IgA). Prolonged remissions can be obtained with long-term antibiotic therapy, but chemotherapy is required for those who fail to respond or who have aggressive disease.

DISEASES OF THE PANCREAS

Acute pancreatitis

Acute pancreatitis accounts for 3% of all cases of abdominal pain admitted to hospital. It affects 2–28 per 100 000 of the population and is increasing in incidence. It is a potentially serious condition with an overall mortality of 10%. About 80% of all cases are mild and have a favourable outcome. About 98% of deaths from pancreatitis occur in the 20% of patients with severe disease and about one-third of these occur within the first week, usually from multi-organ failure. After this time, the majority of deaths result from sepsis, especially that

22.61 Glasgow criteria for prognosis in acute pancreatitis*

- Age > 55 yrs
- PO_2 < 8 kPa (60 mmHg)
- White blood cell count (WBC) > 15×10^9/L
- Albumin < 32 g/L (3.2 g/dL)
- Serum calcium < 2 mmol/L (8 mg/dL) (corrected)
- Glucose > 10 mmol/L (180 mg/dL)
- Urea > 16 mmol/L (45 mg/dL) (after rehydration)
- Alanine aminotransferase (ALT) > 200 U/L
- Lactate dehydrogenase (LDH) > 600 U/L

*Severity and prognosis worsen as the number of these factors increases. More than three implies severe disease.

22.62 Features that predict severe pancreatitis

Initial assessment

- Clinical impression of severity
- Body mass index > 30
- Pleural effusion on chest X-ray
- APACHE II score > 8

24 hrs after admission

- Clinical impression of severity
- APACHE II score > 8
- Glasgow score > 3
- Persisting organ failure, especially if multiple
- CRP > 150 mg/L

48 hrs after admission

- Clinical impression of severity
- Glasgow score > 3
- CRP > 150 mg/L
- Persisting organ failure for 48 hrs
- Multiple or progressive organ failure

(CRP = C-reactive protein)

complicating infected necrosis. At admission, it is possible to predict patients at risk of these complications (Box 22.61). Patients who are predicted to have severe pancreatitis (Box 22.62) and those with necrosis or other complications should be managed in a specialist centre with an intensive therapy unit and multidisciplinary hepatobiliary specialists.

Pathophysiology

Acute pancreatitis occurs as a consequence of premature intracellular trypsinogen activation, releasing proteases which digest the pancreas and surrounding tissue. Triggers for this are many, including alcohol, gallstones and pancreatic duct obstruction (Fig. 22.41). There is simultaneous activation of nuclear factor kappa B (NFκB), leading to mitochondrial dysfunction, autophagy and a vigorous inflammatory response. The normal pancreas has only a poorly developed capsule, and adjacent structures, including the common bile duct, duodenum, splenic vein and transverse colon, are commonly involved in the inflammatory process. The severity of acute pancreatitis is dependent upon the balance between the activity of released proteolytic enzymes and antiproteolytic factors. The latter comprise an intracellular pancreatic trypsin inhibitor protein and circulating

22.63 Causes of acute pancreatitis

Common (90% of cases)

- Gallstones
- Alcohol
- Idiopathic
- Post-ERCP

Rare

- Post-surgical (abdominal, cardiopulmonary bypass)
- Trauma
- Drugs (azathioprine/mercaptopurine, thiazide diuretics, sodium valproate)
- Metabolic (hypercalcaemia, hypertriglyceridaemia)
- Pancreas divisum (p. 894)
- Sphincter of Oddi dysfunction
- Infection (mumps, Coxsackie virus)
- Hereditary
- Renal failure
- Organ transplantation (kidney, liver)
- Severe hypothermia
- Petrochemical exposure

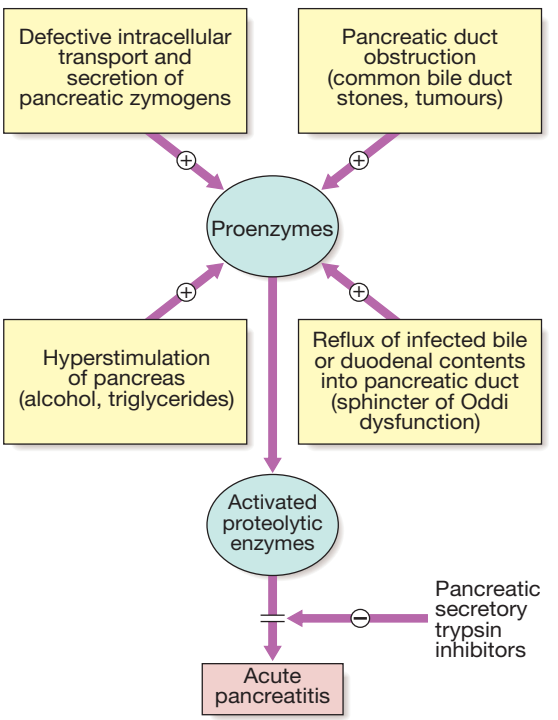

Fig. 22.41 Pathophysiology of acute pancreatitis.

β_2-macroglobulin, α_1-antitrypsin and Cl-esterase inhibitors. The causes of acute pancreatitis are listed in Box 22.63. Acute pancreatitis is often self-limiting, but in some patients with severe disease, local complications, such as necrosis, pseudocyst or abscess, occur, as well as systemic complications that lead to multi-organ failure.

Clinical features

The typical presentation is with severe, constant upper abdominal pain, of increasing intensity over 15–60 minutes, which radiates to the back. Nausea and vomiting are common. There is marked epigastric tenderness, but in the early stages (and in contrast to a perforated peptic ulcer), guarding and rebound

22.64 Complications of acute pancreatitis

Complication	Cause
Systemic	
Systemic inflammatory response syndrome (SIRS)	Increased vascular permeability from cytokine, platelet aggregating factor and kinin release
Hypoxia	Acute respiratory distress syndrome (ARDS) due to microthrombi in pulmonary vessels
Hyperglycaemia	Disruption of islets of Langerhans with altered insulin/glucagon release
Hypocalcaemia	Sequestration of calcium in fat necrosis, fall in ionised calcium
Reduced serum albumin concentration	Increased capillary permeability
Pancreatic	
Necrosis	Non-viable pancreatic tissue and peripancreatic tissue death; frequently infected
Abscess	Circumscribed collection of pus close to the pancreas and containing little or no pancreatic necrotic tissue
Pseudocyst	Disruption of pancreatic ducts
Pancreatic ascites or pleural effusion	Disruption of pancreatic ducts
Gastrointestinal	
Upper gastrointestinal bleeding	Gastric or duodenal erosions
Variceal haemorrhage	Splenic or portal vein thrombosis
Erosion into colon	
Duodenal obstruction	Compression by pancreatic mass
Obstructive jaundice	Compression of common bile duct

tenderness are absent because the inflammation is principally retroperitoneal. Bowel sounds become quiet or absent as paralytic ileus develops. In severe cases, the patient becomes hypoxic and develops hypovolaemic shock with oliguria. Discoloration of the flanks (Grey Turner's sign) or the periumbilical region (Cullen's sign) is a feature of severe pancreatitis with haemorrhage. The differential diagnosis includes a perforated viscus, acute cholecystitis and myocardial infarction. Various complications may occur and these are listed in Box 22.64.

A collection of fluid and debris may develop in the lesser sac, following inflammatory rupture of the pancreatic duct; this is known as a pancreatic fluid collection. It is initially contained within a poorly defined, fragile wall of granulation tissue, which matures over a 6-week period to form a fibrous capsule (Fig. 22.42). Such 'pseudocysts' are common and usually asymptomatic, resolving as the pancreatitis recovers.

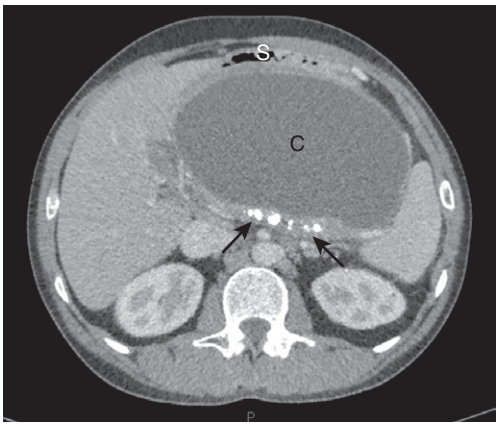

Fig. 22.42 CT showing large pancreatic pseudocyst (C) compressing the stomach (S). The pancreas is atrophic and calcified (arrows).

Pseudocysts greater than 6 cm in diameter seldom disappear spontaneously and can cause constant abdominal pain and compress or erode surrounding structures, including blood vessels, to form pseudoaneurysms. Large pseudocysts can be detected clinically as a palpable abdominal mass.

Pancreatic ascites occurs when fluid leaks from a disrupted pancreatic duct into the peritoneal cavity. Leakage into the thoracic cavity can result in a pleural effusion or a pleuro-pancreatic fistula.

Investigations

The diagnosis is based upon raised serum amylase or lipase concentrations and ultrasound or CT evidence of pancreatic swelling. Plain X-rays should be taken to exclude other diagnoses, such as perforation or obstruction, and to identify pulmonary complications. Amylase is efficiently excreted by the kidneys, and concentrations may have returned to normal if measured 24–48 hours after the onset of pancreatitis. A persistently elevated serum amylase concentration suggests pseudocyst formation. Peritoneal amylase concentrations are massively elevated in pancreatic ascites. Serum amylase concentrations are also elevated (but less so) in intestinal ischaemia, perforated peptic ulcer and ruptured ovarian cyst, whilst the salivary isoenzyme of amylase is elevated in parotitis. If available, serum lipase measurements are preferable to amylase, as they have greater diagnostic accuracy for acute pancreatitis.

Ultrasound scanning can confirm the diagnosis, although in the earlier stages the gland may not be grossly swollen. The ultrasound scan is also useful because it may show gallstones, biliary obstruction or pseudocyst formation.

Contrast-enhanced pancreatic CT 6–10 days after admission can be useful in assessing viability of the pancreas if persisting organ failure, sepsis or clinical deterioration is present, since these features may indicate that pancreatic necrosis has occurred. Necrotising pancreatitis is associated with decreased pancreatic enhancement on CT, following intravenous injection of contrast material. The presence of gas within necrotic material (Fig. 22.43) suggests infection and impending abscess formation, in which case percutaneous aspiration of material for bacterial culture should be carried out and

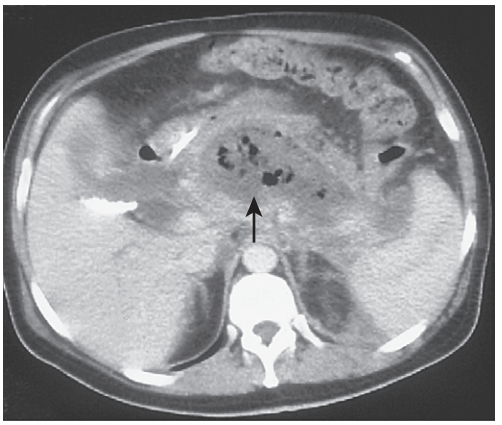

Fig. 22.43 Pancreatic necrosis. Lack of vascular enhancement of the pancreas during contrast-enhanced CT indicates necrosis (arrow). The presence of gas suggests that infection has occurred.

appropriate antibiotics prescribed. Involvement of the colon, blood vessels and other adjacent structures by the inflammatory process is best seen by CT.

Certain investigations stratify the severity of acute pancreatitis and have important prognostic value at the time of presentation (see Boxes 22.61 and 22.62). In addition, serial assessment of C-reactive protein (CRP) is a useful indicator of progress. A peak CRP > 210 mg/L in the first 4 days predicts severe acute pancreatitis with 80% accuracy. It is worth noting that the serum amylase concentration has no prognostic value.

Management

Management comprises several related steps:

- establishing the diagnosis and disease severity
- early resuscitation, according to whether the disease is mild or severe
- detection and treatment of complications
- treating the underlying cause.

Opiate analgesics should be given to treat pain and hypovolaemia should be corrected using normal saline or other crystalloids. All severe cases should be managed in a high-dependency or intensive care unit. A central venous line and urinary catheter should be established to monitor patients with shock. Oxygen should be given to hypoxic patients, and those who develop systemic inflammatory response syndrome (SIRS) may require ventilatory support. Hyperglycaemia should be corrected using insulin, but it is not usually necessary to correct hypocalcaemia by intravenous calcium injection, unless tetany occurs.

Nasogastric aspiration is only required if paralytic ileus is present. Enteral feeding, if tolerated, should be started at an early stage in patients with severe pancreatitis because they are in a severely catabolic state and need nutritional support (Box 22.65). Enteral feeding decreases endotoxaemia and so may reduce systemic complications. Nasogastric feeding is just as effective as the nasojejunal route. Prophylaxis of thromboembolism with subcutaneous low-molecular-weight heparin is also advisable. The use of prophylactic, broad-spectrum intravenous antibiotics, such as imipenem or cefuroxime, to prevent infection of pancreatic necrosis is of unproven benefit but they are often given empirically.

EBM 22.65 Enteral versus total parenteral nutritional (TPN) support in acute pancreatitis

'Enteral nutrition significantly reduced mortality, multiple organ failure, systemic infections and the need for operative interventions, compared to TPN. Enteral nutrition should be considered the standard of care for patients with acute pancreatitis requiring nutritional support.'

- Al-Omran M, et al. Cochrane Database of Systematic Reviews, 2010, issue 1. Art. no. CD002837.

For further information: www.cochrane.org/cochrane-reviews

Patients who present with cholangitis or jaundice in association with severe acute pancreatitis should undergo urgent ERCP to diagnose and treat choledocholithiasis. In less severe cases of gallstone pancreatitis, biliary imaging (using MRCP or EUS) can be carried out after the acute phase has resolved. If the liver function tests return to normal and ultrasound has not demonstrated a dilated biliary tree, laparoscopic cholecystectomy with an on-table cholangiogram is appropriate because any common bile duct stones have probably passed. When the operative cholangiogram detects residual common bile duct stones, these should be removed by laparoscopic exploration of the duct or by post-operative ERCP. Cholecystectomy should be undertaken within 2 weeks of resolution of pancreatitis – and preferably during the same admission – to prevent further potentially fatal attacks of pancreatitis. Patients with necrotising pancreatitis or pancreatic abscess require urgent endoscopic or minimally invasive retroperitoneal pancreatic (MIRP) necrosectomy to debride all cavities of necrotic material. Pancreatic pseudocysts can be treated by drainage into the stomach, duodenum or jejunum. This is usually performed after an interval of at least 6 weeks, once a pseudocapsule has matured, by surgical or endoscopic cystogastrostomy.

Chronic pancreatitis

Chronic pancreatitis is a chronic inflammatory disease characterised by fibrosis and destruction of exocrine pancreatic tissue. Diabetes mellitus occurs in advanced cases because the islets of Langerhans are involved.

Pathophysiology

Around 80% of cases in Western countries result from alcohol misuse. In southern India, severe chronic calcific pancreatitis occurs in non-alcoholics, possibly as a result of malnutrition and cassava consumption. Other causes are listed in Box 22.66. The pathophysiology of chronic pancreatitis is shown in Figure 22.44.

Clinical features

Chronic pancreatitis predominantly affects middle-aged alcoholic men. Almost all present with abdominal pain. In 50%, this occurs as episodes of 'acute pancreatitis', although each attack results in a degree of permanent pancreatic damage. Relentless, slowly progressive chronic pain without acute exacerbations affects 35% of patients, whilst the remainder have no pain but present with diarrhoea. Pain is due to a combination of increased pressure within the pancreatic ducts and

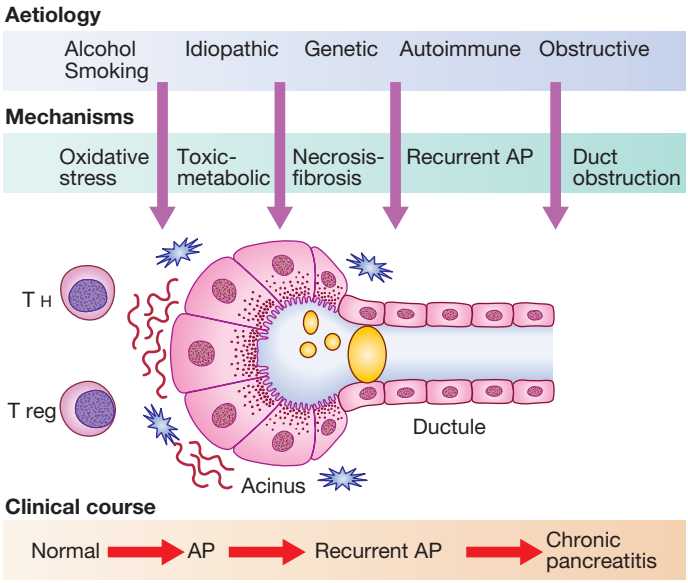

Fig. 22.44 Pathophysiology of chronic pancreatitis. Alcohol and other risk factors may trigger acute pancreatitis (AP) through multiple mechanisms. The first (or 'sentinel') episode of acute pancreatitis initiates an inflammatory response involving T-helper cells. Ongoing exposure to alcohol drives further inflammation but this is modified by regulatory T cells with subsequent fibrosis, via activation of pancreatic stellate cells. A cycle of inflammation and fibrosis ensues, with development of chronic pancreatitis. Alcohol is the most relevant risk factor, as it is involved at multiple steps.

22.66 Causes of chronic pancreatitis*

Toxic–metabolic	
• Alcohol • Tobacco	• Hypercalcaemia • Chronic renal failure
Idiopathic	
• Tropical	• Early-/late-onset types
Genetic	
• Hereditary pancreatitis (cationic trypsinogen mutation)	• *SPINK-1* mutation • Cystic fibrosis
Autoimmune	
• Isolated or as part of multi-organ problem	
Recurrent and severe acute pancreatitis	
• Recurrent acute pancreatitis	• Post-necrotic
Obstructive	
• Ductal adenocarcinoma • Intraductal papillary mucinous neoplasia	• Pancreas divisum • Sphincter of Oddi stenosis

*These can be memorised by the mnemonic 'TIGARO'. Gallstones do not cause chronic pancreatitis but may be observed as an incidental finding.

22.67 Complications of chronic pancreatitis

- Pseudocysts and pancreatic ascites, which occur in both acute and chronic pancreatitis
- Obstructive jaundice due to benign stricture of the common bile duct as it passes through the diseased pancreas
- Duodenal stenosis
- Portal or splenic vein thrombosis leading to segmental portal hypertension and gastric varices
- Peptic ulcer

22.68 Investigations in chronic pancreatitis

Tests to establish the diagnosis
• Ultrasound • CT (may show atrophy, calcification or ductal dilatation) • Abdominal X-ray (may show calcification) • MRCP • Endoscopic ultrasound
Tests of pancreatic function
• Collection of pure pancreatic juice after secretin injection (gold standard but invasive and seldom used) • Pancreolauryl test (see Box 22.12, p. 851) • Faecal pancreatic elastase
Tests of anatomy prior to surgery
• MRCP

direct involvement of peripancreatic nerves by the inflammatory process. Pain may be relieved by leaning forwards or by drinking alcohol. Approximately one-fifth of patients chronically consume opiate analgesics. Weight loss is common and results from a combination of anorexia, avoidance of food because of post-prandial pain, malabsorption and/or diabetes. Steatorrhoea occurs when more than 90% of the exocrine tissue has been destroyed; protein malabsorption only develops in the most advanced cases. Overall, 30% of patients are diabetic, but this figure rises to 70% in those with chronic calcific pancreatitis. Physical examination reveals a thin, malnourished patient with epigastric tenderness. Skin pigmentation over the abdomen and back is common and results from chronic use of a hot water bottle (*erythema ab igne*). Many patients have features of other alcohol- and smoking-related diseases. Complications are listed in Box 22.67.

Investigations

Investigations (Box 22.68 and Fig. 22.45) are carried out to:

- make a diagnosis of chronic pancreatitis
- define pancreatic function
- demonstrate anatomical abnormalities prior to surgical intervention.

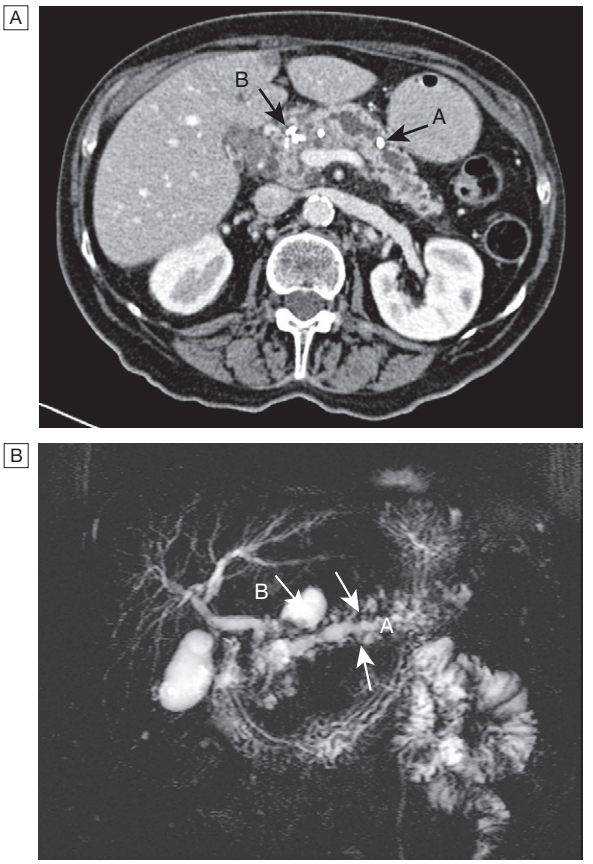

Fig. 22.45 Imaging in chronic pancreatitis. A CT scan showing a grossly dilated and irregular duct with a calcified stone (arrow A). Note the calcification in the head of the gland (arrow B). B MRCP of the same patient showing marked ductal dilatation with abnormal dilated side branches (arrows A). A small cyst is also present (arrow B).

Management

Alcohol misuse

Alcohol avoidance is crucial in halting progression of the disease and reducing pain.

Pain relief

A range of analgesic drugs, particularly NSAIDs, are valuable, but the severe and unremitting nature of the pain often leads to opiate use with the risk of addiction. Oral pancreatic enzyme supplements suppress pancreatic secretion and their regular use reduces analgesic consumption in some patients. Patients who are abstinent from alcohol and who have severe chronic pain which is resistant to conservative measures should be considered for surgical or endoscopic pancreatic therapy (Box 22.69). Coeliac plexus neurolysis sometimes produces long-lasting pain relief, although relapse occurs in the majority of cases. In some patients, MRCP does not show a surgically or endoscopically correctable abnormality and, in these patients, the only surgical approach is total pancreatectomy. Unfortunately, even after this operation, some patients continue to experience pain. Moreover, the procedure causes diabetes, which may be difficult to control, with a high risk of hypoglycaemia (since both insulin and glucagon release are absent), and significant morbidity and mortality.

22.69 Intervention in chronic pancreatitis

Endoscopic therapy
• Dilatation or stenting of pancreatic duct strictures • Removal of calculi (mechanical or shock-wave lithotripsy) • Drainage of pseudocysts
Surgical methods
• Partial pancreatic resection, preserving the duodenum • Pancreatico-jejunostomy

Malabsorption

This is treated by dietary fat restriction (with supplementary medium-chain triglyceride therapy in malnourished patients) and oral pancreatic enzyme supplements. A PPI is added to optimise duodenal pH for pancreatic enzyme activity.

Management of complications

Surgical or endoscopic therapy may be necessary for the management of pseudocysts, pancreatic ascites, common bile duct or duodenal stricture and the consequences of portal hypertension. Many patients with chronic pancreatitis also require treatment for other alcohol- and smoking-related diseases and for the consequences of self-neglect and malnutrition.

Autoimmune pancreatitis

Autoimmune pancreatitis (AIP) is a form of chronic pancreatitis that can mimic cancer but which responds to corticosteroids. It is characterised by abdominal pain, weight loss or obstructive jaundice, without acute attacks of pancreatitis. Blood tests reveal increased serum IgG or IgG4, and the presence of other autoantibodies. Imaging shows a diffusely enlarged pancreas, narrowing of the pancreatic duct and stricturing of the lower bile duct. AIP may occur alone or with other autoimmune disorders, such as Sjögren's syndrome, primary sclerosing cholangitis (PSC) or inflammatory bowel disease. The response to steroids is usually excellent but some patients require azathioprine.

Congenital abnormalities affecting the pancreas

Pancreas divisum

This is due to failure of the primitive dorsal and ventral ducts to fuse during embryonic development of the pancreas. As a consequence, most of the pancreatic drainage occurs through the smaller accessory ampulla rather than through the major ampulla. The condition occurs in 7–10% of the normal population and is usually asymptomatic, but some patients develop acute pancreatitis, chronic pancreatitis or atypical abdominal pain.

Annular pancreas

In this congenital anomaly, the pancreas encircles the second/third part of the duodenum, leading to gastric outlet obstruction. Annular pancreas is associated with malrotation of the intestine, atresias and cardiac anomalies.

Cystic fibrosis

This disease is considered in detail on page 680. The major gastrointestinal manifestations are pancreatic insufficiency and meconium ileus. Peptic ulcer and hepatobiliary disease may also occur. In cystic fibrosis, pancreatic secretions are protein- and mucus-rich. The resultant viscous juice forms plugs which obstruct the pancreatic ductules, leading to progressive destruction of acinar cells. Steatorrhoea is universal and the large-volume bulky stools predispose to rectal prolapse. Malnutrition is compounded by the metabolic demands of respiratory failure and by diabetes, which develops in 40% of patients by adolescence.

Most patients now survive well into adulthood and heart/lung transplantation can further prolong life. Optimal treatment depends upon an assiduous team approach to respiratory, nutritional and hepatobiliary complications. Nutritional counselling and supervision are important to ensure intake of high-energy foods, providing 120–150% of the recommended intake for normal subjects. Fats are an important calorie source and, despite the presence of steatorrhoea, fat intake should not be restricted. Supplementary fat-soluble vitamins are also necessary. High-dose oral pancreatic enzymes are required, in doses sufficient to control steatorrhoea and stool frequency. A PPI aids fat digestion by producing an optimal duodenal pH. Diabetic patients usually require insulin injections rather than oral hypoglycaemic agents.

Meconium ileus

Mucus-rich plugs within intestinal contents can obstruct the small or large intestine. Meconium ileus is treated by the mucolytic agent N-acetylcysteine, given orally, by Gastrografin enema or by gut lavage using polyethylene glycol. In resistant cases of meconium ileus, surgical resection may be necessary.

Tumours of the pancreas

Pancreatic carcinoma affects 10–15 per 100 000 in Western populations, rising to 100 per 100 000 in those over the age of 70. Men are affected twice as often as women. The disease is associated with increasing age, smoking and chronic pancreatitis. Between 5 and 10% of patients have a genetic predisposition (hereditary pancreatitis, MEN, hereditary non-polyposis colon cancer (HNPCC) and familial atypical mole multiple melanoma syndrome (FAMMM). Overall survival is only 3–5%, with median survival of 6–10 months for those with locally advanced disease and 3–5 months if metastases are present.

Pathophysiology

Some 90% of pancreatic neoplasms are adenocarcinomas which arise from the pancreatic ducts. These tumours involve local structures and metastasise to regional lymph nodes at an early stage. Most patients have advanced disease at the time of presentation.

Clinical features

Many patients are asymptomatic until an advanced stage, when they present with central abdominal pain, weight loss and obstructive jaundice (Fig. 22.46). The pain results from invasion of the coeliac plexus and is characteristically incessant and gnawing. It often radiates from the upper abdomen through to the back and may be eased a little by bending forwards. Almost all patients lose weight and many are cachectic. Around 60% of tumours arise from the head of the pancreas, and involvement of the common bile duct results in the development of obstructive jaundice, often with severe pruritus. A few patients present with diarrhoea, vomiting from duodenal obstruction, diabetes mellitus, recurrent venous thrombosis, acute pancreatitis or depression. Physical examination reveals clear evidence of weight loss. An abdominal mass due to the tumour itself, a palpable gallbladder or hepatic metastasis is commonly found. A palpable gallbladder in a jaundiced patient is usually the consequence of distal biliary obstruction by a pancreatic cancer (Courvoisier's sign).

Investigations

The diagnosis is usually made by ultrasound and contrast-enhanced CT (Fig. 22.47). Diagnosis in non-jaundiced patients is often delayed because presenting symptoms are relatively non-specific. Fit patients with small localised tumours should undergo staging to define operability. EUS or laparoscopy with laparoscopic ultrasound will define tumour size, involvement of blood vessels and metastatic spread. In patients unsuitable for surgery because of advanced disease, frailty or comorbidity, EUS or CT-guided cytology or biopsy can be used to confirm the diagnosis. MRCP and ERCP are sensitive methods of diagnosing pancreatic cancer and are valuable when the diagnosis is in doubt, although differentiation between cancer and localised chronic pancreatitis can be difficult. The main role of ERCP is to insert a stent into the common bile duct to relieve obstructive jaundice in inoperable patients.

Management

Surgical resection is the only method of effecting cure, and 5-year survival in patients undergoing a complete resection is around 12%. Recent trials have demonstrated improved survival (21–29%) with adjuvant chemotherapy using gemcitabine. Unfortunately, only 10–15% of tumours are resectable for cure, since most are locally advanced at the time of diagnosis. For the great majority of patients, treatment is palliative. Chemotherapy with FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan and oxaliplatin) improves median survival to 11 months. Pain relief can be achieved using analgesics but, in some patients, coeliac plexus neurolysis may be required. Jaundice can be relieved by choledochojejunostomy in fit patients, whereas percutaneous or endoscopic stenting is preferable in the elderly and those with very advanced disease. Ampullary or periampullary adenocarcinomas are rare neoplasms which arise from the ampulla of Vater or adjacent duodenum. They are often polypoid and may ulcerate; they frequently infiltrate the duodenum but behave less aggressively than pancreatic adenocarcinoma. Around 25% of patients undergoing resection of ampullary or periampullary tumours survive for 5 years, in contrast to patients with pancreatic ductal cancer.

Cystic neoplasms of the pancreas are increasingly being seen with widespread use of CT. These are a heterogeneous group; serous cystadenomas rarely, if ever, become malignant and do not require surgery.

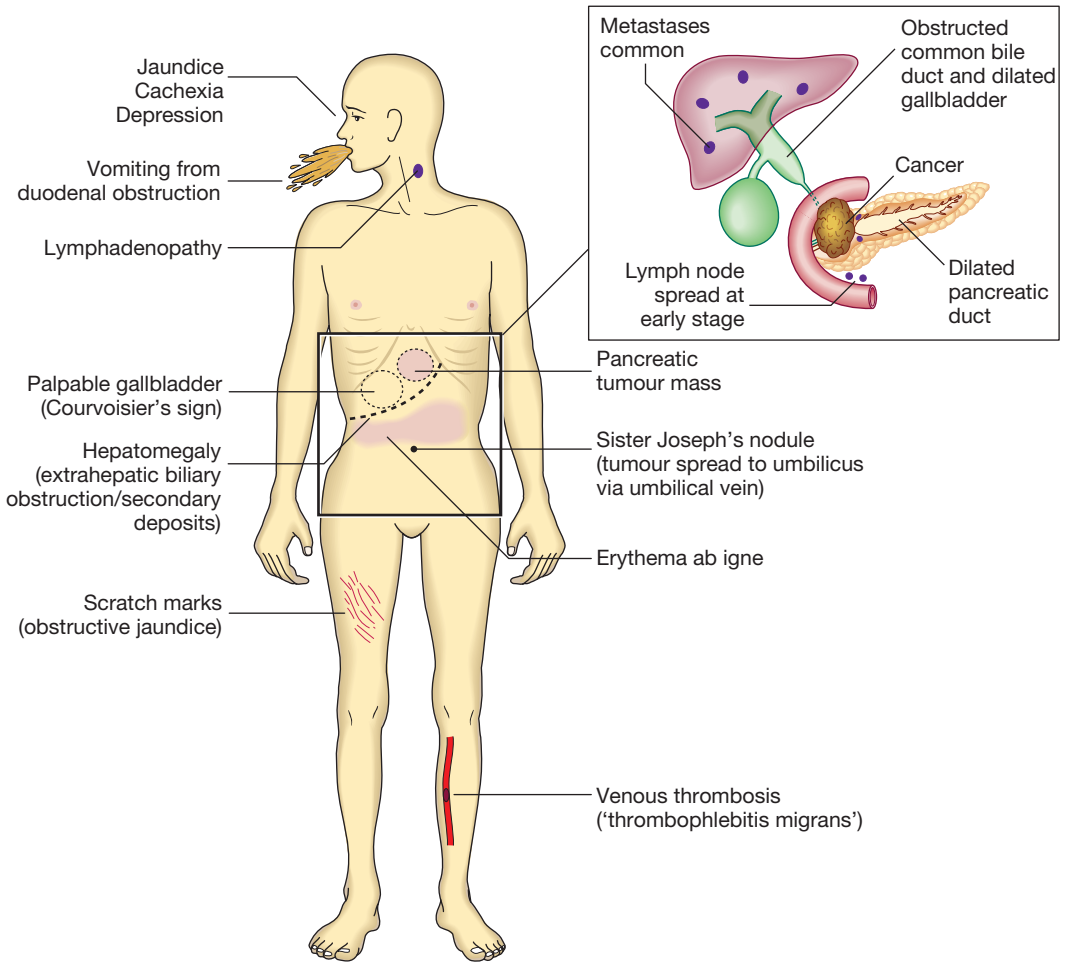

Fig. 22.46 Features of pancreatic cancer.

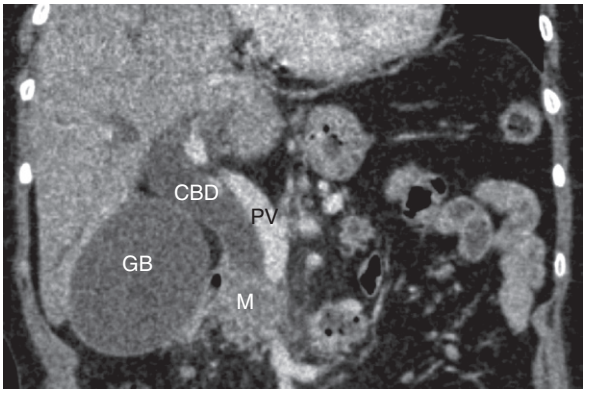

Fig. 22.47 Carcinoma of the pancreatic head. A large mass (M) in the head of pancreas involves the portal vein (PV) and obstructs the common bile duct (CBD). The gallbladder (GB) is distended.

Mucinous cysts occur more often in women, are usually in the pancreatic tail and display a spectrum of behaviour from benign to frankly malignant. Aspiration of the cyst contents for cytology and measurement of carcinoembryonic antigen (CEA) and amylase concentrations in fluid obtained at EUS can help determine whether a lesion is mucinous or not. In fit patients, all mucinous lesions should be resected. A variant, called intraductal papillary mucinous neoplasia (IPMN), is often discovered coincidentally on CT, frequently in elderly men. This may affect the main pancreatic duct with marked dilatation and plugs of mucus, or may affect a side branch. The histology varies from villous adenomatous change to dysplasia or carcinoma. Since IPMN is a premalignant but indolent condition, the decision to resect or to monitor depends on age and fitness of the patient and location, size and evolution of lesions.

Pancreatic neuro-endocrine tumours

These can occur in association with parathyroid and pituitary adenomas (MEN 1, p. 795). The majority of endocrine tumours are non-secretory and, although malignant, grow slowly and metastasise late. Other tumours secrete hormones and present because of their endocrine effects (see Box 20.54, p. 784). Neuro-endocrine pancreatic tumours may be single, but are frequently multifocal and arise from other clusters of neuroendocrine cells derived from neural crest tissues. They are localised by CT and endoscopic ultrasound. ^{111}In-labelled DTPA is very sensitive in the diagnosis of glucagonoma.

INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease are chronic inflammatory bowel diseases which pursue a protracted relapsing and remitting course, usually extending over years. The diseases have many similarities and it is sometimes impossible to differentiate between them. A crucial distinction is that ulcerative colitis only involves the colon, while Crohn's disease can involve any part of the gastrointestinal tract from mouth to anus. A summary of the main features of ulcerative colitis and Crohn's disease is provided in Box 22.70.

The incidence of inflammatory bowel disease (IBD) varies widely between populations. There was a dramatic increase in the incidence of Crohn's disease in the Western world, starting in the second half of the last century and coinciding with the introduction of a more 'hygienic' environment with the advent of domestic refrigeration and the widespread use of antibiotics. The developing world has seen similar patterns, as these countries adopt an increasingly Westernised lifestyle.

In the West, the incidence of ulcerative colitis is stable at 10–20 per 100 000, with a prevalence of 100–200 per 100 000, while the incidence of Crohn's disease is increasing and is now 5–10 per 100 000, with a prevalence of 50–100 per 100 000. Both diseases most commonly start in the second and third decades of life, with a second smaller incidence peak in the seventh decade. Approximately 240 000 people are affected by IBD in the UK (approximately 1.4 million in the USA), equating to a prevalence of about 1 in 250. Life expectancy in patients with IBD is similar to that of the general population. Although many patients require surgery and admission to hospital for other reasons, with substantial associated morbidity, the majority have an excellent work record and pursue a normal life.

Pathophysiology

Inflammatory bowel disease has both environmental and genetic components, and evidence from genome-wide association studies suggests that genetic variants that predispose to Crohn's disease may have undergone positive selection by protecting against infectious diseases, including tuberculosis (Box 22.71). It is thought that IBD develops because these genetically susceptible individuals mount an abnormal inflammatory response to environmental triggers, such as intestinal bacteria. This leads to inflammation of the intestine with release of inflammatory mediators, including TNF, IL-12 and IL-23, which cause tissue damage (Fig. 22.48). In both diseases, the intestinal wall is infiltrated with acute and chronic inflammatory cells but there are important differences between the conditions in the distribution of lesions and in histological features (Fig. 22.49).

Ulcerative colitis

Inflammation invariably involves the rectum (proctitis) and spreads proximally in a continuous manner to involve the entire colon in some cases (pancolitis). In long-standing pancolitis, the bowel can become shortened and post-inflammatory 'pseudopolyps' develop; these are normal or hypertrophied residual mucosa within areas of atrophy. The inflammatory process is limited to the mucosa and spares the deeper layers of the bowel wall (Fig. 22.50). Both acute and chronic inflammatory cells infiltrate the lamina propria and the crypts ('cryptitis'). Crypt abscesses are typical. Goblet cells lose their mucus and, in long-standing cases, glands become distorted. Dysplasia, characterised by heaping

22.70 Comparison of ulcerative colitis and Crohn's disease

	Ulcerative colitis	Crohn's disease
Age group	Any	Any
Gender	M = F	Slight female preponderance
Incidence	Stable	Increasing
Ethnic group	Any	Any; more common in Ashkenazi Jews
Genetic factors	*HLA-DR*103*; colonic epithelial barrier function (*HNF4a*, *LAMB1*, *CDH1*)	Defective innate immunity and autophagy (*NOD2*, *ATG16L1*, *IRGM*)
Risk factors	More common in non-/ex-smokers Appendicectomy protects	More common in smokers
Anatomical distribution	Colon only; begins at anorectal margin with variable proximal extension	Any part of gastrointestinal tract; perianal disease common; patchy distribution, skip lesions
Extra-intestinal manifestations	Common	Common
Presentation	Bloody diarrhoea	Variable; pain, diarrhoea, weight loss all common
Histology	Inflammation limited to mucosa; crypt distortion, cryptitis, crypt abscesses, loss of goblet cells	Submucosal or transmural inflammation common; deep fissuring ulcers, fistulae; patchy changes; granulomas
Management	5-ASA; corticosteroids; azathioprine; biological therapy (anti-TNF); colectomy is curative	Corticosteroids; azathioprine; methotrexate; biological therapy (anti-TNF); nutritional therapy; surgery for complications is not curative; 5-ASA not effective

(5-ASA = 5-aminosalicylic acid; TNF = tumour necrosis factor)

of cells within crypts, nuclear atypia and increased mitotic rate, may herald development of colon cancer.

Crohn's disease

The sites most commonly involved are, in order of frequency, the terminal ileum and right side of colon, colon alone, terminal ileum alone, ileum and jejunum. The entire wall of the bowel is oedematous and thickened, and there are deep ulcers which often appear as linear fissures; thus the mucosa between them is described as 'cobblestone'. These may penetrate through the bowel wall to initiate abscesses or fistulae involving the bowel, bladder, uterus, vagina and skin of the perineum. The

22.71 Factors associated with the development of inflammatory bowel disease

Genetic

- Both CD and UC common in Ashkenazi Jews
- 10% have first-degree relative/≥1 close relative with IBD
- High concordance in identical twins (40–50% CD; 20–25% UC)
- 163 susceptibility loci identified at genome-wide levels of significance; most confer susceptibility to both CD and UC; many are also susceptibility loci for other inflammatory conditions (esp. ankylosing spondylosis and psoriasis)
- UC and CD both associated with genetic variants at HLA locus, and with multiple genes involved with immune signalling (esp. IL-23 and IL-10 pathways)
- CD associated with genetic defects in innate immunity and autophagy (*NOD2*, *ATG16L1* and *IRGM* genes)
- UC associated with genetic defects in barrier function
- *NOD2* associated with ileal and stricturing disease, and hence need for resectional surgery
- *HLA-DR*103* associated with severe UC

Environmental

- UC more common in non-smokers and ex-smokers
- CD more common in smokers (relative risk = 3)
- CD associated with low-residue, high-refined-sugar diet
- Commensal gut microbiota altered (dysbiosis) in CD and UC
- Appendicectomy protects against UC

(CD = Crohn's disease; HLA = human leucocyte antigen; IL = interleukin; IBD = inflammatory bowel disease; UC = ulcerative colitis)

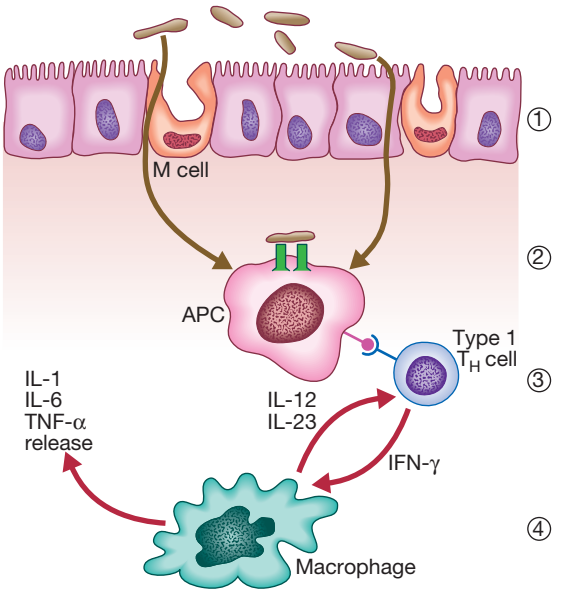

Fig. 22.48 Pathogenesis of inflammatory bowel disease.
(1) Bacterial antigens are taken up by specialised M cells, pass between leaky epithelial cells or enter the lamina propria through ulcerated mucosa. (2) After processing, they are presented to type 1 T-helper cells by antigen-presenting cells (APC) in the lamina propria. (3) T-cell activation and differentiation results in a Th_1 T cell-mediated cytokine response (4) with secretion of cytokines, including interferon-gamma (IFN-γ). Further amplification of T cells perpetuates the inflammatory process with activation of non-immune cells and release of other important cytokines, including interleukin (IL)-12, IL-23, IL-1 IL-6 and tumour necrosis factor (TNF). These pathways occur in all normal individuals exposed to an inflammatory insult and this is self-limiting in healthy subjects. In genetically predisposed persons, dysregulation of innate immunity may trigger inflammatory bowel disease.

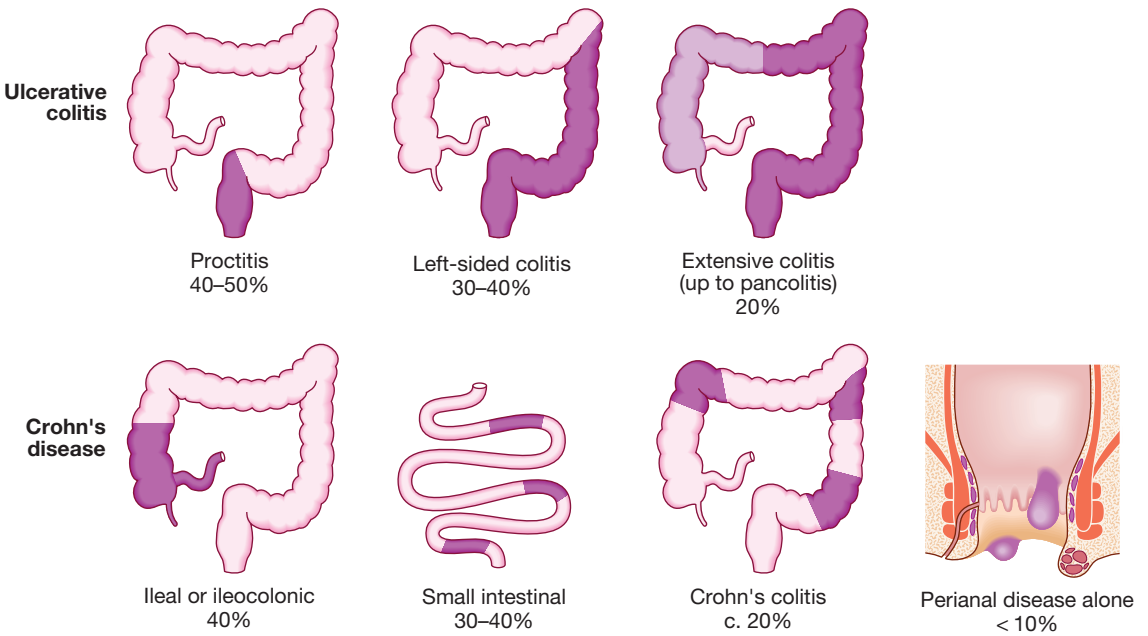

Fig. 22.49 Common patterns of disease distribution in inflammatory bowel disease.

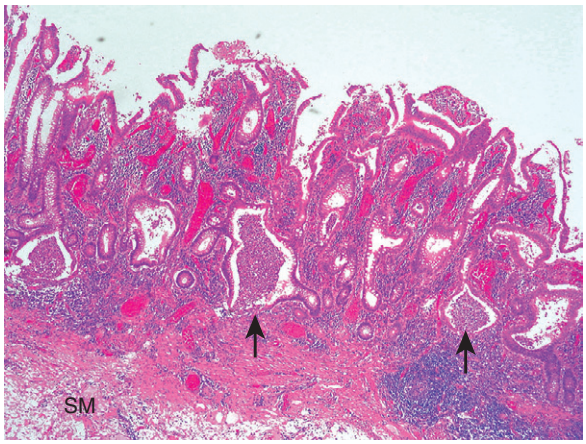

Fig. 22.50 Histology of ulcerative colitis. There is surface ulceration and inflammation is confined to the mucosa with excess inflammatory cells in the lamina propria, loss of goblet cells, and crypt abscesses (arrows). (SM = submucosa)

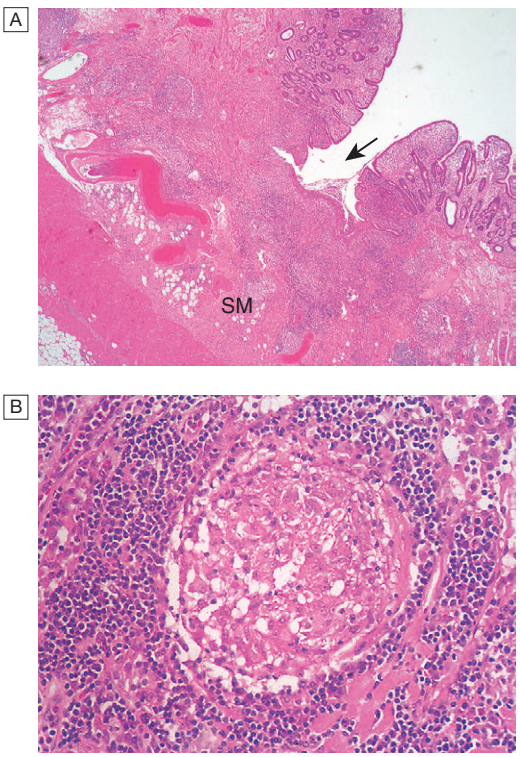

Fig. 22.51 Histology of Crohn's disease. A Inflammation is 'transmural'; there is fissuring ulceration (arrow), with inflammation extending into the submucosa (SM). B At higher power, a characteristic non-caseating granuloma is seen.

mesenteric lymph nodes are enlarged and the mesentery is thickened. Crohn's disease has a patchy distribution and the inflammatory process is interrupted by islands of normal mucosa. On histological examination, the bowel wall is thickened with a chronic inflammatory infiltrate throughout all layers (Fig. 22.51).

Clinical features

Ulcerative colitis

The cardinal symptoms are rectal bleeding with passage of mucus and bloody diarrhoea. The presentation varies,

22.72 Assessment of disease severity in ulcerative colitis

	Mild	Severe
Daily bowel frequency	< 4	≥ 6*
Blood in stools	+/–	+++
Stool volume	< 200 g/24 hrs	> 400 g/24 hrs
Pulse	< 90 beats/min	≥ 90 beats/min*
Temperature	Normal	≥ 37.8°C*
Haemoglobin	Normal	< 100 g/L (< 10 g/dL)*
Erythrocyte sedimentation rate	Normal	> 30 mm/hr* (or equivalent C-reactive protein)
Serum albumin	> 35 g/L (> 3.5 g/dL)	< 30 g/L (< 3 g/dL)
Abdominal X-ray	Normal	Dilated bowel and/or mucosal islands
Sigmoidoscopy	Normal or granular mucosa	Blood in lumen

*The Truelove–Witts criteria for acute severe ulcerative colitis are ≥ 6 bloody stools/24 hrs plus one or more of anaemia, fever, tachycardia and high inflammatory markers.

depending on the site and severity of the disease (see Fig. 22.49), as well as the presence of extra-intestinal manifestations. The first attack is usually the most severe and is followed by relapses and remissions. Emotional stress, intercurrent infection, gastroenteritis, antibiotics or NSAID therapy may all provoke a relapse. Proctitis causes rectal bleeding and mucus discharge, accompanied by tenesmus. Some patients pass frequent, small-volume fluid stools, while others pass pellety stools due to constipation upstream of the inflamed rectum. Constitutional symptoms do not occur. Left-sided and extensive colitis causes bloody diarrhoea with mucus, often with abdominal cramps. In severe cases, anorexia, malaise, weight loss and abdominal pain occur, and the patient is toxic, with fever, tachycardia and signs of peritoneal inflammation (Box 22.72).

Crohn's disease

The major symptoms are abdominal pain, diarrhoea and weight loss. Ileal Crohn's disease (Figs 22.52 and 22.53) may cause subacute or even acute intestinal obstruction. The pain is often associated with diarrhoea, which is usually watery and does not contain blood or mucus. Almost all patients lose weight because they avoid food, since eating provokes pain. Weight loss may also be due to malabsorption, and some patients present with features of fat, protein or vitamin deficiencies. Crohn's colitis presents in an identical manner to ulcerative colitis, but rectal sparing and the presence of perianal disease are features which favour a diagnosis of Crohn's disease. Many patients present with symptoms of both small bowel and colonic disease. A few patients present with isolated perianal disease, vomiting from jejunal strictures or severe oral ulceration.

Physical examination often reveals evidence of weight loss, anaemia with glossitis and angular

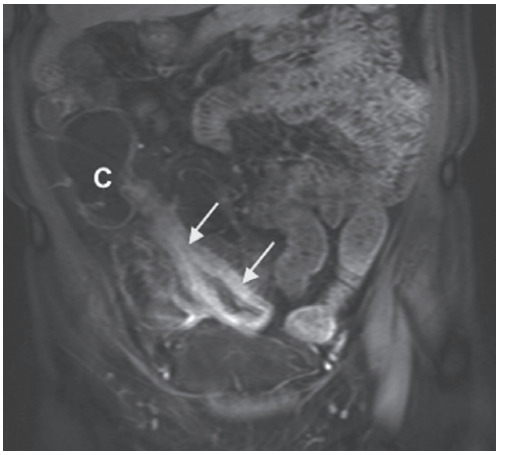

Fig. 22.52 Ileal Crohn's disease. MRI scan showing a thickened narrowed loop of ileum with enhancement after MR contrast (arrows), consistent with active Crohn's disease. Normal small bowel can be seen at the top right of the image. (C = caecum)

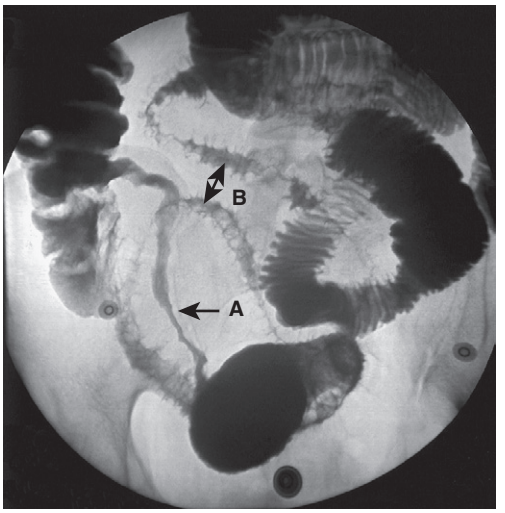

Fig. 22.53 Barium follow-through showing terminal ileal Crohn's disease. A long stricture is present (arrow A), and more proximally there is ulceration with characteristic 'rose thorn' ulcers (arrow B).

stomatitis. There is abdominal tenderness, most marked over the inflamed area. An abdominal mass may be palpable and is due to matted loops of thickened bowel or an intra-abdominal abscess. Perianal skin tags, fissures or fistulae are found in at least 50% of patients.

Differential diagnosis

The differential diagnosis is summarised in Box 22.73. The most important issue is to distinguish the first attack of acute colitis from infection. In general, diarrhoea lasting longer than 10 days in Western countries is unlikely to be the result of infection, whereas a history of foreign travel, antibiotic exposure (pseudomembranous colitis) or homosexual contact increases the possibility of infection, which should be excluded by the appropriate investigations (see below). The diagnosis of Crohn's disease is usually more straightforward and is made on the basis of imaging and clinical presentation, but in atypical cases, biopsy or surgical resection is necessary to exclude other diseases (Box 22.74).

22.73 Conditions which can mimic ulcerative or Crohn's colitis

Infective

Bacterial

- *Salmonella*
- *Shigella*
- *Campylobacter jejuni*
- *E. coli* 0157
- Gonococcal proctitis
- Pseudomembranous colitis
- *Chlamydia* proctitis

Viral

- Herpes simplex proctitis
- Cytomegalovirus

Protozoal

- Amoebiasis

Non-infective

- Ischaemic colitis
- Collagenous colitis
- NSAIDs
- Diverticulitis
- Radiation proctitis
- Behçet's disease
- Colonic carcinoma

22.74 Differential diagnosis of small bowel Crohn's disease

- Other causes of right iliac fossa mass
  - Caecal carcinoma*
  - Appendix abscess*
- Infection (tuberculosis, *Yersinia*, actinomycosis)
- Mesenteric adenitis
- Pelvic inflammatory disease
- Lymphoma

*Common; other causes are rare.

Complications

Life-threatening colonic inflammation

This can occur in both ulcerative colitis and Crohn's colitis. In the most extreme cases, the colon dilates (toxic megacolon) and bacterial toxins pass freely across the diseased mucosa into the portal and then systemic circulation. This complication arises most commonly during the first attack of colitis and is recognised by the features described in Box 22.72. An abdominal X-ray should be taken daily because, when the transverse colon is dilated to more than 6 cm (Fig. 22.54), there is a high risk of colonic perforation, although this complication can also occur in the absence of toxic megacolon.

Haemorrhage

Haemorrhage due to erosion of a major artery is rare but can occur in both conditions.

Fistulae

These are specific to Crohn's disease. Enteroenteric fistulae can cause diarrhoea and malabsorption due to blind loop syndrome. Enterovesical fistulation causes recurrent urinary infections and pneumaturia. An enterovaginal fistula causes a faeculent vaginal discharge. Fistulation from the bowel may also cause perianal or ischiorectal abscesses, fissures and fistulae.

Cancer

The risk of dysplasia and cancer increases with the duration and extent of uncontrolled colonic inflammation. Thus patients who have long-standing, extensive colitis are at highest risk. Oral mesalazine therapy reduces the

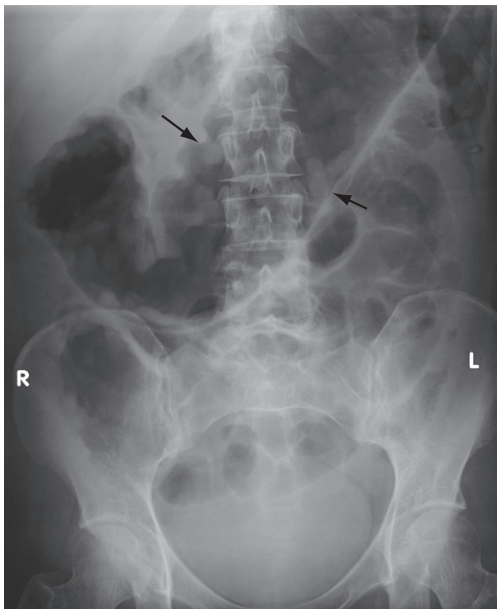

Fig. 22.54 Plain abdominal X-ray showing a grossly dilated colon due to severe ulcerative colitis. There is also marked mucosal oedema and 'thumb-printing' (arrows).

risk of dysplasia and neoplasia in ulcerative colitis. Azathioprine also seems to reduce the risk of colorectal cancer in ulcerative colitis and Crohn's colitis. This protective effect probably extends to any medical treatment that results in sustained healing of the colonic mucosa. The cumulative risk for dysplasia in ulcerative colitis may be as high as 20% after 30 years but is probably lower for Crohn's colitis. The risk is particularly high in patients who have concomitant primary sclerosing cholangitis for unknown reasons. Tumours develop in areas of dysplasia and may be multiple. Patients with long-standing colitis are therefore entered into surveillance programmes beginning 10 years after diagnosis. Targeted biopsies of areas that show abnormalities on staining with indigo carmine or methylene blue increase the chance of detecting dysplasia and this technique (termed pancolonic chromo-endoscopy) has replaced colonoscopy with random biopsies taken every 10 cm in screening for malignancy. The procedure allows patients to be stratified into high-, medium- or low-risk groups to determine the interval between surveillance procedures. If high-grade dysplasia is found, panproctocolectomy is usually recommended because of the high risk of colon cancer.

Extra-intestinal complications

Extra-intestinal complications are common in IBD and may dominate the clinical picture. Some of these occur during relapse of intestinal disease; others appear unrelated to intestinal disease activity (Fig. 22.55).

Investigations

Investigations are necessary to confirm the diagnosis, define disease distribution and activity, and identify complications. Full blood count may show anaemia resulting from bleeding or malabsorption of iron, folic acid or vitamin B_{12}. Serum albumin concentration falls as a consequence of protein-losing enteropathy, inflammatory disease or poor nutrition. The ESR and CRP are elevated in exacerbations and in response to abscess formation. Faecal calproctectin has a high sensitivity for detecting gastrointestinal inflammation and may be elevated, even when the CRP is normal. It is particularly useful in distinguishing inflammatory bowel disease from irritable bowel syndrome at diagnosis, and for subsequent monitoring of disease activity.

Bacteriology

At initial presentation, stool microscopy, culture and examination for *Clostridium difficile* toxin or for ova and cysts, blood cultures and serological tests should be performed. These investigations may need to be repeated in established disease to exclude superimposed enteric infection in patients who present with exacerbations of IBD. During acute flares necessitating hospital admission, three separate stool samples should be sent for bacteriology to maximise sensitivity.

Endoscopy

Patients who present with diarrhoea plus raised inflammatory markers or alarm features, such as weight loss, rectal bleeding and anaemia, should undergo ileocolonoscopy. Flexible sigmoidoscopy is occasionally performed to make a diagnosis, especially during acute severe presentations when ileocolonoscopy may confer an unacceptable risk; ileocolonoscopy should still be performed at a later date, however, in order to evaluate disease extent. In ulcerative colitis, there is loss of vascular pattern, granularity, friability and contact bleeding, with or without ulceration (Fig. 22.56). In Crohn's disease, patchy inflammation, with discrete, deep ulcers, strictures and perianal disease (fissures, fistulae and skin tags), is typically observed, often with rectal sparing. In established disease, colonoscopy may show active inflammation with pseudopolyps or a complicating carcinoma. Biopsies should be taken from each anatomical segment (terminal ileum, right colon, transverse colon, left colon and rectum) to confirm the diagnosis and define disease extent, and also to seek dysplasia in patients with long-standing colitis. In Crohn's disease, wireless capsule endoscopy is useful in the identification of small bowel inflammation but should be avoided in the presence of strictures. Enteroscopy may be required to make a histological diagnosis of small bowel Crohn's disease, when the inflamed segment is out of reach of standard endoscopes. All children and most adults with Crohn's disease should have upper gastrointestinal endoscopy and biopsy to complete their staging. Not only is upper gastrointestinal Crohn's disease relatively common in this group, but it may help to make a definitive diagnosis in patients who otherwise appear to have non-specific colonic inflammation.

Radiology

Barium enema is a less sensitive investigation than colonoscopy in patients with colitis and, where colonoscopy is incomplete, a CT colonogram is preferred. Small bowel imaging is essential to complete staging of Crohn's disease. Traditional contrast imaging by barium follow-through demonstrates affected areas of the bowel as narrowed and ulcerated, often with multiple strictures (see Fig. 22.53). This has now largely been replaced by MRI enterography, which does not involve exposure to radiation and is a sensitive way of detecting extra-intestinal manifestations and of assessing pelvic and

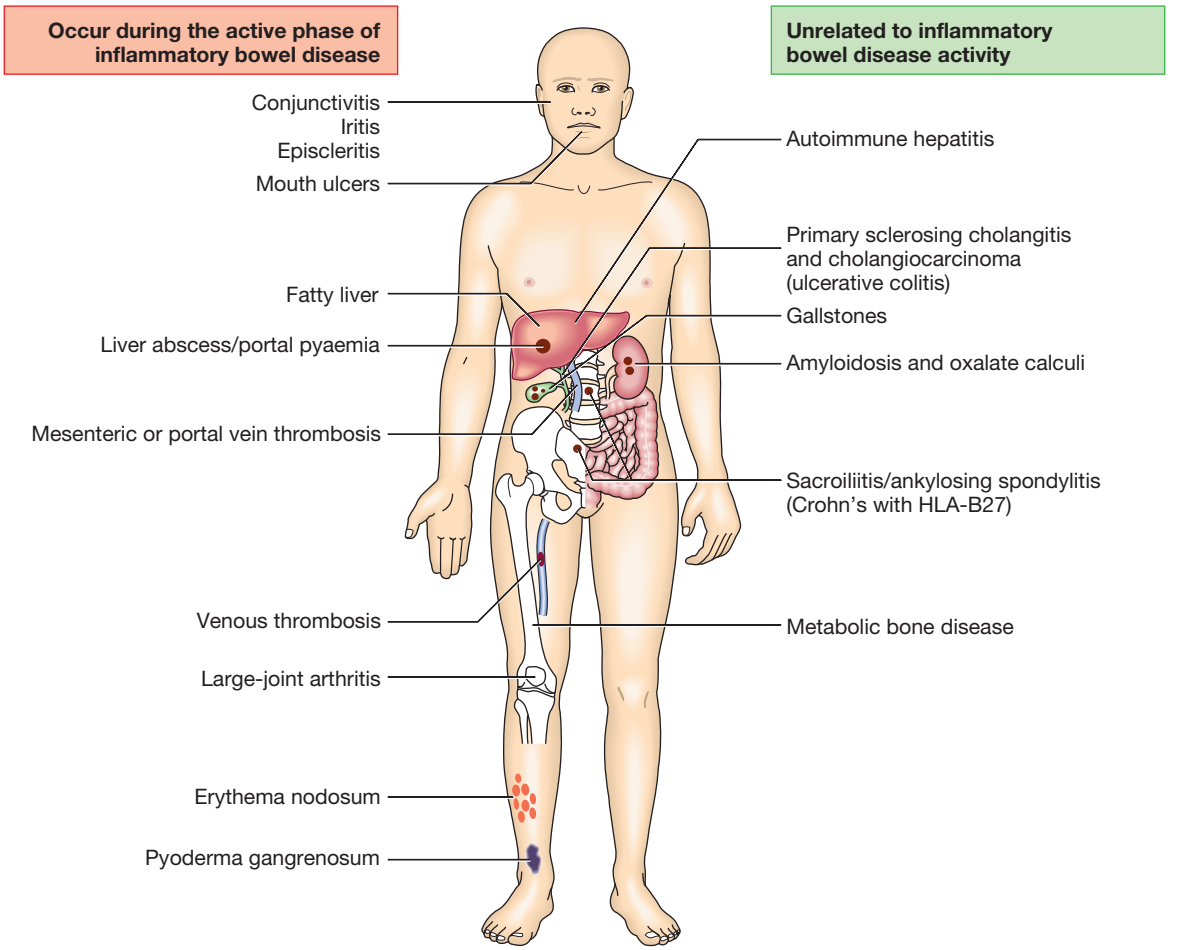

Fig. 22.55 Systemic complications of inflammatory bowel disease. (See also Chs 19 and 20.)

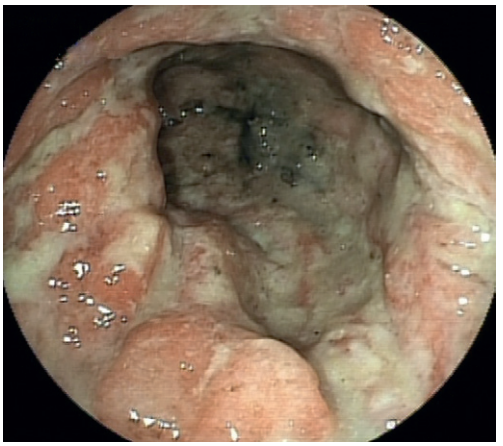

Fig. 22.56 Sigmoidoscopic view of moderately active ulcerative colitis. Mucosa is erythematous and friable with contact bleeding. Submucosal blood vessels are no longer visible.

perineal involvement. These studies use an orally administered small bowel-distending agent and intravenous contrast to provide transmural imaging that can usefully distinguish between predominantly inflammatory strictures (that should respond to anti-inflammatory medical strategies) and fibrotic strictures (that require a mechanical solution, such as surgical resection, stricturoplasty or endoscopic balloon dilatation). A plain abdominal X-ray is essential in the management of patients who present with severe active disease. Dilatation of the colon (see Fig. 22.54), mucosal oedema (thumb-printing) or evidence of perforation may be found. In small bowel Crohn's disease, there may be evidence of intestinal obstruction or displacement of bowel loops by a mass. Ultrasound is a very powerful tool to detect small bowel inflammation and stricture formation, but it is rather operator-dependent. The role of CT is limited to screening for complications, such as perforation or abscess formation, in the acutely unwell.

Management

Drugs that are used in the treatment of IBD are listed in Box 22.75. Although medical therapy plays an important role, optimal management depends on establishing a multidisciplinary team-based approach involving physicians, surgeons, radiologists, nurse specialists and dietitians. Both ulcerative colitis and Crohn's disease are life-long conditions and have important psychosocial implications; specialist nurses, counsellors and patient support groups have key roles in education, reassurance and coping. The key aims of medical therapy are to:

- treat acute attacks (induce remission)
- prevent relapses (maintain remission)

22.75 Drugs used in the treatment of inflammatory bowel disease

Class	Mechanism of action	Notes
Aminosalicylates (mesalazine (Asacol, Salofalk, Pentasa, Mezavant), olsalazine, sulfasalazine, balsalazide)	Modulate cytokine release from mucosa Delivered to colon by one of three mechanisms: 1. pH-dependent (Asacol, Salofalk) 2. time-dependent (Pentasa) 3. bacterial breakdown by colonic bacteria from a carrier molecule (sulfasalazine, balsalazide)	No proven value in CD Available as oral or topical (enema/suppository) Sulfasalazine causes side-effects in 10–45%: headache, nausea, diarrhoea, blood dyscrasias Other aminosalicylates better tolerated; diarrhoea, headache in 2–5% Rarely, renal impairment (check urea and electrolytes 6-monthly)
Corticosteroids (prednisolone, hydrocortisone, budesonide)	Anti-inflammatory Budesonide is a potent corticosteroid efficiently cleared from circulation by liver, thereby minimising adrenocortical suppression and steroid side-effects	Topical, oral or IV, according to disease severity Budesonide considered for active ileitis and ileocolitis High vigilance for complications Never used for maintenance therapy Calcium/vitamin D supplements
Thiopurines (azathioprine, mercaptopurine)	Immunomodulation by inducing T-cell apoptosis Azathioprine is metabolised in liver to mercaptopurine, then by thiopurine methyltransferase (TPMT) to thioguanine nucleotides	Effective after 12 wks of starting therapy Complications leading to drug withdrawal in ~20%. Flu-like syndrome with myalgia, nausea and vomiting Leucopenia in 3%, particularly in inherited TPMT deficiency (TPMT levels checked prior to therapy) Hepatotoxicity; pancreatitis 60% of those intolerant of azathioprine will tolerate mercaptopurine Increase in lymphoma (approximately 2–3-fold) and non-melanoma skin cancer (life-long sun protection advised) Metabolite levels can be measured to tailor therapy
Methotrexate	Anti-inflammatory	Intolerance in 10–18%. Maximal efficacy when given by SC injection once weekly. Nausea, stomatitis, diarrhoea, hepatotoxicity and pneumonitis. Co-prescription of folic acid and antiemetics. Teratogenic; robust contraception required for females of child-bearing age
Ciclosporin	Inhibits T-cell activation	Rescue therapy to prevent surgery in UC responding poorly to corticosteroids. No value in CD Major side-effects in 0–17%: nephrotoxicity, infections, neurotoxicity (including fits) Minor complications in up to 50%: tremor, paraesthesiae, abnormal liver function tests, hirsutism
Anti-TNF antibodies (infliximab and adalimumab)	Suppress inflammation and induce apoptosis of inflammatory cells	Moderately to severely active CD, including fistulating disease Moderate–severe UC and acute severe UC as rescue therapy Acute (anaphylactic) and delayed (serum sickness) infusion reactions after multiple infusions; anti-drug antibody titres and drug levels can be measured Contraindicated in the presence of infections; reactivation of latent tuberculosis Increased risk of infections and possibly of malignancy
Antibiotics	Antibacterial	Useful in perianal CD and pouchitis Major concern is peripheral neuropathy with long-term metronidazole
Antidiarrhoeal agents (loperamide, co-phenoxylate)	Reduce gut motility and small bowel secretion Loperamide improves anal function	Avoided in acute flare-ups of disease May precipitate colonic dilatation

- prevent bowel damage
- detect dysplasia and prevent carcinoma
- select appropriate patients for surgery.

Ulcerative colitis

Active proctitis. Most patients with ulcerative proctitis respond to a 1 g mesalazine suppository but some will additionally require oral 5-aminosalicylate (5-ASA) therapy. Topical corticosteroids are less effective and are reserved for patients who are intolerant of topical mesalazine. Patients with resistant disease may require treatment with systemic corticosteroids and immunosuppressants.

Active left-sided or extensive ulcerative colitis. In mild to moderately active cases, the combination of a once-daily oral and a topical 5-ASA preparation ('top and tail

approach') is usually effective. The topical preparation (1 g foam or liquid enema) is typically withdrawn after 1 month. The oral 5-ASA is continued long-term to prevent relapse and minimise the risk of dysplasia. In patients who do not respond to this approach within 2–4 weeks, oral prednisolone (40 mg daily, tapered by 5 mg/week over an 8-week total course) is indicated. Corticosteroids should never be used for maintenance therapy. At the first signs of corticosteroid resistance (lack of efficacy) or in patients who require high corticosteroid doses to maintain control, immunosuppressive therapy with a thiopurine should be introduced.

Severe ulcerative colitis. Patients who fail to respond to maximal oral therapy and those who present with acute severe colitis (meeting the Truelove–Witts criteria; see Box 22.72) are best managed in hospital and should be monitored jointly by a physician and surgeon:

- clinically: for the presence of abdominal pain, temperature, pulse rate, stool blood and frequency
- by laboratory testing: haemoglobin, white cell count, albumin, electrolytes, ESR and CRP
- radiologically: for colonic dilatation on plain abdominal X-rays.

All patients should be given supportive treatment with intravenous fluids to correct dehydration, and enteral nutritional support should be provided for malnourished patients (Box 22.76). Intravenous corticosteroids (methylprednisolone 60 mg or hydrocortisone 400 mg/day) should be given by intravenous infusion or bolus injection. Topical and oral aminosalicylates have no role to play in the acute severe attack. Response to therapy is judged over the first 3 days. Patients who do not respond promptly to corticosteroids should be considered for medical rescue therapy with ciclosporin (intravenous infusion or oral) or infliximab (5 mg/kg), which, in approximately 60% of cases, can avoid the need for urgent colectomy.

Patients who develop colonic dilatation (> 6 cm), those whose clinical and laboratory measurements deteriorate and those who do not respond after 7–10 days' maximal medical treatment usually require urgent colectomy. Subtotal colectomy can also be performed laparoscopically, given sufficient local expertise.

Maintenance of remission. Life-long maintenance therapy is recommended for all patients with left-sided or extensive disease but is not necessary in those with proctitis (although 20% of these patients will develop proximal 'extension' over the lifetime of their disease).

22.76 Medical management of fulminant ulcerative colitis

- Admit to hospital for intensive therapy and monitoring
- Intravenous fluids and correction of electrolyte imbalance
- Transfusion if haemoglobin < 100 g/L (< 10 g/dL)
- IV methylprednisolone (60 mg daily) or hydrocortisone (400 mg daily)
- Antibiotics until enteric infection excluded
- Nutritional support
- Subcutaneous low-molecular-weight heparin for prophylaxis of venous thromboembolism
- Avoidance of opiates and antidiarrhoeal agents
- Consider infliximab (5 mg/kg) or ciclosporin (2 mg/kg) in stable patients not responding to 3–5 days of corticosteroids

Once-daily oral 5-aminosalicylates are the preferred first-line agents. Sulfasalazine has a higher incidence of side-effects but is equally effective and can be considered in patients with coexistent arthropathy. Patients who frequently relapse despite aminosalicylate drugs should be treated with thiopurines.

Crohn's disease

Principles of treatment. Crohn's disease is a progressive condition which may result in stricture or fistula formation if suboptimally treated. It is therefore important to agree long-term treatment goals with the patient; these are to induce remission and then maintain corticosteroid-free remission with a normal quality of life. Treatment should focus on monitoring the patient carefully for evidence of disease activity and complications (Box 22.77), and ensuring that mucosal healing is achieved.

Induction of remission. Corticosteroids remain the mainstay of treatment for active Crohn's disease. The drug of first choice in patents with ileal disease is budesonide, since it undergoes 90% first-pass metabolism in the liver and has very little systemic toxicity. A typical regimen is 9 mg once daily for 6 weeks, with a gradual reduction in dose over the subsequent 2 weeks when therapy is stopped. If there is no response to budesonide within 2 weeks, the patient should be switched to prednisolone, which has greater potency. This is typically given in a dose of 40 mg daily, reducing by 5 mg/week over 8 weeks, at which point treatment is stopped. Oral prednisolone in the above dose regimen is the treatment of choice for inducing remission in colonic Crohn's disease. Calcium and vitamin D supplements should be co-prescribed in patients who are on corticosteroids, to try to compensate for their inhibitory effect on intestinal calcium absorption.

As an alternative to corticosteroid therapy, enteral nutrition with either an elemental (constituent amino acids) or polymeric (liquid protein) diet may induce remission. Both types of diet are equally effective but the polymeric one is more palatable when taken by mouth. It is particularly effective in children, in whom equal efficacy to corticosteroids has been demonstrated, and in extensive ileal disease in adults. As well as resting the gut and providing excellent nutritional support, it also

22.77 Monitoring of inflammatory bowel disease

- Assess symptoms, including extra-intestinal manifestations
- Examine for abdominal mass or perianal disease
- Perform full blood count, urea and electrolytes, liver function tests, albumin, CRP
- Check haematinics (B_{12}, folate, iron studies) at least annually
- Check faecal calprotectin (to monitor each disease flare/change in therapy and assess response)
- Stool cultures (at each flare to exclude infection)
- Assess mucosal healing: surrogate markers (CRP/calprotectin), ileocolonoscopy and/or small bowel MRI
- Enrol patient in a dedicated IBD clinic (can be nurse-led or phone clinic for stable, uncomplicated patients)
- Arrange IBD multidisciplinary meeting for acutely ill or complex patients
- Check vaccinations are up to date; ensure surveillance colonoscopy scheduled where appropriate

has a direct anti-inflammatory effect. It is an effective bridge to urgent staging investigations at first presentation and can be given by mouth or by nasogastric tube. With sufficient explanation, encouragement and motivation, most patients will tolerate it well.

Some patients with severe colonic disease require admission to hospital for intravenous corticosteroids. In severe ileal or panenteric disease, induction therapy with an anti-TNF agent is appropriate, provided that acute perforating complications, such as abscess, have not occurred. Both infliximab and adalimumab are licensed for use in the UK. Randomised trials have demonstrated that combination therapy with an anti-TNF antibody and a thiopurine is the most effective strategy for inducing and maintaining remission in luminal Crohn's patients. This strategy is more effective than anti-TNF monotherapy, which, in turn, is more effective than thiopurine monotherapy. Following induction of remission, a substantial proportion of patients (20–30%) remain well without the requirement for maintenance therapy. Patients with evidence of persistently active disease require further treatment (see below).

Maintenance therapy. Immunosuppressive treatment with thiopurines (azathioprine and mercaptopurine) forms the core of maintenance therapy, but methotrexate is also effective and can be given once weekly, either orally or by subcutaneous injection. Women of childbearing potential who are prescribed methotrexate must use a robust contraceptive method, since it is teratogenic. Combination therapy with an immunosuppressant and an anti-TNF antibody is the most effective strategy but costs are high and there is an increased risk of serious adverse effects. In the UK, the use of anti-TNF therapy is limited to specific patient subgroups with severe disease (Boxes 22.78 and 22.79). Careful monitoring of disease activity (see Box 22.77) is the key to maintaining sustained remission and preventing the accumulation of bowel damage in Crohn's disease. Cigarette smokers should be strongly counselled to stop smoking at every possible opportunity. Those that do not manage to stop smoking fare much worse, with increased rates of relapse and surgical intervention.

Fistulae and perianal disease. Fistulae may develop in relation to active Crohn's disease and are often associated with sepsis. The first step is to define the site by imaging (usually MRI of the pelvis). Surgical exploration by an examination under anaesthetic is usually then required, to delineate the anatomy and drain abscesses. Seton sutures can be inserted through fistula tracts to ensure adequate drainage and to prevent future sepsis. Corticosteroids are ineffective. For simple perianal disease, metronidazole and/or ciprofloxacin are first-line therapies. Thiopurines can be used in chronic disease but do not usually result in fistula healing. Infliximab and adalimumab can heal fistulae and perianal disease in many patients and are indicated when the measures described above have been ineffective.

22.78 How to give anti-TNF therapy in inflammatory bowel disease

- Infliximab (5 mg/kg IV infusion) is given as 3 loading doses (at 0, 2 and 6 wks), with 8-weekly maintenance thereafter
- Adalimumab is given as SC injections, which patients can be trained to give themselves. Loading dose is 160 mg, followed by 80 mg 2 wks later and 40 mg every second wk thereafter; some patients require dose escalation to 40 mg once weekly
- Concomitant immunosuppression with a thiopurine or methotrexate may be more efficacious than monotherapy but has more side-effects
- Anti-TNF therapy is contraindicated in the presence of active infection and latent tuberculosis without appropriate prophylaxis; it carries an increased risk of opportunistic infections and possible increased risk of malignancy; and, rarely, multiple sclerosis may be unmasked in susceptible individuals. Counselling about the risk–benefit for each patient is important
- Prior to therapy, latent tuberculosis must be excluded
- Certolizumab is effective for luminal Crohn's disease but is not licensed in Europe
- Etanercept is not effective in Crohn's disease

EBM 22.79 Biological therapy in the management of inflammatory bowel disease

'Infliximab or adalimumab is recommended for patients with severely active Crohn's disease not responding to conventional immunosuppressive therapy, including corticosteroids, or where such therapies are contraindicated. Infliximab is also licensed for use in children and for fistulating Crohn's disease, and is an effective rescue therapy for patients with acute severe ulcerative colitis not responding to intravenous corticosteroids. Infliximab and adalimumab are also both effective for moderately active ulcerative colitis.'

- Crohn's disease – management in adults, children and young people. NICE guideline, Oct 2012.

Surgical treatment

Ulcerative colitis

Up to 60% of patients with extensive ulcerative colitis eventually require surgery. The indications are listed in Box 22.80. Impaired quality of life, with impact upon occupation and on social and family life, is the most important of these. Surgery involves removal of the entire colon and rectum, and cures the patient. One-third of those with pancolitis undergo colectomy within 5 years of diagnosis. Before surgery, patients must be counselled by doctors, stoma nurses and patients who have undergone similar surgery. The choice of procedure is either panproctocolectomy with ileostomy, or proctocolectomy with ileal–anal pouch anastomosis. The

22.80 Indications for surgery in ulcerative colitis

Impaired quality of life
- Loss of occupation or education
- Disruption of family life

Failure of medical therapy
- Dependence on oral corticosteroids
- Complications of drug therapy

Fulminant colitis

Disease complications unresponsive to medical therapy
- Arthritis
- Pyoderma gangrenosum

Colon cancer or severe dysplasia

sister surgical text to this book, *Principles and Practice of Surgery*, should be consulted for further details.

Crohn's disease

The indications for surgery are similar to those for ulcerative colitis. Operations are often necessary to deal with fistulae, abscesses and perianal disease, and may also be required to relieve small or large bowel obstruction. In contrast to ulcerative colitis, surgery is not curative and disease recurrence is the rule. The only method that has consistently been shown to reduce post-operative recurrence is smoking cessation. Antibiotics are effective in the short term only. It is common to undertake colonoscopy 6 months after surgery to inspect and biopsy the anastomosis and neo-terminal ileum. Patients with endoscopic recurrence are then prescribed thiopurines.

Surgery should be as conservative as possible in order to minimise loss of viable intestine and to avoid creation of a short bowel syndrome. Obstructing or fistulating small bowel disease may require resection of affected tissue. Patients who have localised segments of Crohn's colitis may be managed by segmental resection and/or multiple stricturoplasties, in which the stricture is not resected but instead incised in its longitudinal axis and sutured transversely. Others who have extensive colitis require total colectomy but ileal–anal pouch formation should be avoided because of the high risk of recurrence within the pouch and subsequent fistulae, abscess formation and pouch failure.

Historical datasets show that around 80% of Crohn's patients undergo surgery at some stage, and 70% of these require more than one operation during their lifetime. Clinical recurrence following resectional surgery is present in 50% of all cases at 10 years. Emerging data demonstrate that aggressive medical therapy, coupled with intense monitoring, probably reduces the requirement for surgery substantially.

IBD in special circumstances

Childhood

Chronic ill health in childhood or adolescent IBD may result in growth failure, metabolic bone disease and delayed puberty. Loss of schooling and social contact, as well as frequent hospitalisation, can have important psychosocial consequences. Treatment is similar to that described for adults and may require corticosteroids, immunosuppressive drugs, biological agents and surgery. Monitoring of height, weight and sexual development is crucial. Children with IBD should be managed by specialised paediatric gastroenterologists and transitioned to adult care in dedicated clinics (Box 22.81).

Pregnancy

A women's ability to become pregnant is adversely affected by active IBD. Pre-conceptual counselling should focus on optimising disease control. During pregnancy, the rule of thirds applies – roughly one-third of women improve, one-third get worse and one third remain stable with active disease. In the post-partum period, these changes sometimes reverse spontaneously. Drug therapy, including aminosalicylates, corticosteroids and azathioprine, can be safely continued throughout pregnancy but methotrexate must be avoided, both during pregnancy and if the patient is trying to conceive (Box 22.82). Anti-TNF agents are transmitted through

22.81 Inflammatory bowel disease in adolescence

- **Delayed growth and pubertal development**: chronic active inflammation, malabsorption, malnutrition and long-term corticosteroids contribute to short stature and delayed development, with physical and psychological consequences.
- **Metabolic bone disease**: more common with chronic disease beginning in childhood, resulting from chronic inflammation, dietary deficiency and malabsorption of calcium and vitamin D.
- **Drug side-effects and compliance issues**: young people are more likely to require azathioprine or biological therapy than adults. Poor compliance with therapy is more common than with adults, as younger patients may feel well, lack self-motivation to adhere and believe that drugs are ineffective or cause side-effects.
- **Loss of time from education**: physical illness, surgery, fatigue in chronic IBD, privacy and dignity issues, and social isolation may all contribute.
- **Emotional difficulties**: may result from difficulties coping with illness, problems forming interpersonal relationships, and issues relating to body image or sexual function.

22.82 Pregnancy and inflammatory bowel disease

Pre-conception

- Outcomes are best when pregnancy is carefully planned and disease is in remission
- Methotrexate must be stopped; other IBD drugs should be continued until discussed with a specialist
- Aminosalicylates and azathioprine are safe in pregnancy
- Corticosteroids are probably safe
- Safety of biological therapy in pregnancy is unclear; use only when absolutely necessary
- Daily folic acid supplements are recommended

Pregnancy

- Two-thirds of patients in remission will remain so in pregnancy
- Active disease is likely to remain active
- Severe active disease carries an increased risk of premature delivery and low birth weight
- Gentle flexible sigmoidoscopy is safe after the first trimester
- X-rays should be avoided
- Colonoscopy can be performed safely if the potential benefits outweigh the risks

Labour

- Needs careful discussion between patient, gastroenterologist and obstetrician
- Normal labour and vaginal delivery are possible for most
- Caesarean section may be preferred for patients with perianal Crohn's or an ileo-anal pouch to reduce risks of pelvic floor damage, fistulation and late incontinence

Breastfeeding

- Safe and does not exacerbate IBD
- Data on the risk to babies from drugs excreted in breast milk are limited; most are probably safe
- Patients should discuss breastfeeding and drug therapy carefully with their doctor

the placenta (but not breast milk) and are usually omitted during the last trimester.

Metabolic bone disease

Patients with IBD are prone to developing osteoporosis due to effects of chronic inflammation, corticosteroids, weight loss, malnutrition and malabsorption. Osteomalacia can also occur in Crohn's disease that is complicated by malabsorption, but is less common than osteoporosis. The risk of osteoporosis increases with age and with the dose and duration of corticosteroid therapy.

Microscopic colitis

Microscopic colitis, which comprises two related conditions, lymphocytic colitis and collagenous colitis, has no known cause. The presentation is with watery diarrhoea. The colonoscopic appearances are normal but histological examination of biopsies shows a range of abnormalities. It is therefore recommended that biopsies of the right and left colon plus terminal ileum should be undertaken in all patients undergoing colonoscopy for diarrhoea. Collagenous colitis is characterised by the presence of a submucosal band of collagen, often with a chronic inflammatory infiltrate. The disease is more common in women and may be associated with rheumatoid arthritis, diabetes, coeliac disease and some drug therapies, such as NSAIDs or PPIs. Treatment with budesonide is usually effective but the condition will recur in some patients on discontinuation of therapy.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is characterised by recurrent abdominal pain in association with abnormal defecation in the absence of a structural abnormality of the gut. About 10–15% of the population are affected at some time but only 10% of these consult their doctors because of symptoms. Nevertheless, IBS is the most common cause of gastrointestinal referral and accounts for frequent absenteeism from work and impaired quality of life. Young women are affected 2–3 times more often than men. Coexisting conditions, such as non-ulcer dyspepsia, chronic fatigue syndrome, dysmenorrhoea and fibromyalgia, are common. Between 5 and 10% of patients have a history of physical or sexual abuse.

Pathophysiology

The cause of IBS is incompletely understood but biopsychosocial factors are thought to play an important role, along with luminal factors, such as diet and the gut microbiota, as discussed below.

Behavioural and psychosocial factors

Most patients seen in general practice do not have psychological problems but about 50% of patients referred to hospital have a psychiatric illness, such as anxiety, depression, somatisation and neurosis. Panic attacks are also common. Acute psychological stress and overt psychiatric disease are known to alter visceral perception and gastrointestinal motility. There is an increased prevalence of abnormal illness behaviour, with frequent consultations for minor symptoms and reduced coping ability (p. 236). These factors contribute to but do not cause IBS.

Physiological factors

There is some evidence that IBS may be a serotoninergic (5-HT) disorder, as evidenced by relatively excessive release of 5-HT in diarrhoea-predominant IBS (D-IBS) and relative deficiency with constipation-predominant IBS (C-IBS). Accordingly, 5-HT_3 receptor antagonists are effective in D-IBS, while 5-HT_4 agonists improve bowel function in C-IBS. There is some evidence that IBS may represent a state of low-grade gut inflammation or immune activation, not detectable by tests, with raised numbers of mucosal mast cells, which sensitise enteric neurons by releasing histamine and tryptase. Some patients respond positively to mast cell stabilisers, such as ketotifen, which supports a pathogenic role of mast cells in at least some patients. Immune activation may be associated with altered CNS processing of visceral pain signals. This is more common in women and in D-IBS, and may be triggered by a prior episode of gastroenteritis with *Salmonella* or *Campylobacter* species.

Luminal factors

Both quantitative and qualitative alterations in intestinal bacterial contents (the gut microbiota) have been reported. Small intestinal bacterial overgrowth (SIBO) may be present in some patients and lead to symptoms. This 'gut dysbiosis' may explain the response to probiotics or the non-absorbable antibiotic rifaximin that has been reported in trials.

Dietary factors are also important. Some patients have chemical food intolerances (not allergy) to poorly absorbed, short-chain carbohydrates (lactose, fructose and sorbitol, among others), collectively known as FODMAPs (fermentable oligo-, di- and monosaccharides, and polyols). Their fermentation in the colon leads to bloating, pain, wind and altered bowel habit. Non-coeliac gluten sensitivity (negative coeliac serology and normal duodenal biopsies) seems to be present in some IBS patients, while others may be intolerant of chemicals such as salicylates or benzoates, found in certain foods.

Clinical features

The most common presentation is that of recurrent abdominal discomfort (Box 22.83). This is usually colicky or cramping in nature, felt in the lower abdomen and relieved by defecation. Abdominal bloating worsens throughout the day; the cause is unknown but it is not due to excessive intestinal gas. The bowel habit is variable. Most patients alternate between episodes of diarrhoea and constipation, but it is useful to classify patients as having predominantly constipation or predominantly diarrhoea. Those with constipation tend to pass infrequent pellety stools, usually in association with abdominal pain or proctalgia. Those with diarrhoea have frequent defecation but produce low-volume stools and rarely have nocturnal symptoms. Passage of mucus is

22.83 Rome III criteria for diagnosis of irritable bowel syndrome

Recurrent abdominal pain or discomfort at least 3 days/mth in the last 3 months, associated with *two or more* of the following:

- Improvement with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

common but rectal bleeding does not occur. Patients do not lose weight and are constitutionally well. Physical examination is generally unremarkable, with the exception of variable tenderness to palpation.

Diagnosis

The diagnosis is clinical in nature and can be made confidently in most patients using the Rome criteria combined with the absence of alarm symptoms, without resorting to complicated tests (Box 22.84). Full blood count and faecal calprotectin, with or without sigmoidoscopy, are usually done and are normal in IBS. Colonoscopy should be undertaken in older patients (over 40 years of age) to exclude colorectal cancer. Endoscopic examination is also required in patients who report rectal bleeding to exclude colon cancer and IBD. Those who present atypically require investigations to exclude other gastrointestinal diseases. Diarrhoea-predominant patients justify investigations to exclude coeliac disease (p. 880), microscopic colitis (p. 907), lactose intolerance (p. 887), bile acid malabsorption (p. 851), thyrotoxicosis (p. 740) and, in developing countries, parasitic infection.

Management

The most important steps are to make a positive diagnosis and reassure the patient. Many patients are concerned that they have developed cancer, and a cycle of anxiety leading to colonic symptoms, which further heighten anxiety, can be broken by explanation that

22.84 Supporting diagnostic features and alarm features in IBS

Features supporting a diagnosis of IBS

- Symptoms > 6 mths
- Frequent consultations for non-gastrointestinal problems
- Previous medically unexplained symptoms
- Stress worsens symptoms

Alarm features

- Age > 50 yrs; male gender
- Weight loss
- Nocturnal symptoms
- Family history of colon cancer
- Anaemia
- Rectal bleeding

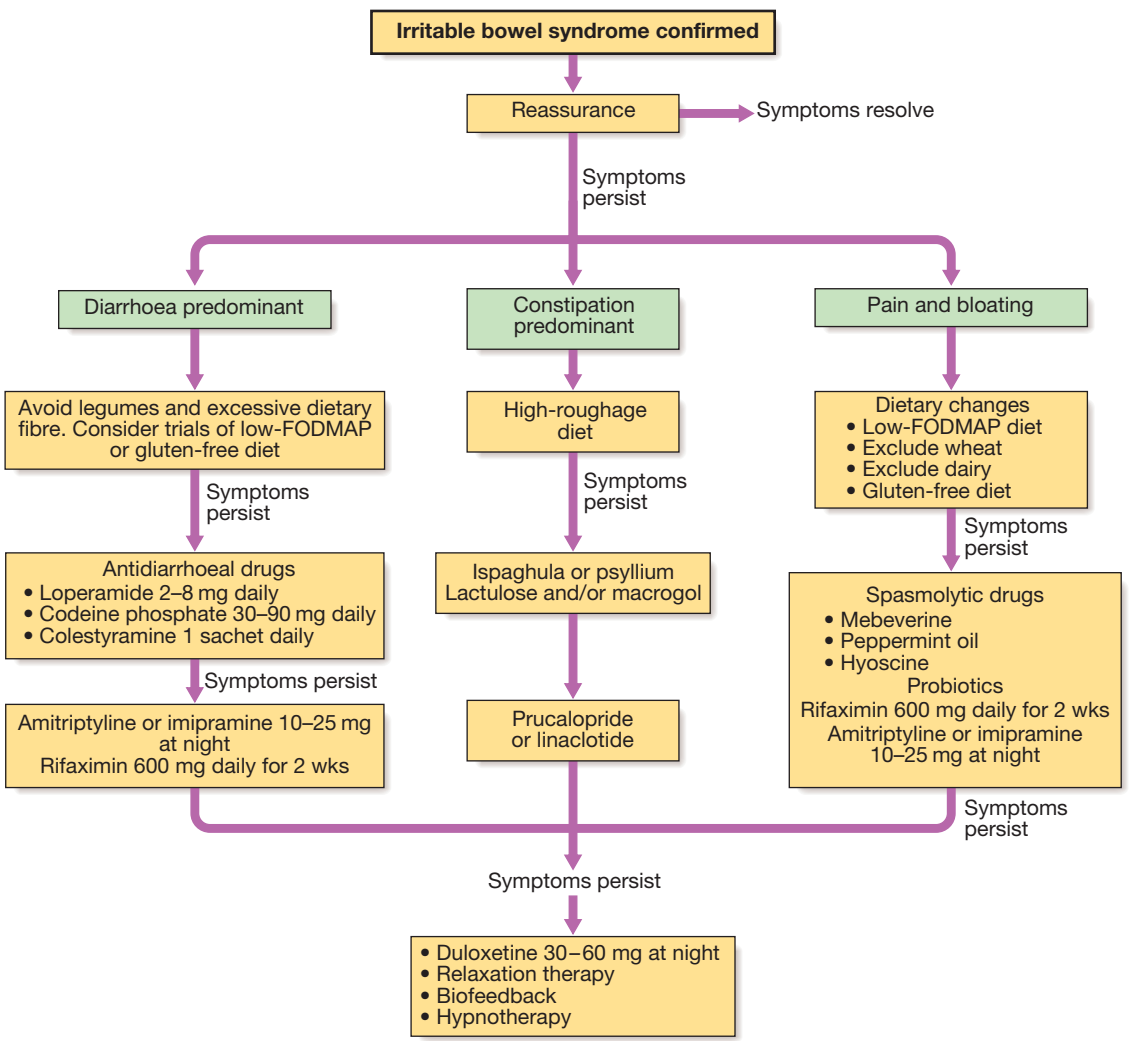

Fig. 22.57 Management of irritable bowel syndrome. (FODMAP = fermentable oligo-, di- and monosaccharides, and polyols)

symptoms are not due to a serious underlying disease but instead are the result of behavioural, psychosocial, physiological and luminal factors described above. In patients who fail to respond to reassurance, treatment is traditionally tailored to the predominant symptoms (Fig. 22.57). Up to 20% may benefit from a wheat-free diet, some may respond to lactose exclusion, and excess intake of caffeine or artificial sweeteners, such as sorbitol, should be addressed. A more restrictive, 'low-FODMAP' diet, supervised by a dietitian, with gradual re-introduction of different food groups, may help some patients, as may a trial of a gluten-free diet. Probiotics, in capsule form, can be effective if taken for several months, although the optimum combination of bacterial strains and dose have yet to be clarified.

Patients with intractable symptoms sometimes benefit from several months of therapy with a tricyclic antidepressant, such as amitriptyline or imipramine (10–25 mg orally at night). Side-effects include dry mouth and drowsiness but these are usually mild and the drug is generally well tolerated, although patients with features of somatisation tolerate the drug poorly and lower doses should be used. It may act by reducing visceral sensation and by altering gastrointestinal motility. Anxiety and affective disorders may also require specific treatment (pp. 242 and 243). The 5-HT_4 agonist prucalopride, the guanylate cyclase-C receptor agonist linaclotide, and chloride channel activators, such as lubiprostone, can be effective in constipation-predominant IBS.

Trials of anti-inflammatory agents, such as ketotifen or mesalazine, and the antibiotic rifaximin may be considered in some patients with difficult symptoms but are best prescribed only after specialist referral.

Psychological interventions, such as cognitive behavioural therapy, relaxation and gut-directed hypnotherapy, should be reserved for the most difficult cases. A range of complementary and alternative therapies exist; most lack a good evidence base but are popular and help some patients (Box 22.85).

Most patients have a relapsing and remitting course. Exacerbations often follow stressful life events, occupational dissatisfaction and difficulties with interpersonal relationships.

22.85 Complementary and alternative therapies for IBS

Manipulative and body-based
• Massage, chiropractic
Mind–body interventions
• Meditation, hypnosis*, cognitive therapy
Biologically based
• Herbal products*, dietary additives, probiotics*
Energy healing
• Biofield therapies (reiki), bio-electromagnetic field therapies
Alternative medical systems
• Ayurvedic, homeopathy, traditional Chinese medicine

*Some evidence for benefit exists.

AIDS AND THE GASTROINTESTINAL TRACT

Patients with HIV-AIDS may develop several symptoms referable to the gastrointestinal tract, as discussed in detail on page 399. Consider HIV testing in all patients with atypical or unexplained gastrointestinal symptoms and those resident in areas of high prevalence.

ISCHAEMIC GUT INJURY

Ischaemic gut injury is usually the result of arterial occlusion. Severe hypotension and venous insufficiency are less frequent causes (p. 198). The presentation is variable, depending on the different vessels involved and the acuteness of the event. Diagnosis is often difficult.

Acute small bowel ischaemia

An embolus from the heart or aorta to the superior mesenteric artery is responsible for 40–50% of cases, thrombosis of underlying atheromatous disease for approximately 25%, and non-occlusive ischaemia due to hypotension complicating myocardial infarction, heart failure, arrhythmias or sudden blood loss for approximately 25%. Vasculitis and venous occlusion are rare causes. The clinical spectrum ranges from transient alteration of bowel function to transmural haemorrhagic necrosis and gangrene. Patients usually have evidence of cardiac disease and arrhythmia. Almost all develop abdominal pain that is more impressive than the physical findings. In the early stages, the only physical signs may be a silent, distended abdomen or diminished bowel sounds, peritonitis only developing later.

Leucocytosis, metabolic acidosis, hyperphosphataemia and hyperamylasaemia are typical. Plain abdominal X-rays show 'thumb-printing' due to mucosal oedema. Mesenteric or CT angiography reveals an occluded or narrowed major artery with spasm of arterial arcades, although most patients undergo laparotomy on the basis of a clinical diagnosis without angiography. Resuscitation, management of cardiac disease and intravenous antibiotic therapy, followed by laparotomy, are key steps. If treatment is instituted early, embolectomy and vascular reconstruction may salvage some small bowel. In these rare cases, a 'second look' laparotomy should be undertaken 24 hours later and further necrotic bowel resected. In patients at high surgical risk, thrombolysis may sometimes be effective. The results of therapy depend on early intervention; patients treated late have a 75% mortality rate. Survivors often have nutritional failure from short bowel syndrome (p. 884) and require intensive nutritional support, including home parenteral nutrition and anticoagulation. Small bowel transplantation is promising in selected patients. Patients with mesenteric venous thrombosis also require surgery if there are signs of peritonitis but are otherwise treated with anticoagulation. Investigations for underlying prothrombotic disorders should be performed (p. 1054).

Acute colonic ischaemia

The splenic flexure and descending colon have little collateral circulation and lie in 'watershed' areas of arterial supply. The spectrum of injury ranges from reversible

colopathy to transient colitis, colonic stricture, gangrene and fulminant pancolitis. Arterial thromboembolism is usually responsible but colonic ischaemia can also follow severe hypotension, colonic volvulus, strangulated hernia, systemic vasculitis or hypercoagulable states. Ischaemia of the descending and sigmoid colon is also a complication of abdominal aortic aneurysm surgery (where the inferior mesenteric artery is ligated). The patient is usually elderly and presents with sudden onset of cramping, left-sided, lower abdominal pain and rectal bleeding. Symptoms usually resolve spontaneously over 24–48 hours and healing occurs in 2 weeks. Some may develop a fibrous stricture or segment of colitis. A minority develop gangrene and peritonitis. The diagnosis is established by colonoscopy within 48 hours of presentation; otherwise, mucosal ulceration may have resolved. Resection is required for peritonitis.

Chronic mesenteric ischaemia

This results from atherosclerotic stenosis of the coeliac axis, superior mesenteric artery and inferior mesenteric artery. At least two of the three vessels must be affected for symptoms to develop. The typical presentation is with dull but severe mid- or upper abdominal pain developing about 30 minutes after eating. Weight loss is common because the patient is reluctant to eat, and some experience diarrhoea. Physical examination shows evidence of generalised arterial disease. An abdominal bruit is sometimes audible but is non-specific. The diagnosis is made by mesenteric angiography. Treatment is by vascular reconstruction or percutaneous angioplasty, if the patient's clinical condition permits. The condition is frequently complicated by intestinal infarction, if left untreated.

DISORDERS OF THE COLON AND RECTUM

Tumours of the colon and rectum

Polyps and polyposis syndromes

Polyps may be neoplastic or non-neoplastic. The latter include hamartomas, metaplastic ('hyperplastic') polyps and inflammatory polyps. These have no malignant potential. Polyps may be single or multiple and vary from a few millimetres to several centimetres in size.

Colorectal adenomas are extremely common in the Western world and the prevalence rises with age; 50% of people over 60 years of age have adenomas, and in half of these the polyps are multiple. They are more common in the rectum and distal colon and are either pedunculated or sessile. Histologically, they are classified as either tubular, villous or tubulovillous, according to the glandular architecture. Nearly all forms of colorectal carcinoma develop from adenomatous polyps, although not all polyps carry the same degree of risk. Features associated with a higher risk of subsequent malignancy are listed in Box 22.86.

Adenomas are usually asymptomatic and discovered incidentally. Occasionally, they cause bleeding and anaemia. Villous adenomas can secrete large amounts of mucus, causing diarrhoea and hypokalaemia.

22.86 Risk factors for malignant change in colonic polyps

- Large size (> 2 cm)
- Multiple polyps
- Villous architecture
- Dysplasia

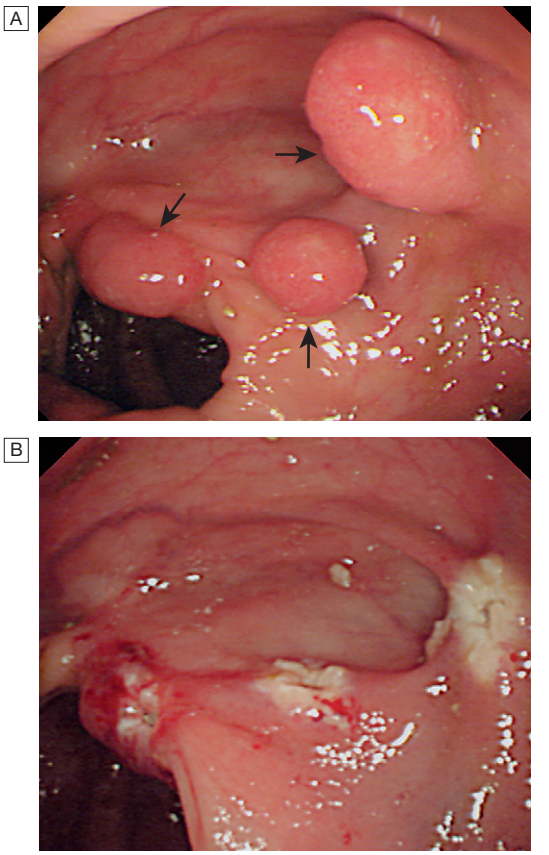

Fig. 22.58 Adenomatous colonic polyps. A Before colonoscopic polypectomy (arrows show polyps). B After polypectomy.

Discovery of a polyp at sigmoidoscopy is an indication for colonoscopy because proximal polyps are present in 40–50% of such patients. Colonoscopic polypectomy should be carried out wherever possible, as this considerably reduces subsequent colorectal cancer risk (Fig. 22.58). Very large or sessile polyps can sometimes be removed safely by endoscopic mucosal resection (EMR) but many require surgery. Once all polyps have been removed, surveillance colonoscopy should be undertaken at 3–5-year intervals, as new polyps develop in 50% of patients. Patients over 75 years of age do not require repeated colonoscopies, as their subsequent lifetime cancer risk is low.

Between 10 and 20% of polyps show histological evidence of malignancy. When cancer cells are found within 2 mm of the resection margin of the polyp, when the polyp cancer is poorly differentiated or when lymphatic invasion is present, segmental colonic resection is recommended because residual tumour or lymphatic spread (in up to 10%) may be present. Malignant polyps without these features can be followed up by surveillance colonoscopy.

Polyposis syndromes are classified by histopathology (Box 22.87). It should be noted that, while the

22.87 Gastrointestinal polyposis syndromes

	Neoplastic	Non-neoplastic*			
	Familial adenomatous polyposis	Peutz–Jeghers syndrome	Juvenile polyposis	Cronkhite–Canada syndrome	Cowden's disease
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant in 1/3	None	Autosomal dominant
Oesophageal polyps	–	–	–	+	+
Gastric polyps	+	+	+	+++	+++
Small bowel polyps	++	+++	++	++	++
Colonic polyps	+++	++	++	+++	+
Other features	Colorectal cancer, bleeding, extra-intestinal features (Box 22.88)	Pigmentation, bleeding, intussusception, bowel and other cancers	Colorectal cancer	Hair loss, pigmentation, nail dystrophy, malabsorption	Many congenital anomalies, oral and cutaneous hamartomas, thyroid and breast tumours

– absent; + may occur; ++ common; +++ very common. *The polyps themselves are not neoplastic but cancer risk is increased in several syndromes.

hamartomatous polyps in Peutz–Jeghers syndrome and juvenile polyposis are not themselves neoplastic, these disorders are associated with an increased risk of malignancy of the breast, colon, ovary and thyroid.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an uncommon autosomal dominant disorder affecting 1 in 13 000 of the population and accounting for 1% of all colorectal cancers. It results from germline mutation of the tumour suppressor *APC* gene, followed by acquired mutation of the remaining allele (Ch. 3). The *APC* gene is large and over 1400 different mutations have been reported, but most are loss-of-function mutations resulting in a truncated APC protein. This protein normally binds to and sequesters β-catenin but is unable to do so when mutated, allowing β-catenin to translocate to the nucleus, where it up-regulates the expression of many genes.

Around 20% of cases arise as new mutations and have no family history. Hundreds to thousands of adenomatous colonic polyps develop in 80% of patients by age 15 (Fig. 22.59), with symptoms such as rectal bleeding beginning a few years later. In those affected, cancer will develop within 10–15 years of the appearance of adenomas and 90% of patients will develop colorectal cancer by the age of 50 years. Despite surveillance, approximately 1 in 4 patients with FAP have cancer by the time they undergo colectomy.

A second gene involved in base excision repair (MutY homolog, *MUTYH*) has been identified which may give rise to colonic polyposis. *MUTYH* displays autosomal recessive inheritance and leads to tens to hundreds of polyps and proximal colon cancer. This variant is referred to as *MUTYH*-associated polyposis (MAP).

Non-neoplastic cystic fundic gland polyps occur in the stomach but adenomatous polyps also occur uncommonly. Duodenal adenomas occur in over 90% and are most common around the ampulla of Vater. Malignant transformation to adenocarcinoma occurs in 10% and is the leading cause of death in those who have had prophylactic colectomy. Many extra-intestinal features are also seen in FAP (Box 22.88).

Fig. 22.59 Familial adenomatous polyposis. There are hundreds of adenomatous polyps throughout the colon.

22.88 Extra-intestinal features of familial adenomatous polyposis

- Congenital hypertrophy of the retinal pigment epithelium (CHRPE, 70–80%)
- Epidermoid cysts (extremities, face, scalp)* (50%)
- Benign osteomas, especially skull and angle of mandible* (50–90%)
- Dental abnormalities (15–25%)*
- Desmoid tumours (10–15%)
- Other malignancies (brain, thyroid, liver, 1–3%)

*Gardner's syndrome.

Desmoid tumours occur in up to one-third of patients and usually arise in the mesentery or abdominal wall. Although benign, they may become very large, causing compression of adjacent organs, intestinal obstruction or vascular compromise, and are difficult to remove. They

sometimes respond to hormonal therapy with tamoxifen, and the NSAID sulindac may lead to regression in some, by unknown mechanisms. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in some and is seen as dark, round, pigmented retinal lesions. When present in an at-risk individual, they are 100% predictive of the presence of FAP. A variant, Turcot's syndrome, is characterised by FAP with primary CNS tumours (astrocytoma or medulloblastoma).

Early identification of affected individuals before symptoms develop is essential. The diagnosis can be excluded if sigmoidoscopy is normal. In newly diagnosed cases, genetic testing should be carried out to confirm the diagnosis and identify the causal mutation. Subsequently, all first-degree relatives should also undergo testing (p. 60). In families with known FAP, family members should undergo mutation testing at 13–14 years of age and patients who are found to have the mutation should be offered colectomy after school or college education has been completed. The operation of choice is total proctocolectomy with ileal pouch–anal anastomosis. Periodic upper gastrointestinal endoscopy every 1–3 years is recommended to detect and monitor duodenal and periampullary adenomas. If large, these may be amenable to endoscopic resection.

Peutz–Jeghers syndrome

Multiple hamartomatous polyps occur in the small intestine and colon, as well as melanin pigmentation of the lips, mouth and digits (Fig. 22.60). Most cases are asymptomatic, although chronic bleeding, anaemia or intussusception can occur. There is a significant risk of small bowel or colonic adenocarcinoma and of cancer of the pancreas, lung, ovary, breast and endometrium. It is an autosomal dominantly inherited disorder, most commonly resulting from truncating mutations in a serine–threonine kinase gene on chromosome 19p (*STK11*). Diagnosis requires two of the three following features:

- small bowel polyposis
- mucocutaneous pigmentation
- a family history suggesting autosomal dominant inheritance.

The diagnosis can be made by genetic testing but this may be inconclusive, since mutations in genes other than *STK11* can cause the disorder. Affected people should undergo regular upper endoscopy, colonoscopy, and small bowel and pancreatic imaging. Polyps greater than 1 cm in size should be removed. Testicular examination is essential for men, while women should undergo pelvic examination, cervical smears and regular mammography. Asymptomatic relatives of affected patients should also undergo screening.

Fig. 22.60 Peutz–Jeghers syndrome. Typical lip pigmentation.

Juvenile polyposis

In juvenile polyposis (JPS), tens to hundreds of mucus-filled hamartomatous polyps are found in the colorectum. One-third of cases are inherited in an autosomal dominant manner and up to 20% develop colorectal cancer before the age of 40. The criteria for diagnosis are:

- ten or more colonic juvenile polyps
- juvenile polyps elsewhere in the gut, *or*
- any polyps in those with a family history.

Germline mutations in the *SMAD4* gene are often found, as are *PTEN* mutations. Colonoscopy with polypectomy should be performed every 1–3 years and colectomy considered for extensive involvement.

Colorectal cancer

Although relatively rare in the developing world, colorectal cancer is the second most common internal malignancy and the second leading cause of cancer deaths in Western countries. In the UK, the incidence is 50–60 per 100 000, equating to 30 000 cases per year. The condition becomes increasingly common over the age of 50 years.

Pathophysiology

Both environmental and genetic factors are important in colorectal carcinogenesis (Fig. 22.61). Environmental factors account for 70% of all 'sporadic' colorectal cancers. This figure is based on the wide geographical variation in incidence and the decrease in risk seen in migrants who move from high- to low-risk countries. Dietary factors are most important and these are summarised in Box 22.89; other recognised risk factors are listed in Box 22.90.

Colorectal cancer development results from the accumulation of multiple genetic mutations arising from two major pathways: chromosomal instability and microsatellite instability (Fig. 22.62).

- *Chromosomal instability*. Mutations or deletions of portions of chromosomes arise, with loss of heterozygosity (LOH) and inactivation of specific tumour suppressor genes. In LOH, one allele of a gene is deleted but gene inactivation only occurs when a subsequent unrelated mutation affects the other allele.
- *Microsatellite instability*. This involves germline mutations in one of six genes encoding enzymes involved in repairing errors that occur normally during DNA replication (DNA mismatch repair); these genes are designated *hMSH2*, *hMSH6*, *hMLH1*, *hMLH3*, *hPMS1* and *hPMS2*. Replication errors accumulate and can be detected in 'microsatellites' of repetitive DNA sequences. They also occur in important regulatory genes, resulting in a genetically unstable phenotype and accumulation of multiple somatic mutations throughout the genome that eventually lead to cancer. A few sporadic cancers develop this way, as do most cases of hereditary non-polyposis colon cancer (HNPCC).

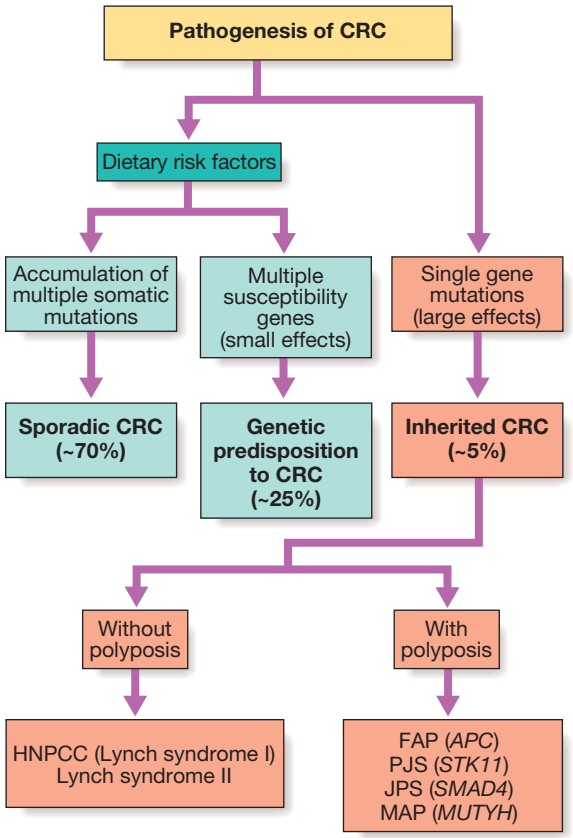

Fig. 22.61 Pathogenesis of colorectal cancer (CRC). (FAP = familial adenomatous polyposis; HNPCC = hereditary non-polyposis colon cancer; JPS = juvenile polyposis syndrome; MAP = *MUTYH*-associated polyposis; PJS = Peutz–Jeghers syndrome)

22.89 Dietary risk factors for colorectal cancer

Risk factor	Comments
Increased risk	
Red meat*	High saturated fat and protein content Carcinogenic amines formed during cooking
Saturated animal fat*	High faecal bile acid and fatty acid levels May affect colonic prostaglandin turnover
Decreased risk	
Dietary fibre*	Effects vary with fibre type; shortened transit time, binding of bile acids and effects on bacterial flora proposed
Fruit and vegetables	Green vegetables contain anticarcinogens, such as flavonoids Little evidence for protection from vitamins A, C, E
Calcium	Binds and precipitates faecal bile acids
Folic acid	Reverses DNA hypomethylation
Omega-3 fatty acids	May be of modest benefit

*Evidence is inconsistent and a clear relationship is unproven.

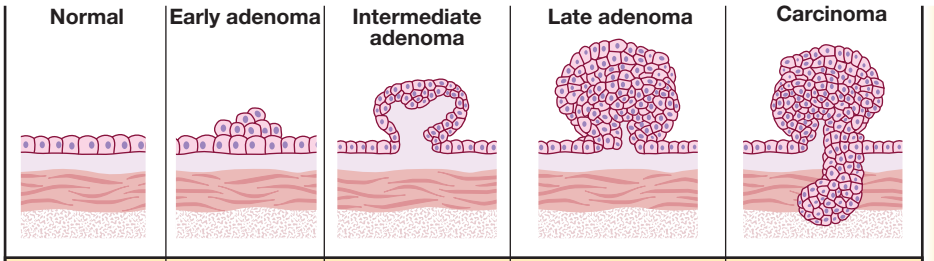
22.90 Non-dietary risk factors for colorectal cancer

Medical conditions

- Colorectal adenomas (p. 910)
- Long-standing extensive ulcerative colitis or Crohn's colitis (p. 897), especially if associated with primary sclerosing cholangitis (PSC)
- Ureterosigmoidostomy
- Acromegaly
- Pelvic radiotherapy

Others

- Obesity and sedentary lifestyle – may be related to diet
- Smoking (relative risk 1.5–3.0)
- Alcohol (weak association)
- Cholecystectomy (effect of bile acids in right colon)
- Type 2 diabetes (hyperinsulinaemia)
- Use of aspirin or NSAIDs (COX-2 inhibition) and perhaps statins associated with *reduced* risk

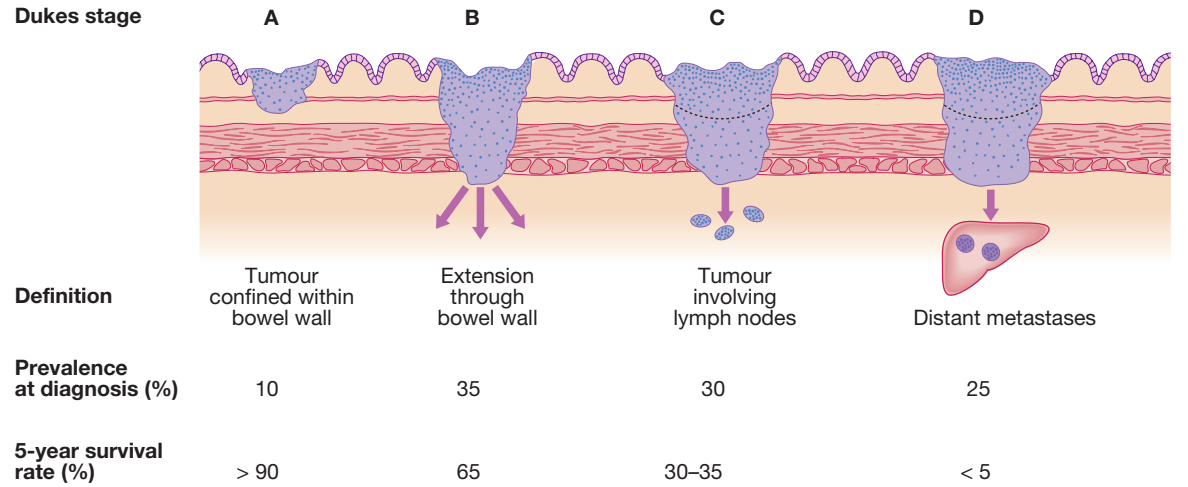


22.91 Modified Amsterdam criteria* for hereditary non-polyposis colon cancer

- Three or more relatives with colon cancer (at least one first-degree)
- Colorectal cancer in two or more generations
- At least one member affected under 50 yrs of age
- FAP excluded

*These criteria are strict and may miss some families with mutations. HNPCC should also be considered in individuals with colorectal or endometrial cancer under 45 yrs of age.

About 5–10% of colon cancers are caused by HNPCC. Pedigrees with this disorder have an autosomal dominant mode of inheritance and a positive family history of colon cancer occurring at a young age. The lifetime risk in affected individuals is 80%, with a mean age at cancer development of 45 years. In contrast to sporadic colon cancer, two-thirds of tumours occur proximally. The diagnostic criteria are listed in Box 22.91. In a subset of patients, there is also an increased incidence of cancers of the endometrium, ovary, urinary tract, stomach, pancreas, small intestine and CNS, related to inheritance of different mismatch repair gene mutations. Those who fulfil the criteria for HNPCC should be referred for pedigree assessment, genetic testing (see above) and colonoscopy. These should begin around 25 years of age or 5–10 years earlier than the youngest case of cancer in the family. Colonoscopy needs to be repeated every 1–2 years but, even then, interval cancers can still occur.



A family history of colorectal cancer can be obtained in 20% of patients who do not fulfil the criteria for HNPCC. In these families, the lifetime risk of developing colon cancer is 1 in 12 and 1 in 6, respectively, when one or two first-degree relatives are affected. The risk is even higher if relatives were affected at an early age. The genes responsible for these cases are unknown, however. Most tumours arise from malignant transformation of a benign adenomatous polyp. Over 65% occur in the rectosigmoid and a further 15% recur in the caecum or ascending colon. Synchronous tumours are present in 2–5% of patients. Spread occurs through the bowel wall. Rectal cancers may invade the pelvic viscera and side walls. Lymphatic invasion is common at presentation, as

	Normal	Early adenoma	Intermediate adenoma	Late adenoma	Carcinoma
Key gene(s)		*APC* (adenomatous polyposis coli)	*K-ras*	*DCC* (deleted in colon cancer) *SMAD4*	*p53*
Chromosome		5q	12p	18q	17p
Normal function		Inhibits translocation of β-catenin to nucleus and suppresses cell growth	Transmembrane GTP-binding protein mediating mitogenic signals (p21)	*DCC* regulates apoptosis and has a tumour suppressor function *SMAD4* regulates cell growth	Upregulated during cell damage to arrest cell cycle and allow DNA repair or apoptosis to occur
Alteration		Truncating mutations	Gain-of-function mutations	Allelic deletion or silencing (*DCC*) Gain-of-function mutations (*SMAD4*)	Allelic deletion; gain-of-function mutations
Effect		Progression to early adenoma development	Cell proliferation	Enhanced tumour growth, invasion and metastasis	Cell proliferation; impaired apoptosis

Further mutations
- Anchorage independence
- Protease synthesis
- Telomerase synthesis
- Multidrug resistance
- Evasion of immune system

Fig. 22.62 **The multistep origin of cancer: molecular events implicated in colorectal carcinogenesis.** (GTP = guanine triphosphate)

Dukes stage	A	B	C	D
Definition	Tumour confined within bowel wall	Extension through bowel wall	Tumour involving lymph nodes	Distant metastases
Prevalence at diagnosis (%)	10	35	30	25
5-year survival rate (%)	> 90	65	30–35	< 5

Fig. 22.63 **Modified Dukes classification and survival in colorectal cancer.**

is spread through both portal and systemic circulations to reach the liver and, less commonly, the lungs. Tumour stage at diagnosis is the most important determinant of prognosis (Fig. 22.63).

Clinical features

Symptoms vary depending on the site of the carcinoma. In tumours of the left colon, fresh rectal bleeding is common and obstruction occurs early. Tumours of the right colon present with anaemia from occult bleeding or with altered bowel habit, but obstruction is a late feature. Colicky lower abdominal pain is present in two-thirds of patients and rectal bleeding occurs in 50%. A minority present with features of either obstruction or perforation, leading to peritonitis, localised abscess or fistula formation. Carcinoma of the rectum usually causes early bleeding, mucus discharge or a feeling of incomplete emptying. Between 10 and 20% of patients present with iron deficiency anaemia or weight loss. On examination, there may be a palpable mass, signs of anaemia or hepatomegaly from metastases. Low rectal tumours may be palpable on digital examination.

Investigations

Colonoscopy is the investigation of choice because it is more sensitive and specific than barium enema. Furthermore, lesions can be biopsied and polyps removed. Patients in whom colonoscopy is incomplete and those

who are at high risk of complications can be investigated by CT colonography (virtual colonoscopy). This is a sensitive and non-invasive technique for diagnosing tumours and polyps of more than 6 mm diameter. When the diagnosis of colon cancer has been made, CT of chest, abdomen and pelvis should be performed as a staging investigation, particularly to detect hepatic metastases. Pelvic MRI or endoanal ultrasound should be used for local staging of rectal cancer. Measurement of serum carcinoembryonic antigen (CEA) levels are of limited value in diagnosis, since values are normal in many patients, but CEA testing can be helpful during follow-up to monitor for the prescience of recurrence.

Management

Surgery

All patients should be discussed at a multidisciplinary team meeting. Those with locally advanced rectal cancer should be offered neoadjuvant radiotherapy or chemoradiotherapy to increase the subsequent chance of a complete (R0) surgical resection. A 1-week course of radiotherapy just prior to surgery reduces the risk of local recurrence in operable rectal cancer. The tumour should be removed, along with adequate resection margins and pericolic lymph nodes. Continuity should be restored by direct anastomosis, wherever possible. Carcinomas within 2 cm of the anal verge may require abdominoperineal resection and formation of a colostomy. All patients should be counselled pre-operatively about the possible need for a stoma. Total mesorectal excision (TME) reduces recurrence rates and increases survival in rectal cancer. Metastatic disease confined to liver or lung should be considered for resection, as this can be potentially curative if there is truly no disease at other sites. Post-operatively, patients should undergo colonoscopy after 6–12 months and then at 5 years to search for local recurrence or development of new lesions, which occur in 6% of cases.

Adjuvant therapy

About 30–40% of patients have lymph node involvement at presentation (see Fig. 22.63) and are, therefore, at risk of recurrence. Most recurrences are within 3 years of diagnosis and affect the liver, lung, distant lymph nodes and peritoneum. Adjuvant chemotherapy with 5-fluorouracil/folinic acid or capecitabine, preferably in combination with oxaliplatin, can reduce the risk of recurrence in patients with Dukes stage C cancers and some high-risk Dukes B cancers. Post-operative radiotherapy reduces the risk of local recurrence in rectal cancer if operative resection margins are involved.

Palliation of advanced disease

Surgical resection of the primary tumour is appropriate for some patients with metastases to treat obstruction, bleeding or pain. Palliative chemotherapy with 5-fluorouracil/folinic acid, capecitabine, oxaliplatin or irinotecan improves survival. Patients with advanced metastatic disease may be treated with monoclonal antibodies using bevacizumab or cetuximab, either alone or together with chemotherapy. Pelvic radiotherapy is sometimes useful for distressing rectal symptoms such as pain, bleeding or severe tenesmus. Endoscopic laser therapy or insertion of an expandable metal stent can be used to relieve obstruction (Fig. 22.64).

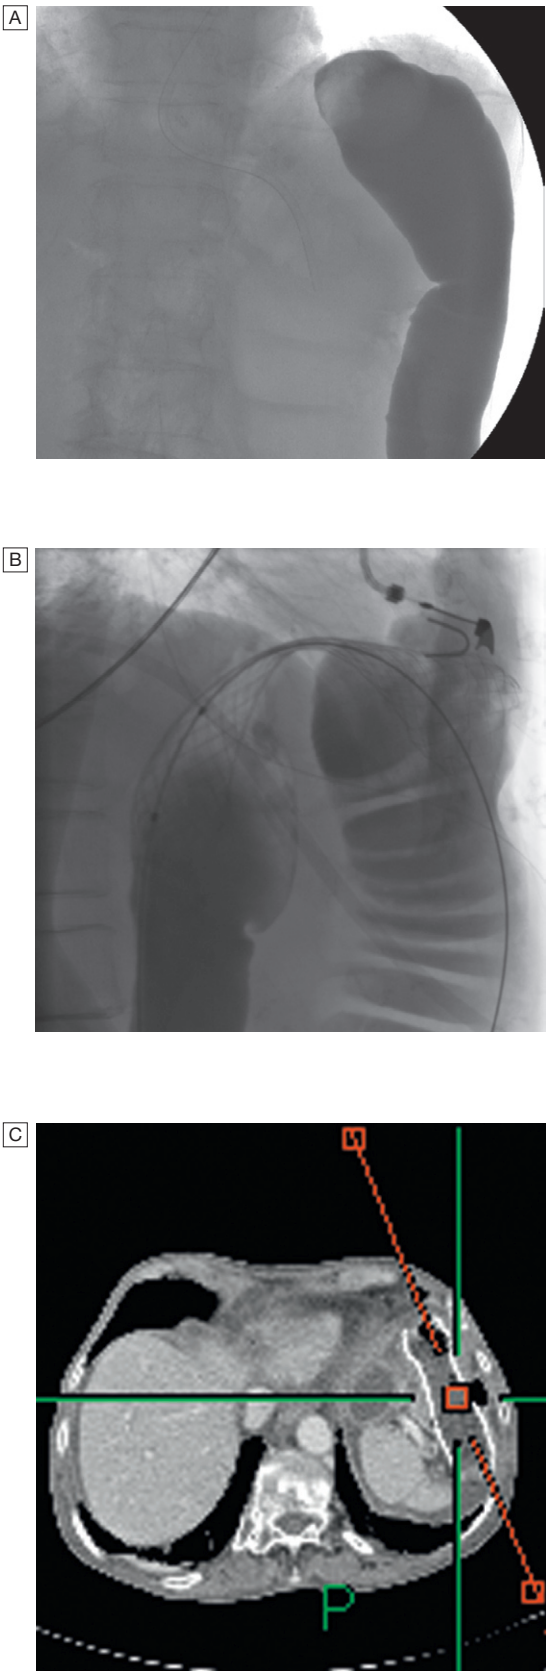


Fig. 22.64 Placement of a colonic stent for an inoperable cancer with impending obstruction. A The contrast study demonstrates an obstruction. B The stent is deployed across the tumour. C A satisfactory position is demonstrated on subsequent CT scanning.

EBM 22.92 Faecal occult blood (FOB) testing and colon cancer mortality

'Combined results from four randomised controlled trials show that participants allocated to screening by FOB testing had a 16% reduction in the relative risk of colorectal cancer mortality (RR 0.84, CI: 0.78–0.90). When adjusted for screening attendance, there was a 25% relative risk reduction (RR 0.75, CI: 0.66–0.84) for those attending at least one round of FOB screening.'

- Hewitson P, et al. Screening for colorectal cancer using the faecal occult blood test, Hemoccult. Cochrane Database of Systematic Reviews, 2007, issue 1. Art. no. CD001216; CD001216.pub2 (up to date 2010).

For further information: www.cochrane.org/cochrane-reviews

Prevention and screening

Secondary prevention aims to detect and remove lesions at an early or pre-malignant stage. Several potential methods exist:

- Population-based screening of people over the age of 50 years by regular *faecal occult blood (FOB) testing* reduces colorectal cancer mortality (Box 22.92) and increases the proportion of early cancers detected. The sensitivity and specificity of these tests need to be improved.
- *Colonoscopy* remains the gold standard but is expensive and carries risks; many countries lack the resources to offer this form of screening.
- *Flexible sigmoidoscopy* is an alternative option and has been shown to reduce overall colorectal cancer mortality by approximately 35% (70% for cases arising in the rectosigmoid). It is recommended in the USA every 5 years in all persons over the age of 50.
- Screening for high-risk patients by *molecular genetic analysis* is an exciting prospect but is not yet available.

Diverticulosis

Diverticula are acquired and are most common in the sigmoid and descending colon of middle-aged people. Asymptomatic diverticula (diverticulosis) are present in over 50% of people above the age of 70 years. Symptomatic diverticular disease supervenes in 10–25% of cases, while complicated diverticulosis (acute diverticulitis, pericolic abscess, bleeding, perforation or stricture) is uncommon.

Pathophysiology

A life-long refined diet with a relative deficiency of fibre is widely thought to be responsible and the condition is rare in populations with a high dietary fibre intake, such as in Asia, where it more often affects the right side of the colon. It is postulated that small-volume stools require high intracolonic pressures for propulsion and this leads to herniation of mucosa between the taeniae coli (Fig. 22.65). Diverticula consist of protrusions of mucosa covered by peritoneum. There is commonly hypertrophy of the circular muscle coat. Inflammation is thought to result from impaction of diverticula with faecoliths. This may resolve spontaneously or progress to cause haemorrhage, perforation, local abscess formation, fistula and peritonitis. Repeated attacks of inflammation lead to thickening of the bowel wall, narrowing of the lumen and eventual obstruction.

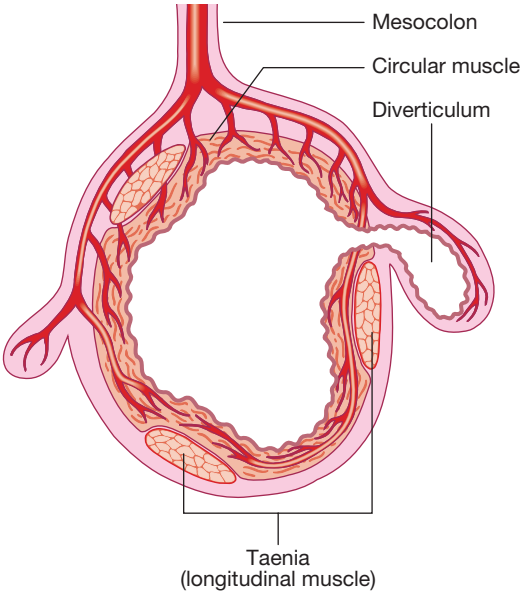

Fig. 22.65 The human colon in diverticulosis. The colonic wall is weak between the taeniae. The blood vessels that supply the colon pierce the circular muscle and weaken it further by forming tunnels. Diverticula usually emerge through these points of least resistance.

Clinical features

Symptoms are usually the result of associated constipation or spasm. Colicky pain is suprapubic or felt in the left iliac fossa. The sigmoid colon may be palpable and, in attacks of diverticulitis, there is local tenderness, guarding, rigidity ('left-sided appendicitis') and sometimes a palpable mass. During these episodes, there may be diarrhoea, rectal bleeding or fever. The differential diagnosis includes colorectal cancer, ischaemic colitis, inflammatory bowel disease and infection. Diverticular disease may be complicated by perforation, pericolic abscess, fistula formation (usually colovesical) or acute rectal bleeding. These complications are more common in patients who take NSAIDs or aspirin. After one attack of diverticulitis, the recurrence rate is around 3% per year. Over 10–30 years, perforation, obstruction or bleeding may occur, each affecting 5% of patients.

Investigations

Investigations are usually performed to exclude colorectal neoplasia. Barium enema can be used to confirm the presence of diverticula (see Fig. 22.11C, p. 847), strictures and fistulae. If barium studies are performed, flexible sigmoidoscopy is also necessary to exclude a coexisting neoplasm, which is easily missed radiologically. In severe diverticulosis, colonoscopy requires expertise and carries a risk of perforation. CT is used to assess complications, such as perforation or pericolic abscess.

Management

Diverticular disease that is asymptomatic and discovered coincidentally requires no treatment. Constipation can be relieved by a high-fibre diet, with or without a

bulking laxative (ispaghula husk, 1–2 sachets daily), taken with plenty of fluids. Stimulant laxatives (see Box 22.93 below) should be avoided. Antispasmodics may sometimes help. Acute attacks of diverticulitis should be treated with 7 days of metronidazole (400 mg 3 times daily orally), along with co-amoxiclav (500/125 mg 4 times daily). Severe cases require intravenous fluids, intravenous antibiotics, analgesia and nasogastric suction, but randomised trials show no benefit from acute resection compared to conservative management, and emergency surgery is reserved for severe haemorrhage or perforation. Percutaneous drainage of acute paracolic abscesses can be effective and avoids the need for emergency surgery. Patients who have repeated attacks of obstruction should undergo elective surgery once the acute episode has settled, in order to resect the affected segment of bowel with restoration of continuity by primary anastomosis.

Constipation and disorders of defecation

The clinical approach to patients with constipation and its aetiology have been described on page 860.

Simple constipation

Simple constipation is extremely common and does not signify underlying organic disease. It usually responds to increased dietary fibre or the use of bulking agents; an adequate fluid intake is also essential. Many types of laxative are available, and these are listed in Box 22.93.

Severe idiopathic constipation

This occurs almost exclusively in young women and often begins in childhood or adolescence. The cause is unknown but some have 'slow transit' with reduced motor activity in the colon. Others have 'obstructed defecation', resulting from inappropriate contraction of the external anal sphincter and puborectalis muscle (anismus). The condition is often resistant to treatment. Bulking agents may exacerbate symptoms but prokinetic agents or balanced solutions of polyethylene glycol '3350' benefit some patients with slow transit. Glycerol suppositories and biofeedback techniques are used for those with obstructed defecation. Others benefit from agents such as prucalopride or linaclotide. Rarely, subtotal colectomy may be necessary as a last resort.

22.93 Laxatives

Class	Examples
Bulk-forming	Ispaghula husk, methylcellulose
Stimulants	Bisacodyl, dantron (only for terminally ill patients), docusate, senna
Faecal softeners	Docusate, arachis oil enema
Osmotic laxatives	Lactulose, lactitol, magnesium salts
Others	Polyethylene glycol (PEG)*, phosphate enema*

*Used mainly for bowel preparation prior to investigation or surgery.

Faecal impaction

In faecal impaction, a large, hard mass of stool fills the rectum. This tends to occur in disabled, immobile or institutionalised patients, especially the frail elderly or those with dementia. Constipating drugs, autonomic neuropathy and painful anal conditions also contribute. Megacolon, intestinal obstruction and urinary tract infections may supervene. Perforation and bleeding from pressure-induced ulceration are occasionally seen. Treatment involves adequate hydration and careful digital disimpaction after softening the impacted stool with arachis oil enemas. Stimulants should be avoided.

Melanosis coli and laxative misuse syndromes

Long-term consumption of stimulant laxatives leads to accumulation of lipofuscin pigment in macrophages in the lamina propria. This imparts a brown discoloration to the colonic mucosa, often described as resembling 'tiger skin'. The condition is benign and resolves when the laxatives are stopped. Prolonged laxative use may rarely result in megacolon or 'cathartic colon', in which barium enema demonstrates a featureless mucosa, loss of haustra and shortening of the bowel. Surreptitious laxative misuse is a psychiatric condition seen in young women, some of whom have a history of bulimia or anorexia nervosa (pp. 255 and 256). They complain of refractory watery diarrhoea. Laxative use is usually denied and may continue, even when patients are undergoing investigation. Screening of urine for laxatives may reveal the diagnosis.

Hirschsprung's disease

This disease is characterised by constipation and colonic dilatation (megacolon) due to congenital absence of ganglion cells in the large intestine. The incidence is approximately 1:5000. About one-third of patients have a positive family history and, in these families, the disease is inherited in an autosomal dominant manner with incomplete penetrance. About 50% of familial cases and 15% of sporadic cases have mutations affecting the *RET* proto-oncogene, which is also implicated in multiple endocrine neoplasia type 2 (MEN 2) (p. 795). Unlike MEN 2, which is caused by activating *RET* mutations, Hirschsprung's disease is caused by loss-of-function mutations. Although *RET* is the most important susceptibility gene, some patients with *RET* mutations do not develop clinical disease, and mutations in other genes have been identified which interact to cause the disease. All of the genes are implicated in Hirschsprung's disease are involved in the regulation of enteric neurogenesis, and the mutations cause failure of migration of neuroblasts into the gut wall during embryogenesis. Ganglion cells are absent from nerve plexuses, most commonly in a short segment of the rectum and/or sigmoid colon. As a result, the internal anal sphincter fails to relax. Constipation, abdominal distension and vomiting usually develop immediately after birth but a few cases do not present until childhood or adolescence. The rectum is empty on digital examination.

Barium enema shows a small rectum and colonic dilatation above the narrowed segment. Full-thickness biopsies are required to demonstrate nerve plexuses and

confirm the absence of ganglion cells. Histochemical stains for acetylcholinesterase are also used. Anorectal manometry demonstrates failure of the rectum to relax with balloon distension. Treatment involves resection of the affected segment.

Acquired megacolon

This may develop in childhood as a result of voluntary withholding of stool during toilet training. In such cases, it presents after the first year of life and is distinguished from Hirschsprung's disease by the urge to defecate and the presence of stool in the rectum. It usually responds to osmotic laxatives.

In adults, acquired megacolon has several causes. It is seen in depressed or demented patients, either as part of the condition or as a side-effect of antidepressant drugs. Prolonged misuse of stimulant laxatives may cause degeneration of the myenteric plexus, while interruption of sensory or motor innervation may be responsible in a number of neurological disorders. Patients taking large doses of opioid analgesics can develop a megacolon: so-called 'narcotic bowel syndrome'. Scleroderma and hypothyroidism are other recognised causes.

Most patients can be managed conservatively by treatment of the underlying cause, high-residue diets, laxatives and the judicious use of enemas. Prokinetics are helpful in a minority of patients. Subtotal colectomy is a last resort for the most severely affected patients.

Acute colonic pseudo-obstruction

Acute colonic pseudo-obstruction (Ogilvie's syndrome) has many causes (Box 22.95) and is characterised by sudden onset of painless, massive enlargement of the proximal colon; there are no features of mechanical obstruction. Bowel sounds are normal or high-pitched, rather than absent. Left untreated, it may progress to perforation, peritonitis and death.

Abdominal X-rays show colonic dilatation with air extending to the rectum. Caecal diameter greater than 10 cm is associated with a high risk of perforation. Single-contrast or water-soluble barium enemas demonstrate the absence of mechanical obstruction.

Management consists of treating the underlying disorder and correcting any biochemical abnormalities. The anticholinesterase, neostigmine, is effective in enhancing parasympathetic activity and gut motility. Decompression, either with a rectal tube or by colonoscopy, may be effective but needs to be repeated until the condition resolves. In severe cases, surgical or fluoroscopic defunctioning caecostomy is necessary.

22.94 Constipation in old age

- **Evaluation**: particular attention should be paid to immobility, dietary fluid and fibre intake, drugs and depression.
- **Immobility**: predisposes to constipation by increasing the colonic transit time; the longer this is, the greater the fluid absorption and the harder the stool.
- **Bulking agents**: can make matters worse in patients with slow transit times and should be avoided.
- **Overflow diarrhoea**: if faecal impaction develops, paradoxical overflow diarrhoea may occur. If antidiarrhoeal agents are given, the underlying impaction may worsen and result in serious complications, such as stercoral ulceration and bleeding.

22.95 Causes of acute colonic pseudo-obstruction

- Trauma, burns
- Recent surgery
- Drugs (opiates, phenothiazines)
- Respiratory failure
- Electrolyte and acid–base disorders
- Diabetes mellitus
- Uraemia

Anorectal disorders

Faecal incontinence

The normal control of anal continence is described on page 844. Common causes of incontinence are listed in Box 22.96. High-risk patients include frail older people, women after childbirth and those with severe neurological/spinal disorders, learning difficulties or cognitive impairment.

Patients are often embarrassed to admit incontinence and may complain only of 'diarrhoea'. A careful history and examination, especially of the anorectum and perineum, may help to establish the underlying cause. Endoanal ultrasound is valuable for defining the integrity of the anal sphincters, while anorectal physiology and MR proctography are also useful investigations.

Management

This is often very difficult. Underlying disorders should be treated and diarrhoea managed with loperamide, diphenoxylate or codeine phosphate. Attention must be paid to a proper diet and adequate fluid intake. Pelvic floor exercises, biofeedback and bowel retraining techniques help some patients, and those with confirmed anal sphincter defects may benefit from sphincter repair operations. Where sphincter repair is not appropriate, a trial of sacral nerve stimulation is undertaken with a view to insertion of a permanent stimulator but, if unsuccessful, creation of a neo-sphincter may be possible, by graciloplasty or by an artificial anal sphincter.

22.96 Causes of faecal incontinence

- Obstetric trauma: childbirth, hysterectomy
- Severe diarrhoea
- Faecal impaction
- Congenital anorectal anomalies
- Anorectal disease: haemorrhoids, rectal prolapse, Crohn's disease
- Neurological disorders: spinal cord or cauda equina lesions, dementia

Haemorrhoids

Haemorrhoids (commonly known as piles) arise from congestion of the internal and/or external venous plexuses around the anal canal. They are extremely common in adults. The aetiology is unknown, although they are associated with constipation and straining, and may develop for the first time during pregnancy. First-degree piles bleed, while second-degree piles prolapse but

retract spontaneously. Third-degree piles are those which require manual replacement after prolapsing. Bright red rectal bleeding occurs after defecation. Other symptoms include pain, pruritus ani and mucus discharge. Treatment involves measures to prevent constipation and straining. Band ligation is effective for many, but a minority of patients require haemorrhoidectomy, which is usually curative. Recently, haemorrhoidal artery ligation operation (HALO) procedures have been developed and may replace surgery. HALO involves using Doppler ultrasound to identify all the arteries feeding the haemorrhoids and ligating them.

Pruritus ani

This is common and can stem from many causes (Box 22.97), most of which result in contamination of the perianal skin with faecal contents.

Itching may be severe and results in an itch–scratch–itch cycle which exacerbates the problem. When no underlying cause is found, all local barrier ointments and creams must be stopped. Good personal hygiene is essential, with careful washing after defecation. The perineal area must be kept dry and clean. Bulk-forming laxatives may reduce faecal soiling.

22.97 Causes of pruritus ani

Local anorectal conditions	
• Haemorrhoids • Fistula, fissures	• Poor hygiene
Infections	
• Threadworms	• Candidiasis
Skin disorders	
• Contact dermatitis • Psoriasis	• Lichen planus
Other	
• Diarrhoea or incontinence of any cause	• Irritable bowel syndrome • Anxiety

Solitary rectal ulcer syndrome

This is most common in young adults and occurs on the anterior rectal wall. It is thought to result from localised chronic trauma and/or ischaemia associated with disordered puborectalis function and mucosal prolapse. The ulcer is seen at sigmoidoscopy and biopsies show a characteristic accumulation of collagen.

Symptoms include minor bleeding and mucus per rectum, tenesmus and perineal pain. Treatment is often difficult but avoidance of straining at defecation is important and treatment of constipation may help. Marked mucosal prolapse is treated surgically.

Anal fissure

In this common problem, traumatic or ischaemic damage to the anal mucosa results in a superficial mucosal tear, most commonly in the midline posteriorly. Spasm of the internal anal sphincter exacerbates the condition. Severe pain occurs on defecation and there may be minor bleeding, mucus discharge and pruritus. The skin may be indurated and an oedematous skin tag, or 'sentinel pile', adjacent to the fissure is common.

Avoidance of constipation with bulk-forming laxatives and increased fluid intake is important. Relaxation of the internal sphincter is normally mediated by nitric oxide, and 0.2% glyceryl trinitrate, which donates nitric oxide and improves mucosal blood flow, is effective in 60–80% of patients. Diltiazem cream (2%) can be used as an alternative. Resistant cases may respond to injection of botulinum toxin into the internal anal sphincter to induce relaxation. Manual dilatation under anaesthesia leads to long-term incontinence and should not be considered. The majority of cases can be treated without surgery, but where these measures fail, healing can be achieved surgically by lateral internal anal sphincterotomy or advancement anoplasty.

Anorectal abscesses and fistulae

Perianal abscesses develop between the internal and external anal sphincters and may point at the perianal skin. Ischiorectal abscesses occur lateral to the sphincters in the ischiorectal fossa. They usually result from infection of anal glands by normal intestinal bacteria. Crohn's disease (p. 897) is sometimes responsible.

Patients complain of extreme perianal pain, fever and/or discharge of pus. Spontaneous rupture may lead to the development of fistulae. These may be superficial or track through the anal sphincters to reach the rectum. Abscesses are drained surgically and superficial fistulae are laid open with care to avoid sphincter damage.

Diseases of the peritoneal cavity

Peritonitis

Surgical peritonitis occurs as the result of a ruptured viscus (for details see this book's companion text, *Principles and Practice of Surgery*). Peritonitis may also complicate ascites in chronic liver disease (spontaneous bacterial peritonitis, p. 941) or may occur in children in the absence of ascites, due to infection with *Streptococcus pneumoniae* or β-haemolytic streptococci (p. 331).

Chlamydial peritonitis is a complication of pelvic inflammatory disease (p. 422). The patient presents with right upper quadrant pain, pyrexia and a hepatic rub (the Fitz-Hugh–Curtis syndrome). Tuberculosis may cause peritonitis and ascites (p. 688).

Tumours

The most common is secondary adenocarcinoma from the ovary or gastrointestinal tract. Mesothelioma is a rare tumour complicating asbestos exposure. It presents as a diffuse abdominal mass, due to omental infiltration, and with ascites. The prognosis is extremely poor.

Other disorders

Endometriosis

Ectopic endometrial tissue can become embedded on the serosal aspect of the intestine, most frequently in the sigmoid and rectum. The overlying mucosa is usually

intact. Cyclical engorgement and inflammation result in pain, bleeding, diarrhoea, constipation, and adhesions or obstruction. Low backache is frequent. The onset is usually between 20 and 45 years and is more common in nulliparous women. Bimanual examination may reveal tender nodules in the pouch of Douglas. Endoscopic studies only reveal the diagnosis if carried out during menstruation, when a bluish mass with intact overlying mucosa is apparent. In some patients, laparoscopy is required. Treatment options include laparoscopic diathermy and hormonal therapy with progestogens (e.g. norethisterone), gonadotrophin-releasing hormone analogues or danazol.

Pneumatosis cystoides intestinalis

In this rare condition, multiple gas-filled submucosal cysts line the colonic and small bowel walls. The cause is unknown, but the condition may be seen in patients with chronic cardiac or pulmonary disease, pyloric obstruction, scleroderma or dermatomyositis. Most patients are asymptomatic, although there may be abdominal cramp, diarrhoea, tenesmus, rectal bleeding and mucus discharge. The cysts are recognised on sigmoidoscopy, plain abdominal X-rays or barium enema. Therapies reported to be effective include prolonged high-flow oxygen, elemental diets and antibiotics.

CLINICAL EXAMINATION OF THE ABDOMEN FOR LIVER AND BILIARY DISEASE

Insets (*Spider naevi*) From Hayes and Simpson 1995; (*Aspiration*) Strachan 2008; (*Palmar erythema*) Martin 2011 – see p. 988.

History and significance of abdominal signs

Presenting clinical features of liver disease

Presenting features of liver disease represent combined effects of:

Impairment of liver function and metabolic sequelae of this

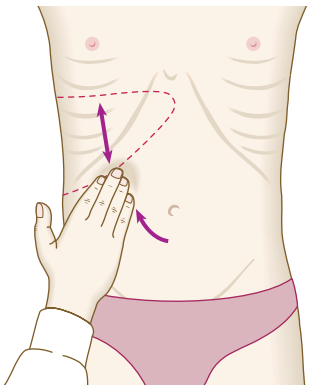
- Jaundice (failure of bilirubin clearance)
- Encephalopathy (failure of clearance of by-products of metabolism)
- Bleeding (impaired liver synthesis of clotting factors)
- Hypoglycaemia

Ongoing presence of aetiological factors (e.g. alcohol)

- Effects of aetiological agent, e.g. intoxication, withdrawal, cognitive impairment *versus*
- Effects of liver injury from agent, e.g. encephalopathy

Effects of chronic liver injury (> 6 mths)

Catabolic status (± poor nutrition)
- Skin thinning ('paper-money skin')
- Loss of muscle bulk
- Leuconychia

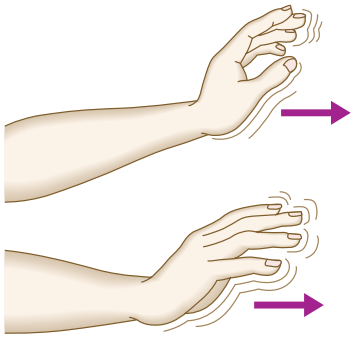


Impaired albumin synthesis
- Reduced oncotic pressure (contributes to ascites)

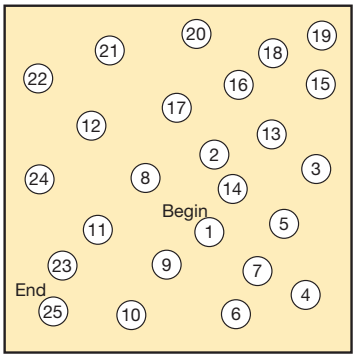
Reduced aldosterone clearance
- Na^+ retention (contributes to ascites)

Reduced oestrogen clearance
- Mild feminisation of males (loss of body hair, gynaecomastia)

5 Assessment of liver size

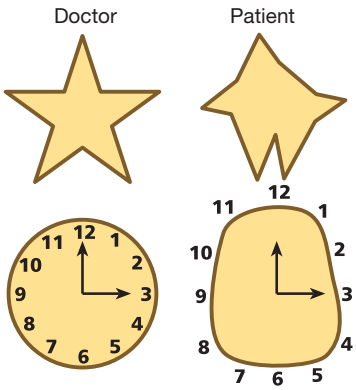


Clinical assessment of hepatomegaly is important in diagnosing liver disease.
- Start in the right iliac fossa.
- Progress up the abdomen 2 cm with each breath (through open mouth).
- Confirm the lower border of the liver by percussion.
- Detect if smooth or irregular, tender or non-tender; ascertain shape.
- Identify the upper border by percussion.



Ascites

Causes	Associated clinical findings
Exudative (high protein)	
Carcinoma	Weight loss ± hepatomegaly
Tuberculosis	Weight loss + fever
Transudative (low protein)	
Cirrhosis	Hepatomegaly Splenomegaly Spider naevi
Renal failure (including nephrotic syndrome)	Generalised oedema
Congestive heart failure	Peripheral oedema Elevated jugular venous pressure (JVP)



1 Assessment of encephalopathy

Flapping tremor. Jerky forward movements every 5–10 seconds when arms are outstretched and hands are dorsiflexed suggest hepatic encephalopathy. The movements are coarser than those seen in tremor.

Number connection test. These 25 numbered circles can normally be joined together within 30 seconds. Serial observations may provide useful information as long as the position of the numbers is varied to avoid the patient learning their pattern.

Constructional apraxia. Drawing stars and clocks may reveal marked abnormality.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Applied anatomy

Normal liver structure and blood supply

The liver weighs 1.2–1.5 kg and has multiple functions, including key roles in metabolism, control of infection, elimination of toxins and by-products of metabolism. It is classically divided into left and right lobes by the falciform ligament, but a more useful functional division is into the right and left hemilivers, based on blood supply (Fig. 23.1). These are further divided into eight segments according to subdivisions of the hepatic and portal veins. Each segment has its own branch of the hepatic artery and biliary tree. The segmental anatomy of the liver has an important influence on imaging and treatment of liver tumours, given the increasing use of surgical resection. A liver segment is made up of multiple smaller units known as lobules, comprised of a central vein, radiating sinusoids separated from each other by single liver cell (hepatocyte) plates, and peripheral portal tracts. The functional unit of the liver is the hepatic acinus (Fig. 23.2).

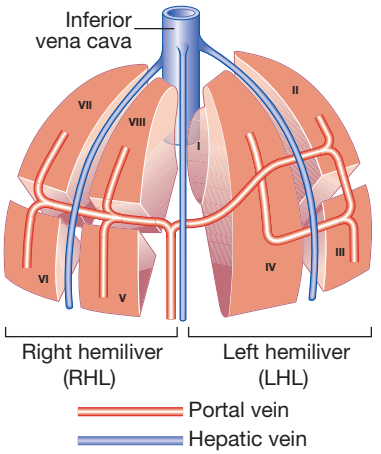


Fig. 23.1 Liver blood supply.

Blood flows into the acinus via a single branch of the portal vein and hepatic artery situated centrally in the portal tracts. Blood flows outwards along the hepatic sinusoids into one of several tributaries of the hepatic vein at the periphery of the acinus. Bile, formed by active and passive excretion by hepatocytes into channels called cholangioles which lie between them, flows in the opposite direction from the periphery of the acinus. The cholangioles converge in interlobular bile ducts in the portal tracts. The hepatocytes in each acinus lie in three zones, depending on their position relative to the portal tract. Those in zone 1 are closest to the terminal branches of the portal vein and hepatic artery, and are richly supplied with oxygenated blood, and blood containing the highest concentration of nutrients and toxins. Conversely, hepatocytes in zone 3 are furthest from the portal tracts and closest to the hepatic veins, and are therefore relatively hypoxic and exposed to lower concentrations of nutrients and toxins compared to zone 1. The different perfusion and toxin exposure patterns, and thus vulnerability, of hepatocytes in the different zones contribute to the often-patchy nature of liver injury.

Liver cells

Hepatocytes comprise 80% of liver cells. The remaining 20% are the endothelial cells lining the sinusoids,

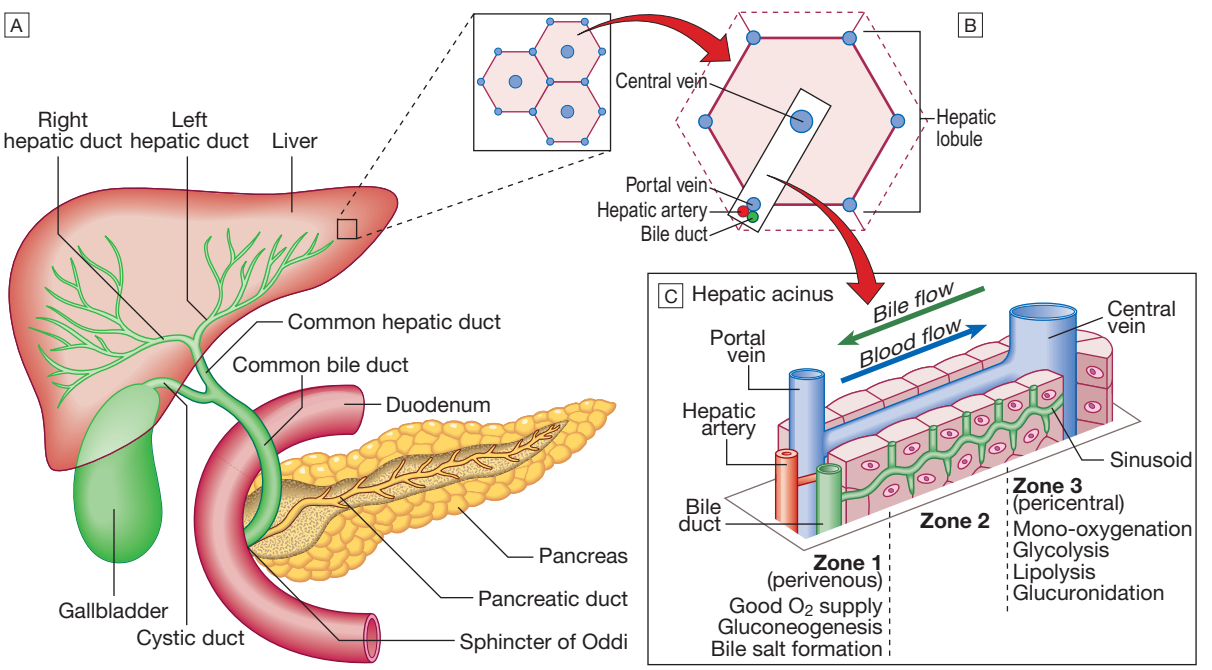

Fig. 23.2 Liver structure and microstructure. A Liver anatomy showing relationship with pancreas, bile duct and duodenum. B Hepatic lobule. C Hepatic acinus.

epithelial cells lining the intrahepatic bile ducts, cells of the immune system (including macrophages (Kupffer cells) and unique populations of atypical lymphocytes), and a key population of non-parenchymal cells called stellate or Ito cells.

Endothelial cells line the sinusoids (Fig. 23.3), a network of capillary vessels that differ from other capillary beds in the body in that there is no basement membrane. The endothelial cells have gaps between them (fenestrae) of about 0.1 micron in diameter, allowing free flow of fluid and particulate matter to the hepatocytes. Individual hepatocytes are separated from the leaky sinusoids by the space of Disse, which contains stellate cells that store vitamin A and play an important part in regulating liver blood flow. They may also be immunologically active and play a role in the liver's contribution to defence against pathogens. The key role of stellate cells in terms of pathology is in the development of hepatic fibrosis, the precursor of cirrhosis. They undergo activation in response to cytokines produced following liver injury, differentiating into myofibroblasts, which are the major producers of the collagen-rich matrix that forms fibrous tissue (Fig. 23.4).

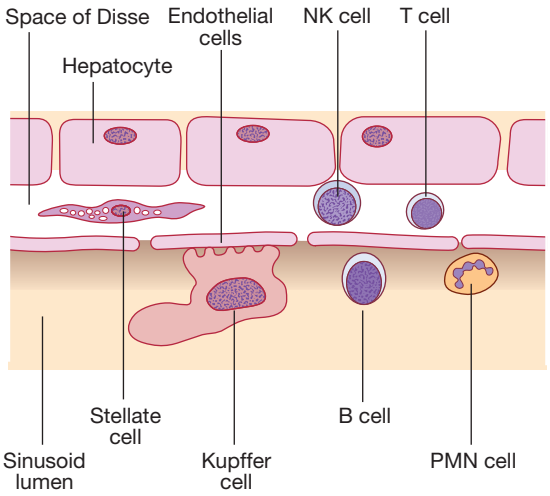

Fig. 23.3 Non-parenchymal liver cells. (B = B lymphocytes; NK = natural killer cells; PMN = polymorphonuclear leucocytes; T = T lymphocytes).

Blood supply

The liver is unique as an organ as it has dual perfusion, receiving a majority of its supply via the portal vein, which drains blood from the gut via the splanchnic circulation and is the principal route for nutrient trafficking to the liver, and a minority from the hepatic artery. The portal venous contribution is 50–90%. The dual perfusion system, and the variable contribution from portal vein and hepatic artery, can have important effects on the clinical expression of liver ischaemia (which typically exhibits a less dramatic pattern than

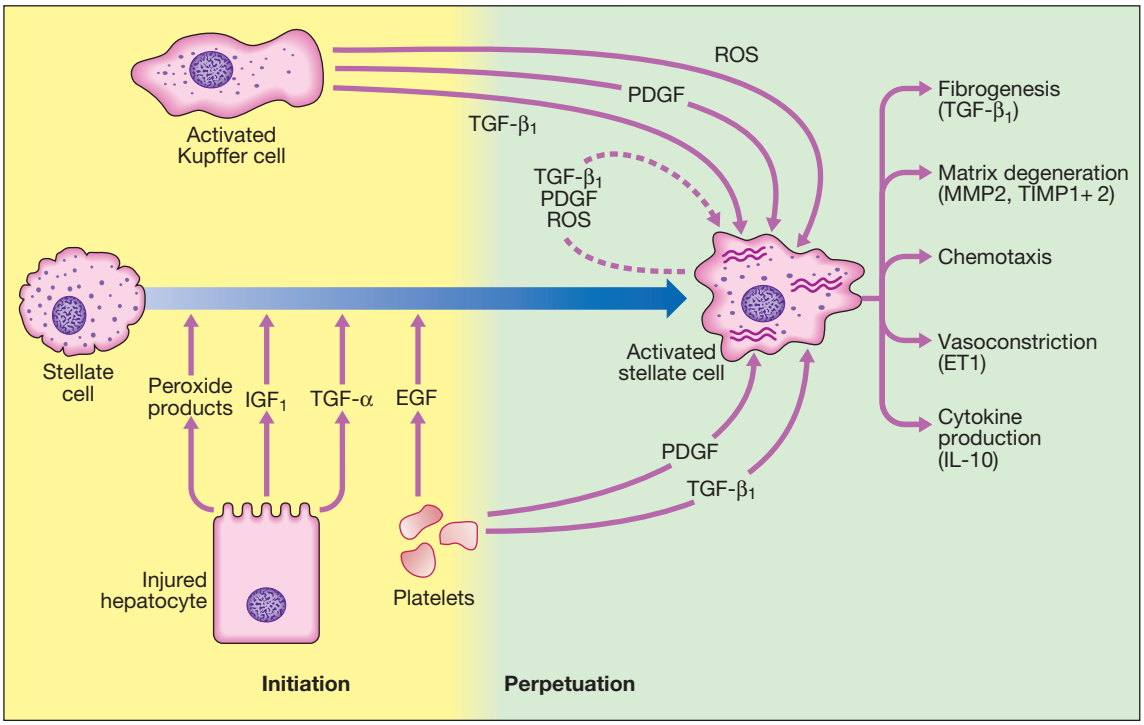

Fig. 23.4 Pathogenic mechanisms in hepatic fibrosis. Stellate cell activation occurs under the influence of cytokines released by other cell types in the liver, including hepatocytes, Kupffer cells (tissue macrophages), platelets and lymphocytes. Once stellate cells become activated, they can perpetuate their own activation by synthesis of transforming growth factor-beta (TGF-β_1,) and platelet-derived growth factor (PDGF) through autocrine loops. Activated stellate cells produce TGF-β_1, stimulating the production of collagen matrix, as well as inhibitors of collagen breakdown. The inhibitors of collagen breakdown, matrix metalloproteinase 2 and 9 (MMP2 and MMP9), are inactivated in turn by tissue inhibitors TIMP1 and TIMP2, which are increased in fibrosis. Inflammation also contributes to fibrosis, with the cytokine profile produced by Th2 lymphocytes, such as interleukin-6 and 13 (IL-6 and IL-13). Activated stellate cells also produce endothelin 1 (ET1), which may contribute to portal hypertension. (EGF = epidermal growth factor; IGF_1 = insulin-like growth factor 1; ROS = reactive oxygen species).

ischaemia in other organs, a fact that can sometimes lead to it being missed clinically), and can raise practical challenges in liver transplant surgery.

Biliary system and gallbladder

Hepatocytes provide the driving force for bile flow by creating osmotic gradients of bile acids, which form micelles in bile (bile acid-dependent bile flow), and of sodium (bile acid-independent bile flow). Bile is secreted by hepatocytes and flows from cholangioles to the biliary canaliculi. The canaliculi join to form larger intrahepatic bile ducts, which in turn merge to form the right and left hepatic ducts. These ducts join as they emerge from the liver to form the common hepatic duct, which becomes the common bile duct after joining the cystic duct (see Fig. 23.2). The common bile duct is approximately 5 cm long and 4–6 mm wide. The distal portion of the duct passes through the head of the pancreas and usually joins the pancreatic duct before entering the duodenum through the ampullary sphincter (sphincter of Oddi). It should be noted, though, that the anatomy of the lower common bile duct can vary widely. Common bile duct pressure is maintained by rhythmic contraction and relaxation of the sphincter of Oddi; this pressure exceeds gallbladder pressure in the fasting state, so that bile normally flows into the gallbladder, where it is concentrated tenfold by resorption of water and electrolytes.

The gallbladder is a pear-shaped sac typically lying under the right hemiliver, with its fundus located anteriorly behind the tip of the 9th costal cartilage. Anatomical variation is common and should be considered when assessing patients clinically and radiologically. The function of the gallbladder is to concentrate, and provide a reservoir for, bile. Gallbladder tone is maintained by vagal activity, and cholecystokinin released from the duodenal mucosa during feeding causes gallbladder contraction and reduces sphincter pressure, so that bile flows into the duodenum. The body and neck of the gallbladder pass postero-medially towards the porta hepatis, and the cystic duct then joins it to the common hepatic duct. The cystic duct mucosa has prominent crescentic folds (valves of Heister), giving it a beaded appearance on cholangiography.

Hepatic function

Carbohydrate, amino acid and lipid metabolism

The liver plays a central role in carbohydrate, lipid and amino acid metabolism, and is also involved in metabolising drugs and environmental toxins (Fig. 23.5). An important and increasingly recognised role for the liver is in the integration of metabolic pathways, regulating the response of the body to feeding and starvation. Abnormality in metabolic pathways and their regulation can play an important role both in liver disease (e.g. non-alcoholic fatty liver disease (NAFLD)) and in diseases that are not conventionally regarded as diseases of the liver (such as type II diabetes mellitus and inborn errors of metabolism). Hepatocytes have specific pathways to handle each of the nutrients absorbed from the gut and carried to the liver via the portal vein.

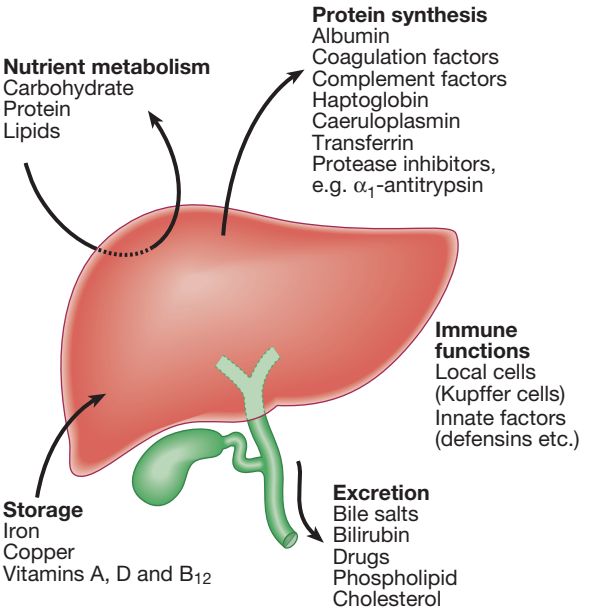

Fig. 23.5 Important liver functions.

- Amino acids from dietary proteins are used for synthesis of plasma proteins, including albumin. The liver produces 8–14 g of albumin per day, and this plays a critical role in maintaining oncotic pressure in the vascular space and in the transport of small molecules like bilirubin, hormones and drugs throughout the body. Amino acids that are not required for the production of new proteins are broken down, with the amino group being converted ultimately to urea.
- Following a meal, more than half of the glucose absorbed is taken up by the liver and stored as glycogen or converted to glycerol and fatty acids, thus preventing hyperglycaemia. During fasting, glycogen is broken down to release glucose (gluconeogenesis), thereby preventing hypoglycaemia (p. 800).
- The liver plays a central role in lipid metabolism, producing very low-density lipoproteins and further metabolising low- and high-density lipoproteins (see Fig. 16.14, p. 452). Dysregulation of lipid metabolism is thought to have a critical role in the pathogenesis of NAFLD. Lipids are now recognised to play a key part in the pathogenesis of hepatitis C, facilitating viral entry into hepatocytes.

Clotting factors

The liver produces key proteins that are involved in the coagulation cascade. Many of these coagulation factors (II, VII, IX and X) are post-translationally modified by vitamin K-dependent enzymes, and their synthesis is impaired in vitamin K deficiency (p. 997). Reduced clotting factor synthesis is an important and easily accessible biomarker of liver function in the setting of liver injury. Prothrombin time (PT; or the International Normalised Ratio, INR) is therefore one of the most important clinical tools available for the assessment of hepatocyte function. Note that the deranged PT or INR

seen in liver disease may not directly equate to increased bleeding risk, as these tests do not capture the concurrent reduced synthesis of *anticoagulant* factors, including protein C and protein S. In general, therefore, correction of PT using blood products before minor invasive procedures should be guided by clinical risk rather than the absolute value of the PT.

Bilirubin metabolism and bile

The liver plays a central role in the metabolism of bilirubin and is responsible for the production of bile (Fig. 23.6). Between 425 and 510 mmol (250–300 mg) of unconjugated bilirubin is produced from the catabolism of haem daily. Bilirubin in the blood is normally almost all unconjugated and, because it is not water-soluble, is bound to albumin and does not pass into the urine. Unconjugated bilirubin is taken up by hepatocytes at the sinusoidal membrane, where it is conjugated in the endoplasmic reticulum by UDP-glucuronyl transferase, producing bilirubin mono- and diglucuronide. Impaired conjugation by this enzyme is a cause of inherited hyperbilirubinaemias (see Box 23.17, p. 937). These bilirubin conjugates are water-soluble and are exported into the bile canaliculi by specific carriers on the hepatocyte membranes. The conjugated bilirubin is excreted in the bile and passes into the duodenal lumen.

Once in the intestine, conjugated bilirubin is metabolised by colonic bacteria to form stercobilinogen, which may be further oxidised to stercobilin. Both stercobilinogen and stercobilin are then excreted in the stool, contributing to its brown colour. Biliary obstruction results in reduced stercobilinogen in the stool, and the stools become pale. A small amount of stercobilinogen (4 mg/day) is absorbed from the bowel, passes through the liver, and is excreted in the urine, where it is known as urobilinogen or, following further oxidisation, urobilin. The liver secretes 1–2 L of bile daily. Bile contains bile acids (formed from cholesterol), phospholipids, bilirubin and cholesterol. Several biliary transporter proteins have been identified (Fig. 23.7). Mutations in genes encoding these proteins have been identified in inherited intrahepatic biliary diseases presenting in childhood, and in adult-onset disease such as intrahepatic cholestasis of pregnancy and gallstone formation.

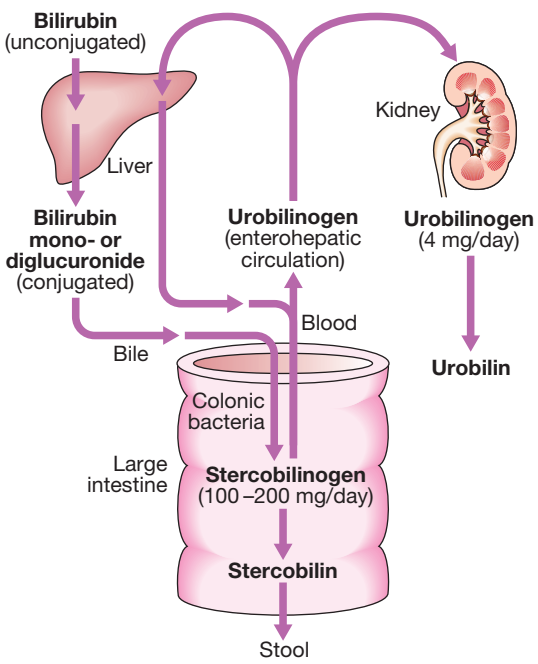

Fig. 23.6 Pathway of bilirubin excretion.

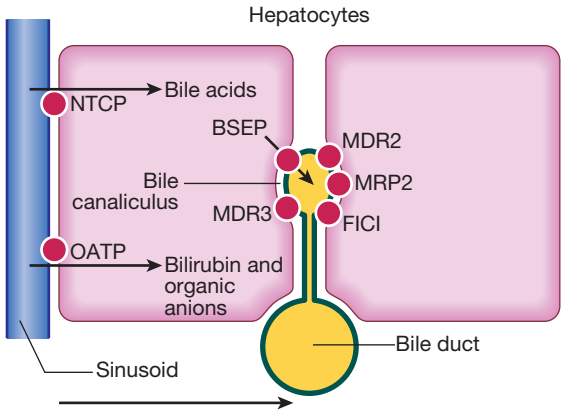

Fig. 23.7 Biliary transporter proteins. On the hepatocyte basolateral membrane, NTCP (sodium taurocholate co-transporting polypeptide) mediates uptake of conjugated bile acids from portal blood. At the canalicular membrane, these bile acids are secreted via BSEP (bile salt export pump) into bile. MDR3 (multidrug resistance protein 3), also situated on the canalicular membrane, transports phospholipid to the outer side of the membrane. This solubilises bile acids, forming micelles and protecting bile duct membranes from bile salt damage. FIC1 (familial intrahepatic cholestasis 1) moves phosphatidylserine from the inside to the outside of the canalicular membrane; mutations result in familial cholestasis syndrome in childhood. MDR2 (multidrug resistance 2) regulates transport of glutathione. MRP2 (multidrug resistance protein 2) transports bilirubin and is induced by rifampicin. OATP (organic anion transporter protein) transports bilirubin and organic anions.

Storage of vitamins and minerals

Vitamins A, D and B_{12} are stored by the liver in large amounts, while others, such as vitamin K and folate, are stored in smaller amounts and disappear rapidly if dietary intake is reduced. The liver is also able to metabolise vitamins to more active compounds, e.g. 7-dehydrocholesterol to 25(OH) vitamin D. Vitamin K is a fat-soluble vitamin and so the inability to absorb fat-soluble vitamins, as occurs in biliary obstruction, results in a coagulopathy. The liver also stores minerals such as iron, in ferritin and haemosiderin, and copper, which is excreted in bile.

Immune regulation

Approximately 9% of the normal liver is composed of immune cells (see Fig. 23.3). Cells of the innate immune system include Kupffer cells derived from blood monocytes, the liver macrophages and natural killer (NK) cells, as well as 'classical' B and T cells of the adaptive immune response (p. 76). An additional type of atypical lymphocyte, with phenotypic features of both T cells and NK cells is thought to play an important role in host defence, through linking of innate and adaptive immunity. The enrichment of such cells in the liver reflects the unique importance of the liver in preventing microorganisms from the gut entering the systemic circulation.

Kupffer cells constitute the largest single mass of tissue-resident macrophages in the body and account for 80% of the phagocytic capacity of this system. They remove aged and damaged red blood cells, bacteria, viruses, antigen–antibody complexes and endotoxin. They also produce a wide variety of inflammatory mediators that can act locally or may be released into the systemic circulation.

The immunological environment of the liver is unique in that antigens presented within it tend to induce immunological tolerance. This is of importance in liver transplantation, where classical major histocompatibility (MHC) barriers may be crossed, and also in chronic viral infections, when immune responses may be attenuated. The mechanisms that underlie this phenomenon have not been fully defined.

INVESTIGATION OF LIVER AND HEPATOBILIARY DISEASE

Investigations play an important role in the management of liver disease in three settings:

- identification of the presence of liver disease
- establishing the aetiology
- understanding disease severity (in particular, identification of cirrhosis with its complications).

When planning investigations it is important to be clear as to which of these goals is being addressed.

Suspicion of the presence of liver disease is normally based on blood biochemistry abnormality ('liver function tests', or 'LFTs'), undertaken either as a result of clinical suspicion or, increasingly, in the setting of health screening. Less commonly, suspicion arises after a structural abnormality is identified on imaging.

Aetiology is typically established through a combination of history, specific blood tests and, where appropriate, imaging and liver biopsy.

Staging of disease (in essence, the identification of cirrhosis) is largely histological, although there is increasing interest in non-invasive approaches, including novel imaging modalities, serum markers of fibrosis and the use of predictive scoring systems.

The aims of investigation in patients with suspected liver disease are shown in Box 23.1.

Liver blood biochemistry

Liver blood biochemistry (LFTs) includes the measurement of serum bilirubin, aminotransferases, alkaline phosphatase, gamma-glutamyl transferase and albumin. Most analytes measured by LFTs are not truly 'function' tests but, given that they are released by injured hepatocytes, instead provide biochemical evidence of liver cell damage. Liver function per se is best assessed by the serum albumin, PT and bilirubin because of the role played by the liver in synthesis of albumin and clotting factors and in clearance of bilirubin. Although LFT abnormalities are often non-specific, the patterns are frequently helpful in directing further investigations. Also, levels of bilirubin and albumin and the PT are related to clinical outcome in patients with severe liver disease, reflected by their use in several prognostic scores: the Child–Pugh and MELD scores in cirrhosis (see Boxes 23.30 and 23.32, p. 944), the Glasgow score in alcoholic hepatitis (see Box 23.54, p. 959) and the King's College Hospital criteria for liver transplantation in acute liver failure (see Box 23.11, p. 934).

23.1 Aims of investigations in patients with suspected liver disease

- Detect hepatic abnormality
- Measure the severity of liver damage
- Detect the pattern of liver function test abnormality: hepatitic or obstructive/cholestatic
- Identify the specific cause
- Investigate possible complications

Bilirubin and albumin

The degree of elevation of bilirubin can reflect the degree of liver damage. A raised bilirubin often occurs earlier in the natural history of biliary disease (e.g. primary biliary cirrhosis) than in disease of the liver parenchyma (e.g. cirrhosis) where the hepatocytes are primarily involved. Swelling of the liver within its capsule in inflammation can, however, sometimes impair bile flow and cause an elevation of bilirubin level that is disproportionate to the degree of liver injury. Caution is therefore needed in interpreting the level of liver injury purely on the basis of bilirubin elevation.

Serum albumin levels are often low in patients with liver disease. This is due to a change in the volume of distribution of albumin, and reduced synthesis. Since the plasma half-life of albumin is about 2 weeks, albumin levels may be normal in acute liver failure but are almost always reduced in chronic liver failure.

Alanine aminotransferase and aspartate aminotransferase

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are located in the cytoplasm of the hepatocyte; AST is also located in the hepatocyte mitochondria. Although both transaminase enzymes are widely distributed, expression of ALT outside the liver is relatively low and this enzyme is therefore considered more specific for hepatocellular damage. Large increases of aminotransferase activity favour hepatocellular damage, and this pattern of LFT abnormality is known as 'hepatitic'.

Alkaline phosphatase and gamma-glutamyl transferase

Alkaline phosphatase (ALP) is the collective name given to several different enzymes that hydrolyse phosphate esters at alkaline pH. These enzymes are widely distributed in the body, but the main sites of production are the liver, gastrointestinal tract, bone, placenta and kidney. ALPs are post-translationally modified, resulting in the production of several different isoenzymes, which differ in abundance in different tissues. ALP enzymes in the liver are located in cell membranes of the hepatic sinusoids and the biliary canaliculi. Accordingly, levels rise with intrahepatic and extrahepatic biliary obstruction and with sinusoidal obstruction, as occurs in infiltrative liver disease.

23.2 'Hepatitic' and 'cholestatic'/'obstructive' liver function tests

Pattern	AST/ALT	GGT	ALP
Biliary obstruction	↑	↑↑	↑↑↑
Hepatitis	↑↑↑	↑	↑
Alcohol/enzyme-inducing drugs	N/↑	↑↑	N

N = normal; ↑ mild elevation (< twice normal); ↑↑ moderate elevation (2–5 times normal); ↑↑↑ marked elevation (> 5 times normal).
(ALT = alanine aminotransferase; ALP = alkaline phosphatase; AST = aspartate aminotransferase; GGT = gamma-glutamyltransferase)

23.3 Drugs that increase levels of gamma-glutamyltransferase

- Barbiturates
- Carbamazepine
- Ethanol
- Griseofulvin
- Isoniazid
- Rifampicin
- Phenytoin

Gamma-glutamyl transferase (GGT) is a microsomal enzyme found in many cells and tissues of the body. The highest concentrations are located in the liver, where it is produced by hepatocytes and by the epithelium lining small bile ducts. The function of GGT is to transfer glutamyl groups from gamma-glutamyl peptides to other peptides and amino acids.

The pattern of a modest increase in aminotransferase activity and large increases in ALP and GGT activity favours biliary obstruction and is commonly described as 'cholestatic' or 'obstructive' (Box 23.2). Isolated elevation of the serum GGT is relatively common, and may occur during ingestion of microsomal enzyme-inducing drugs, including alcohol (Box 23.3), but also in NAFLD.

Other biochemical tests

Other widely available biochemical tests may become altered in patients with liver disease:

- Hyponatraemia occurs in severe liver disease due to increased production of antidiuretic hormone (ADH; Fig. 16.5, p. 435).
- Serum urea may be reduced in hepatic failure, whereas levels of urea may be increased following gastrointestinal haemorrhage.
- When high levels of urea are accompanied by raised bilirubin, high serum creatinine and low urinary sodium, this suggests hepatorenal failure, which carries a grave prognosis.
- Significantly elevated ferritin suggests haemochromatosis. Modest elevations can be seen in inflammatory disease and alcohol excess.

Haematological tests

Blood count

The peripheral blood count is often abnormal and can give a clue to the underlying diagnosis:

- *A normochromic normocytic anaemia* may reflect recent gastrointestinal haemorrhage, whereas chronic blood loss is characterised by a hypochromic microcytic anaemia secondary to iron deficiency. A high erythrocyte mean cell volume (macrocytosis) is associated with alcohol misuse, but target cells in any jaundiced patient also result in a macrocytosis. Macrocytosis can persist for a long period of time after alcohol cessation, making it a poor marker of ongoing consumption.
- *Leucopenia* may complicate portal hypertension and hypersplenism, whereas leucocytosis may occur with cholangitis, alcoholic hepatitis and hepatic abscesses. Atypical lymphocytes are seen in infectious mononucleosis, which may be complicated by an acute hepatitis.
- *Thrombocytopenia* is common in cirrhosis and is due to reduced platelet production, and increased breakdown because of hypersplenism. Thrombopoietin, required for platelet production, is produced in the liver and levels fall with worsening liver function. Thus platelet levels are usually more depressed than white cells and haemoglobin in the presence of hypersplenism in patients with cirrhosis. A low platelet count is often an indicator of chronic liver disease, particularly in the context of hepatomegaly. Thrombocytosis is unusual in patients with liver disease but may occur in those with active gastrointestinal haemorrhage and, rarely, in hepatocellular carcinoma.

Coagulation tests

These are often abnormal in patients with liver disease. The normal half-lives of the vitamin K-dependent coagulation factors in the blood are short (5–72 hours) and so changes in the prothrombin time occur relatively quickly following liver damage; these changes provide valuable prognostic information in patients with both acute and chronic liver failure. An increased PT is evidence of severe liver damage in chronic liver disease. Vitamin K does not reverse this deficiency if it is due to liver disease, but will correct the PT if the cause is vitamin K deficiency, as may occur with biliary obstruction due to non-absorption of fat-soluble vitamins.

Immunological tests

A variety of tests are available to evaluate the aetiology of hepatic disease (Boxes 23.4 and 23.5). The presence of liver-related autoantibodies can be suggestive of the presence of autoimmune liver disease (although false-positive results can occur in non-autoimmune inflammatory disease such as NAFLD). Elevation in overall

23.4 Chronic liver disease screen

- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver autoantibodies (antinuclear antibody, smooth muscle antibody, antimitochondrial antibody)
- Immunoglobulins
- Ferritin
- α_1-antitrypsin
- Caeruloplasmin

23.5 How to identify the cause of LFT abnormality

Diagnosis	Clinical clue	Initial test	Additional tests
Alcoholic liver disease	History	LFTs AST > ALT; high MCV	Random blood alcohol
Non-alcoholic fatty liver disease (NAFLD)	Metabolic syndrome (central obesity, diabetes, hypertension)	LFTs	Liver biopsy
Chronic hepatitis B	Injection drug use; blood transfusion	HBsAg	HBeAg, HBeAb HBV-DNA
Chronic hepatitis C		HCV antibody	HCV-RNA
Primary biliary cirrhosis	Itching; raised ALP	AMA	Liver biopsy
Primary sclerosing cholangitis	Inflammatory bowel disease	MRCP	ANCA
Autoimmune hepatitis	Other autoimmune diseases	ASMA, ANA, LKM, immunoglobulin	Liver biopsy
Haemochromatosis	Diabetes/joint pain	Transferrin saturation, ferritin	HFE gene test
Wilson's disease	Neurological signs; haemolysis	Caeruloplasmin	24-hr urinary copper
α_1-antitrypsin	Lung disease	α_1-antitrypsin level	α_1-antitrypsin genotype
Drug-induced liver disease	Drug/herbal remedy history	LFTs	Liver biopsy
Coeliac disease	Malabsorption	Endomysial antibody	Small bowel biopsy

(ALP = alkaline phosphatase; ALT = alanine aminotransferase; AMA = antimitochondrial antibody; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibodies; ASMA = anti-smooth muscle antibody; AST = aspartate aminotransferase; HBeAb = antibody to hepatitis B e antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HFE = haemochromatosis (high iron/Fe); LKM = liver-kidney microsomal antibody; MCV = mean cell volume; MRCP = magnetic resonance cholangiopancreatography)

serum immunoglobulin levels can also be suggestive of autoimmunity (immunoglobulin (Ig)G and IgM). Elevated serum IgA can be seen, often in more advanced alcoholic liver disease and NAFLD, although the association is not specific.

Imaging

Several imaging techniques can be used to determine the site and general nature of structural lesions in the liver and biliary tree. In general, however, imaging techniques are unable to identify hepatic inflammation and have poor sensitivity for liver fibrosis unless advanced cirrhosis with portal hypertension is present.

Ultrasound

Ultrasound is non-invasive and most commonly used as a 'first-line' test to identify gallstones, biliary obstruction (Fig. 23.8) or thrombosis in the hepatic vasculature. Ultrasound is good for the identification of splenomegaly and abnormalities in liver texture, but is less effective at identifying diffuse parenchymal disease. Focal lesions, such as tumours, may not be detected if they are below 2 cm in diameter and have echogenic characteristics similar to normal liver tissue. Bubble-based contrast media are now routinely used and can enhance discriminant capability. Doppler ultrasound allows blood flow in the hepatic artery, portal vein and hepatic veins to be investigated. Endoscopic ultrasound provides high-resolution images of the pancreas, biliary tree and liver (see Fig. 23.45, p. 985).

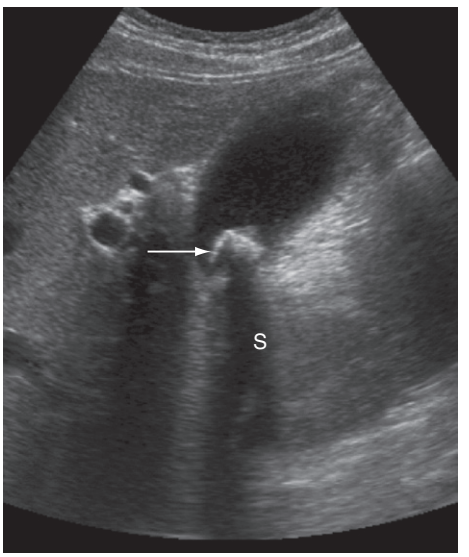

Fig. 23.8 Ultrasound showing a stone in the gallbladder. Stone (arrow) with acoustic shadow (S).

Computed tomography and magnetic resonance imaging

Computed tomography (CT) detects smaller focal lesions in the liver, especially when combined with contrast injection (Fig. 23.9). Magnetic resonance imaging (MRI) can also be used to localise and confirm the aetiology of focal liver lesions, particularly primary and secondary tumours.

Fig. 23.9 CT scan in a patient with cirrhosis. The liver is small and has an irregular outline (black arrow), the spleen is enlarged (long white arrow), fluid (ascites) is seen around the liver, and collateral vessels are present around the proximal stomach (short white arrow).

Hepatic angiography is seldom used nowadays as a diagnostic tool, since CT and MRI are both able to provide images of hepatic vasculature, but it still has a therapeutic role in the embolisation of vascular tumours such as hepatocellular carcinoma. Hepatic venography is now rarely performed.

Cholangiography

Cholangiography can be undertaken by magnetic resonance cholangiopancreatography (MRCP, Fig. 23.10), endoscopy (endoscopic retrograde cholangiopancreatography, ERCP, Fig. 23.11) or the percutaneous approach (percutaneous transhepatic cholangiography, PTC). The latter does not allow the ampulla of Vater or pancreatic duct to be visualised. MRCP is as good as ERCP at providing images of the biliary tree but has fewer complications and is the diagnostic test of choice.

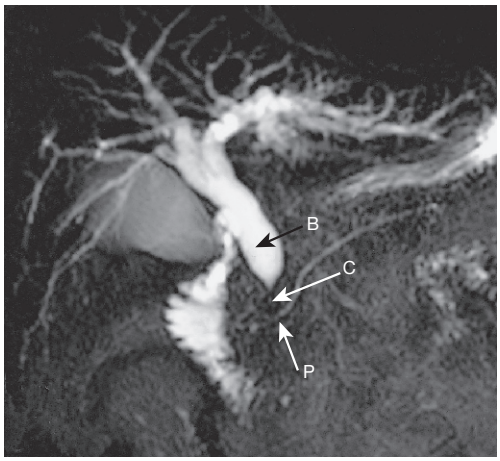

Fig. 23.10 MRCP showing a biliary stricture due to cholangiocarcinoma in the distal common bile duct (C). The proximal common bile duct (B) is dilated but the pancreatic duct (P) is normal.

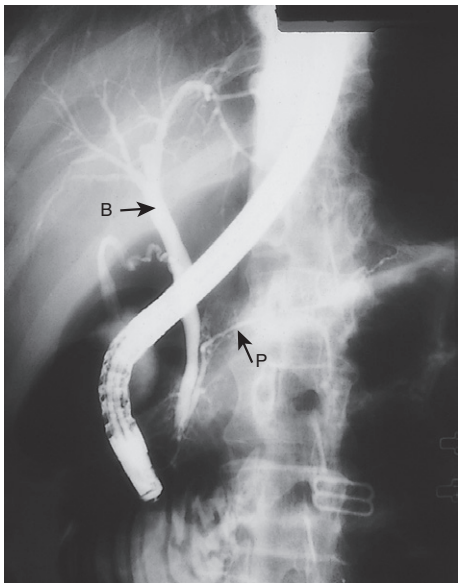

Fig. 23.11 ERCP showing the normal biliary (B) and pancreatic (P) duct system.

Both endoscopic and percutaneous approaches allow therapeutic interventions, such as the insertion of biliary stents across malignant bile duct strictures. The percutaneous approach is only used if it is not possible to access the bile duct endoscopically.

Histological examination

An ultrasound-guided liver biopsy can confirm the severity of liver damage and provide aetiological information. It is performed percutaneously with a Trucut or Menghini needle, usually through an intercostal space under local anaesthesia, or radiologically using a transjugular approach.

Percutaneous liver biopsy is a relatively safe procedure if the conditions detailed in Box 23.6 are met, but carries a mortality of about 0.01%. The main complications are abdominal and/or shoulder pain, bleeding and biliary peritonitis. Biliary peritonitis is rare and usually occurs when a biopsy is performed in a patient with obstruction of a large bile duct. Liver biopsies can be carried out in patients with defective haemostasis if:

- the defect is corrected with fresh frozen plasma and platelet transfusion
- the biopsy is obtained by the transjugular route, *or*

23.6 Conditions required for safe percutaneous liver biopsy

- Cooperative patient
- Prothrombin time < 4 secs prolonged
- Platelet count > 80 × 10^9/L
- Exclusion of bile duct obstruction, localised skin infection, advanced chronic obstructive pulmonary disease, marked ascites and severe anaemia

- the procedure is conducted percutaneously under ultrasound control and the needle track is then plugged with procoagulant material.

In patients with potentially resectable malignancy, biopsy should be avoided due to the potential risk of tumour dissemination. Operative or laparoscopic liver biopsy may sometimes be valuable.

Although the pathological features of liver disease are complex, with several features occurring together, liver disorders can be broadly classified histologically into fatty liver (steatosis), hepatitis (inflammation, 'grade') and cirrhosis (fibrosis, 'stage'). The use of special histological stains can help in determining aetiology. The clinical features and prognosis of these changes are dependent on the underlying aetiology, and are discussed in the relevant sections below.

Non-invasive markers of hepatic fibrosis

Non-invasive markers of liver fibrosis have been developed and can reduce the need for liver biopsy to assess the extent of fibrosis in some settings.

Serological markers of hepatic fibrosis, such as α_2-macroglobulin, haptoglobin and routine clinical biochemistry tests, are used in the Fibrotest®. The ELF® (Enhanced Liver Fibrosis) serological assay uses a combination of hyaluronic acid, procollagen peptide III (PIIINP) and tissue inhibitor of metalloproteinase 1 (TIMP1). These tests are good at differentiating severe fibrosis from mild scarring, but are limited in their ability to detect subtle changes. A number of non-commercial scores based on standard biochemical and anthropometric indices have also been described that provide similar levels of sensitivity and specificity (e.g. the FIB4 Score).

An alternative to serological markers is transient elastography in which ultrasound-based shock waves are sent through the liver to measure liver stiffness as a surrogate for hepatic fibrosis. Once again, this test is good at differentiating severe fibrosis from mild scarring, but is limited in its ability to detect subtle changes, and validity may be affected by obesity.

PRESENTING PROBLEMS IN LIVER DISEASE

Liver injury may be either acute or chronic. The main causes are listed in Figure 23.12 and discussed in detail later in the chapter.

- *Acute liver injury* may present with non-specific symptoms of fatigue and abnormal LFTs, or with jaundice and acute liver failure.
- *Chronic liver injury* is defined as hepatic injury, inflammation and/or fibrosis occurring in the liver for more than 6 months. In the early stages, patients can be asymptomatic with fluctuating abnormal LFTs. With more severe liver damage, however, the presentation can be with jaundice, portal hypertension or other signs of cirrhosis and hepatic decompensation (Box 23.7).

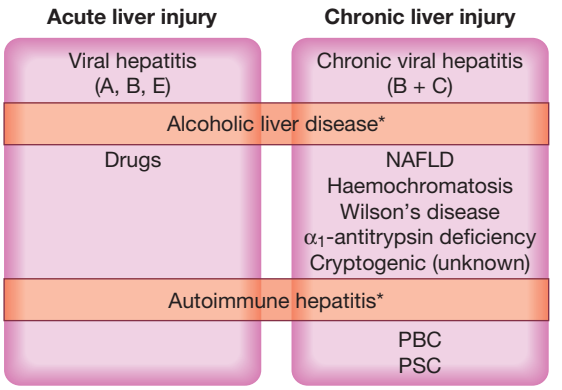

Fig. 23.12 Causes of acute and chronic liver injury. *Although there is often evidence of chronic liver disease at presentation, may present acutely with jaundice. In alcoholic liver disease this is due to superimposed alcoholic hepatitis. (NAFLD = non-alcoholic fatty liver disease; PBC = primary biliary cirrhosis; PSC = primary sclerosing cholangitis).

23.7 Presentation of liver disease

Severity	Acute liver injury	Chronic liver injury
Mild/moderate	Abnormal LFTs	Abnormal LFTs
Severe	Jaundice	Signs of cirrhosis ± portal hypertension
Very severe	Acute liver failure	Chronic liver failure* Jaundice Ascites Hepatic encephalopathy Portal hypertension with variceal bleeding

*May not occur until several years after cirrhosis has presented.

Acute liver failure

Acute liver failure is an uncommon but serious condition. The presentation is with progressive deterioration in liver function and mental changes progressing from confusion to coma. The syndrome was originally defined further as occurring within 8 weeks of onset of the precipitating illness, in the absence of evidence of pre-existing liver disease. This distinguishes it from instances in which hepatic encephalopathy represents a deterioration in chronic liver disease.

Liver failure occurs when there is insufficient metabolic and synthetic function for the needs of the patient. Although the direct cause is usually acute loss of functional hepatocytes, this can occur in different settings, which have implications for outcome and treatment. In a patient whose liver was previously normal (fulminant liver failure), the level of injury needed to cause liver failure, and thus the patient risk, is very high. In a patient with pre-existing chronic liver disease, the additional acute insult needed to precipitate liver failure is much less. It is critical, therefore, to understand whether liver failure is a true acute event or an acute

deterioration on a background of pre-existing injury (which may itself not have been diagnosed). Although ultimately liver biopsy may be necessary, it is the presence or absence of the clinical features suggesting chronicity that guides the clinician.

More recently, newer classifications have been developed to reflect differences in presentation and outcome of acute liver failure. One such classification divides acute liver failure into hyperacute, acute and subacute, according to the interval between onset of jaundice and encephalopathy (Box 23.8).

Pathophysiology

Any cause of liver damage can produce acute liver failure, provided it is sufficiently severe (Fig. 23.13). Acute viral hepatitis is the most common cause worldwide, whereas paracetamol toxicity (p. 212) is the most frequent cause in the UK. Acute liver failure occurs occasionally with other drugs, or from *Amanita phalloides* (mushroom) poisoning, in pregnancy, in Wilson's disease, following shock (p. 190) and, rarely, in extensive malignant disease of the liver. In 10% of cases the cause of acute liver failure remains unknown and these patients are often labelled as having 'non-A–E viral hepatitis' or 'cryptogenic' acute liver failure.

23.8 Classification of acute liver failure

Type	Time: jaundice to encephalopathy	Cerebral oedema	Common causes
Hyperacute	< 7 days	Common	Viral, paracetamol
Acute	8–28 days	Common	Cryptogenic, drugs
Subacute	29 days–12 weeks	Uncommon	Cryptogenic, drugs

Clinical assessment

Cerebral disturbance (hepatic encephalopathy and/or cerebral oedema) is the cardinal manifestation of acute liver failure, but in the early stages this can be mild and episodic and so its absence does not exclude a significant acute liver injury. The initial clinical features are often subtle and include reduced alertness and poor concentration, progressing through behavioural abnormalities such as restlessness and aggressive outbursts, to drowsiness and coma (Box 23.9). Cerebral oedema may occur due to increased intracranial pressure, causing unequal or abnormally reacting pupils, fixed pupils, hypertensive episodes, bradycardia, hyperventilation, profuse sweating, local or general myoclonus, focal fits or decerebrate posturing. Papilloedema occurs rarely and is a late sign. More general symptoms include weakness, nausea and vomiting. Right hypochondrial discomfort is an occasional feature.

The patient may be jaundiced; however, this may not be present at the outset (e.g. in paracetamol overdose) and there are a number of exceptions, including Reye's syndrome, in which jaundice is rare. Occasionally, death may occur in fulminant cases of acute liver failure before

23.9 How to assess clinical grade of hepatic encephalopathy

Clinical grade	Clinical signs
Grade 1	Poor concentration, slurred speech, slow mentation, disordered sleep rhythm
Grade 2	Drowsy but easily rousable, occasional aggressive behaviour, lethargic
Grade 3	Marked confusion, drowsy, sleepy but responds to pain and voice, gross disorientation
Grade 4	Unresponsive to voice, may or may not respond to painful stimuli, unconscious

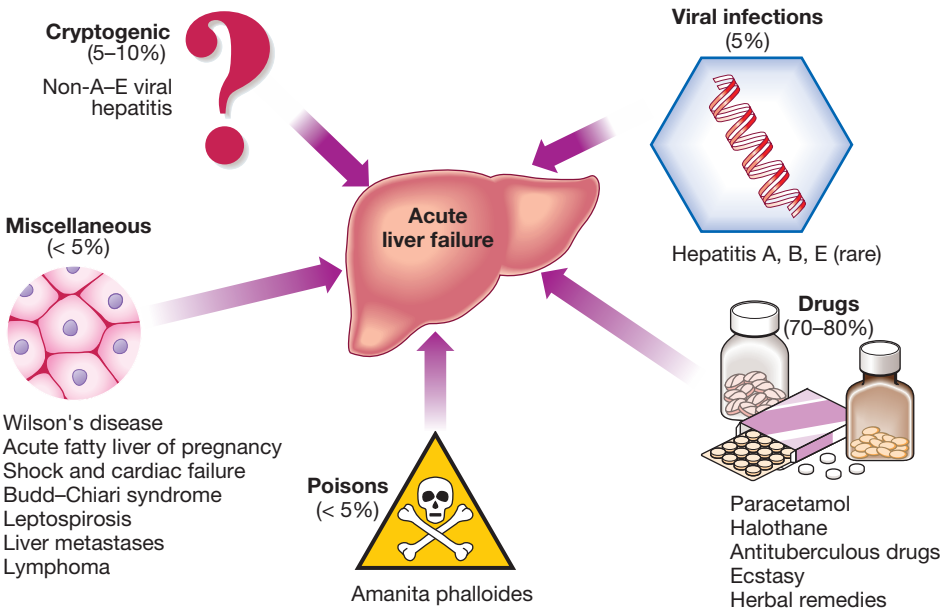

Fig. 23.13 Causes of acute liver failure in the UK. The relative frequency of the different causes varies according to geographical area.

jaundice develops. Fetor hepaticus can be present. The liver is usually of normal size but later becomes smaller. Hepatomegaly is unusual and, in the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd–Chiari syndrome, p. 976). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy. Other features are related to the development of complications (see below).

Investigations

The patient should be investigated to determine the cause of the liver failure and the prognosis (Boxes 23.10 and 23.11). Hepatitis B core IgM antibody is the best screening test for acute hepatitis B infection, as liver damage is due to the immunological response to the virus, which has often been eliminated, and the test for HBsAg may be negative. The PT rapidly becomes prolonged as coagulation factor synthesis fails; this is the laboratory test of greatest prognostic value and should be carried out at least twice daily. Its prognostic importance emphasises the necessity of avoiding the use of fresh frozen plasma to correct raised PT in acute liver failure, except in the setting of frank bleeding. Factor V levels can be used instead of the PT to assess the degree of liver impairment. The plasma bilirubin reflects the degree of jaundice. Plasma aminotransferase activity is particularly high after paracetamol overdose, reaching 100–500 times normal, but falls as liver damage progresses and is not helpful in determining prognosis. Plasma albumin remains normal unless the course is prolonged. Percutaneous liver biopsy is contraindicated because of the severe coagulopathy, but biopsy can be undertaken using the transjugular route if appropriate.

Management

Patients with acute liver failure should be treated in a high-dependency or intensive care unit as soon as progressive prolongation of the PT occurs or hepatic encephalopathy is identified (Box 23.12), so that prompt treatment of complications can be initiated (Box 23.13). Conservative treatment aims to maintain life in the hope that hepatic regeneration will occur, but early transfer to a specialised transplant unit should always be considered. *N*-acetylcysteine therapy may improve

23.10 Investigations to determine the cause of acute liver failure

- Toxicology screen of blood and urine
- HBsAg, IgM anti-HBc
- IgM anti-HAV
- Anti-HEV, HCV, cytomegalovirus, herpes simplex, Epstein–Barr virus
- Caeruloplasmin, serum copper, urinary copper, slit-lamp eye examination
- Autoantibodies: ANA, ASMA, LKM, SLA
- Immunoglobulins
- Ultrasound of liver and Doppler of hepatic veins

(ANA = antinuclear antibody; ASMA = anti-smooth muscle antibody; LKM = liver-kidney microsomal antibody; SLA = soluble liver antigen)

23.11 Adverse prognostic criteria in acute liver failure*

- H^+ > 50 nmol/L (pH < 7.3) at or beyond 24 hrs following the overdose

Or

- Serum creatinine > 300 μmol/L (≅ 3.38 mg/dL) *plus* prothrombin time > 100 secs *plus* encephalopathy grade 3 or 4

Non-paracetamol cases

- Prothrombin time > 100 secs

Or

- Any three of the following:
  - Jaundice to encephalopathy time > 7 days
  - Age < 10 or > 40 yrs
  - Indeterminate or drug-induced causes
  - Bilirubin > 300 μmol/L (≅ 17.6 mg/dL)
  - Prothrombin time > 50 secs

Or

- Factor V level < 15% and encephalopathy grade 3 or 4

*Predict a mortality rate of ≥ 90% and are an indication for referral for possible liver transplantation.

23.12 Monitoring in acute liver failure

Cardiorespiratory

- Pulse
- Blood pressure
- Central venous pressure
- Respiratory rate

Neurological

- Intracranial pressure monitoring (specialist units, p. 198)
- Conscious level

Fluid balance

- Hourly output (urine, vomiting, diarrhoea)
- Input: oral, intravenous

Blood analyses

- Arterial blood gases
- Peripheral blood count (including platelets)
- Sodium, potassium, HCO^{3-}, calcium, magnesium
- Creatinine, urea
- Glucose (2-hourly in acute phase)
- Prothrombin time

Infection surveillance

- Cultures: blood, urine, throat, sputum, cannula sites
- Chest X-ray
- Temperature

23.13 Complications of acute liver failure

- Encephalopathy and cerebral oedema
- Hypoglycaemia
- Metabolic acidosis
- Infection (bacterial, fungal)
- Renal failure
- Multi-organ failure (hypotension and respiratory failure)

outcome, particularly in patients with acute liver failure due to paracetamol poisoning. Liver transplantation is an increasingly important treatment option for acute liver failure, and criteria have been developed to identify patients unlikely to survive without a transplant (see Box 23.11). Patients should, wherever possible, be transferred to a transplant centre before these criteria are met to allow time for assessment and to maximise the time for a donor liver to become available. Survival following liver transplantation for acute liver failure is improving, and 1-year survival rates of about 60% can be expected.

Abnormal liver function tests

Frequently, LFTs are requested in patients who have no symptoms or signs of liver disease, as part of routine health checks, insurance medicals and drug monitoring. When abnormal results are found, it is important for the clinician to be able to interpret them and to investigate patients appropriately. Many patients with chronic liver disease are asymptomatic or have vague, non-specific symptoms. Apparently asymptomatic abnormal LFTs are therefore a common occurrence. When LFTs are measured routinely prior to elective surgery, 3.5% of patients are discovered to have mildly elevated transaminases. The prevalence of abnormal LFTs has been reported to be as high as 10% in some studies. The most common abnormalities are alcoholic (p. 957) or non-alcoholic fatty liver disease (p. 959). Since effective medical treatments are now available for many types of chronic liver disease, further evaluation is usually warranted to make sure the patient does not have a treatable condition. Although transient mild abnormalities in LFTs may not be clinically significant, the majority of patients with persistently abnormal LFTs do have significant liver disease. Biochemical abnormalities in chronic liver disease often fluctuate over time, and therefore even mild abnormalities can indicate significant underlying disease and so warrant follow-up and investigation.

When abnormal LFTs are detected, a thorough history should be compiled to determine the patient's alcohol consumption, drug use (prescribed drugs or otherwise), risk factors for viral hepatitis (e.g. blood transfusion, injecting drug use, tattoos), the presence of autoimmune diseases, family history, neurological symptoms, and the presence of features of the metabolic syndrome (p. 805), including diabetes and/or obesity (see Box 23.5, p. 930, and Box 5.18, p. 115). The presence or absence of stigmata of chronic liver disease does not reliably identify those individuals with significant disease, and investigations are indicated, even in the absence of these signs.

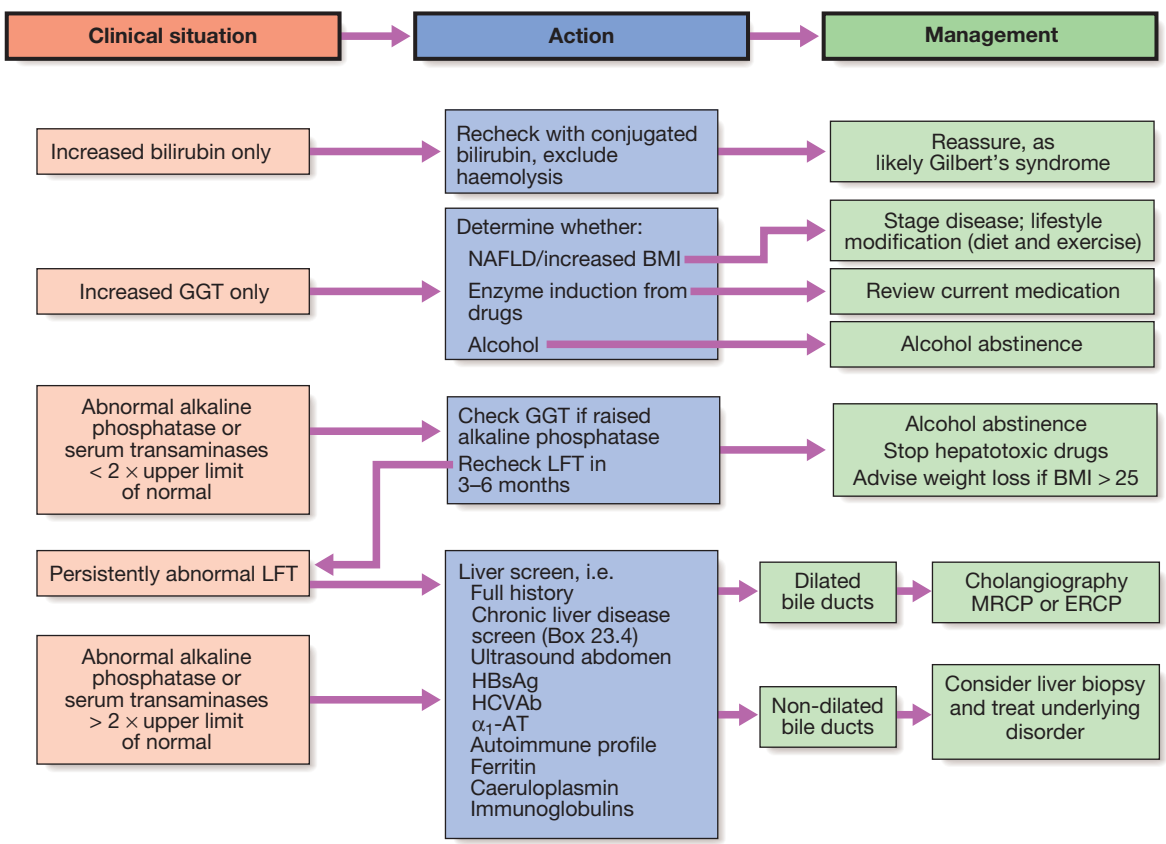

Fig. 23.14 **Suggested management of abnormal LFTs in asymptomatic patients.** *No further investigation needed.

23.14 Common causes of elevated serum transaminases

Minor elevation (< 100 U/L*)

- Chronic hepatitis C
- Chronic hepatitis B
- Haemochromatosis
- Fatty liver disease

Moderate elevation (100–300 U/L*)

As above plus:

- Alcoholic hepatitis
- Non-alcoholic steatohepatitis
- Autoimmune hepatitis
- Wilson's disease

Major elevation (> 300 U/L*)

- Drugs (e.g. paracetamol)
- Acute viral hepatitis
- Autoimmune liver disease
- Ischaemic liver
- Toxins (e.g. *Amanita phalloides* poisoning)
- Flare of chronic hepatitis B

*Note: These ranges are indicative but do not rigidly discriminate between different aetiologies

23.15 Causes of cholestatic jaundice

Intrahepatic

- Primary biliary cirrhosis
- Primary sclerosing cholangitis
- Alcohol
- Drugs
- Hepatic infiltrations (lymphoma, granuloma, amyloid, metastases)
- Cystic fibrosis
- Severe bacterial infections
- Pregnancy (p. 977)
- Inherited cholestatic liver disease, e.g. benign recurrent intrahepatic cholestasis
- Chronic right heart failure

Extrahepatic

- Carcinoma
  - Ampullary
  - Pancreatic
  - Bile duct (cholangiocarcinoma)
  - Liver metastases
- Choledocholithiasis
- Parasitic infection
- Traumatic biliary strictures
- Chronic pancreatitis

Both the pattern of LFT abnormality, hepatitic or obstructive, and the degree of elevation are helpful in determining the cause of underlying liver disease (Boxes 23.14 and 23.15). The investigations that make up a standard liver screen and additional or confirmatory tests are shown in Boxes 23.4 and 23.5. An algorithm for investigating abnormal LFTs is provided in Figure 23.14.

Jaundice

Jaundice is usually detectable clinically when the plasma bilirubin exceeds 40 µmol/L (~2.5 mg/dL). The causes of jaundice overlap with the causes of abnormal LFTs discussed above. In a patient with jaundice it is useful to consider whether the cause might be pre-hepatic, hepatic or post-hepatic and there are often important clues in the history (Box 23.16).

23.16 Key history points in patients with jaundice

Symptoms*

- Itching preceding jaundice
- Abdominal pain (suggests stones)
- Weight loss (chronic liver disease and malignancy)
- Dark urine and pale stools
- Fever ± rigors
- Dry eyes/dry mouth
- Fatigue

Recent drug history

Other

- Exposure to intravenous drug or blood transfusions
- Travel history and country of birth
- Metabolic syndrome (increased body mass index ± type 2 diabetes/hypertension)
- Autoimmune disease history
- Alcohol history
- Inflammatory bowel disease
- Family history of liver disease, autoimmune disease or the metabolic syndrome

*Symptoms may be absent and abnormal LFTs detected incidentally.

Pre-hepatic jaundice

This is caused either by haemolysis or by congenital hyperbilirubinaemia, and is characterised by an isolated raised bilirubin level.

In haemolysis, destruction of red blood cells or their marrow precursors causes increased bilirubin production. Jaundice due to haemolysis is usually mild because a healthy liver can excrete a bilirubin load six times greater than normal before unconjugated bilirubin accumulates in the plasma. This does not apply to newborns, who have less capacity to metabolise bilirubin.

The most common form of non-haemolytic hyperbilirubinaemia is Gilbert's syndrome, an inherited disorder of bilirubin metabolism (Box 23.17). Other inherited disorders of bilirubin metabolism are very rare.

Hepatocellular jaundice

Hepatocellular jaundice results from an inability of the liver to transport bilirubin into the bile, occurring as a consequence of parenchymal disease. Bilirubin transport across the hepatocytes may be impaired at any point between uptake of unconjugated bilirubin into the cells and transport of conjugated bilirubin into the canaliculi. In addition, swelling of cells and oedema resulting from the disease itself may cause obstruction of the biliary canaliculi. In hepatocellular jaundice the concentrations of both unconjugated and conjugated bilirubin in the blood increase. Hepatocellular jaundice can be due to acute or chronic injury (see Fig. 23.12), and clinical features of acute or chronic liver disease may be detected clinically (see Box 23.7, p. 932).

Characteristically, jaundice due to parenchymal liver disease is associated with increases in transaminases (AST, ALT), but increases in other LFTs, including cholestatic enzymes (GGT, ALP) may occur, and suggest specific aetiologies (see below). Acute jaundice in the presence of an ALT of greater than 1000 U/L is highly suggestive of an infectious cause (e.g. hepatitis A, B), drugs (e.g. paracetamol) or hepatic ischaemia.

23.17 Congenital non-haemolytic hyperbilirubinaemia

Syndrome	Inheritance	Abnormality	Clinical features	Treatment
Unconjugated hyperbilirubinaemia				
Gilbert's	Autosomal dominant	↓ Glucuronyl transferase ↓ Bilirubin uptake	Mild jaundice, especially with fasting	No treatment necessary
Crigler–Najjar				
Type I	Autosomal recessive	Absent glucuronyl transferase	Rapid death in neonate (kernicterus)	
Type II	Autosomal dominant	↓↓ Glucuronyl transferase	Presents in neonate	Phenobarbital, ultraviolet light or liver transplant
Conjugated hyperbilirubinaemia				
Dubin–Johnson	Autosomal recessive	↓ Canalicular excretion of organic anions, including bilirubin	Mild	No treatment necessary
Rotor's	Autosomal recessive	↓ Bilirubin uptake ↓ Intrahepatic binding	Mild	No treatment necessary

Imaging is essential, in particular to identify features suggestive of cirrhosis, to define the patency of the hepatic vasculature, and to obtain evidence of portal hypertension. Liver biopsy has an important role in defining the aetiology of hepatocellular jaundice and the extent of liver injury.

Obstructive (cholestatic) jaundice

Cholestatic jaundice may be caused by:

- failure of hepatocytes to initiate bile flow
- obstruction of the bile ducts or portal tracts
- obstruction of bile flow in the extrahepatic bile ducts between the porta hepatis and the papilla of Vater.

In the absence of treatment, cholestatic jaundice tends to become progressively more severe because conjugated bilirubin is unable to enter the bile canaliculi and passes back into the blood, and also because there is a failure of clearance of unconjugated bilirubin arriving at the liver cells. The causes of cholestatic jaundice are listed in Box 23.15. Cholestasis may result from defects at more than one of these levels. Those confined to the extrahepatic bile ducts may be amenable to surgical or endoscopic correction.

Clinical features (Box 23.18) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 23.19). Obstruction of the bile duct drainage due to blockage of the extrahepatic biliary tree is characteristically associated with pale stools and dark urine. Pruritus may be a dominant feature and can be accompanied by skin excoriations. Peripheral stigmata of chronic liver disease are absent. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically

23.18 Clinical features and complications of cholestatic jaundice

Cholestasis

Early features

- Jaundice
- Dark urine
- Pale stools
- Pruritus

Late features

- Malabsorption (vitamins A, D, E and K): weight loss, steatorrhoea, osteomalacia, bleeding tendency
- Xanthelasma and xanthomas

Cholangitis

- Fever
- Rigors
- Pain (if gallstones present)

23.19 Clinical features suggesting an underlying cause of cholestatic jaundice*

Clinical feature	Causes
Jaundice	
Static or increasing	Carcinoma Primary biliary cirrhosis Primary sclerosing cholangitis
Fluctuating	Choledocholithiasis Stricture Pancreatitis Choledochal cyst Primary sclerosing cholangitis
Abdominal pain	Choledocholithiasis Pancreatitis Choledochal cyst
Cholangitis	Stone Stricture Choledochal cyst
Abdominal scar	Stone Stricture
Irregular hepatomegaly	Hepatic carcinoma
Palpable gallbladder	Carcinoma below cystic duct (usually pancreas)
Abdominal mass	Carcinoma Pancreatitis (cyst) Choledochal cyst
Occult blood in stools	Ampullary tumour

*Each of the diseases listed here can give rise to almost any of the clinical features shown, but the box indicates the most likely cause of the clinical features listed.

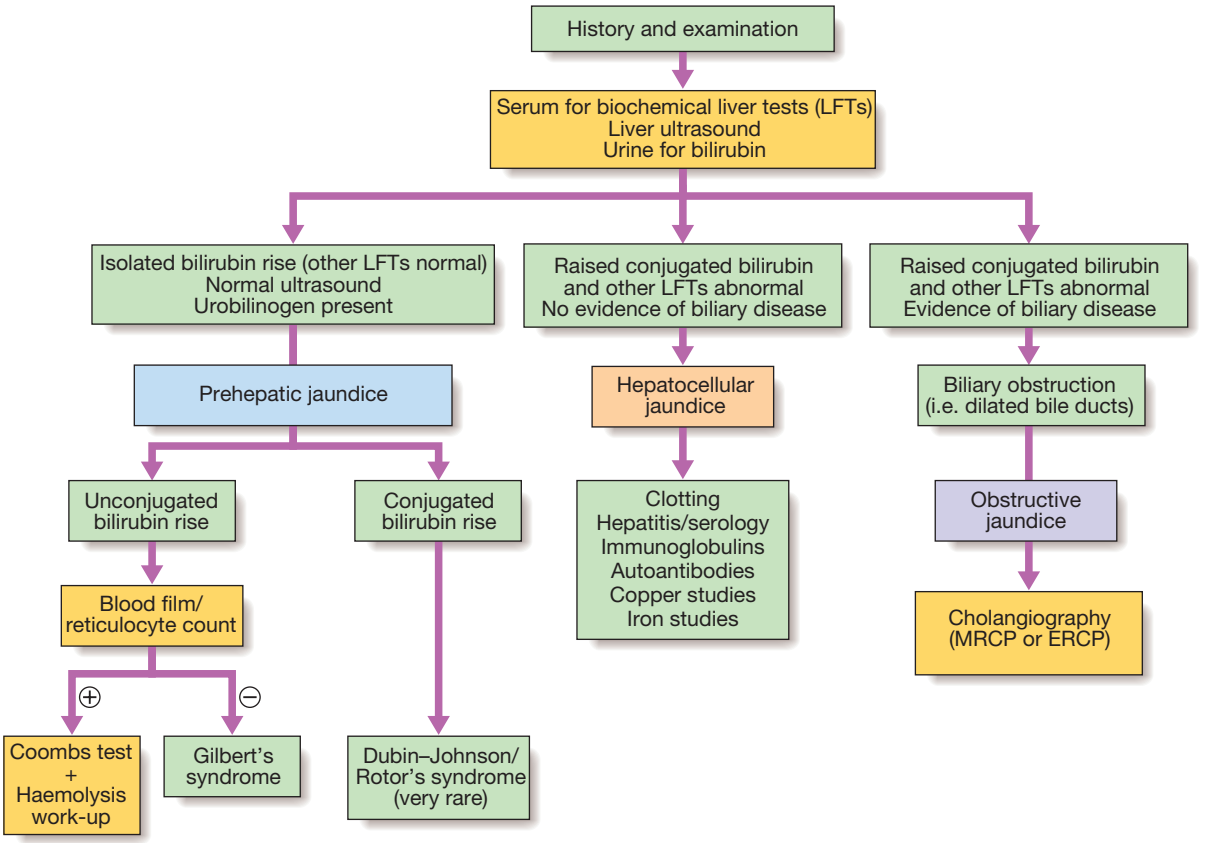

Fig. 23.15 Investigation of jaundice.

inflamed stone-containing gallbladder cannot readily dilate. This is Courvoisier's Law, and suggests that jaundice is due to a malignant biliary obstruction (e.g. pancreatic cancer). Cholangitis is characterised by 'Charcot's triad' of jaundice, right upper quadrant pain and fever. Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than the aminotransferases.

Ultrasound is indicated to determine whether there is evidence of mechanical obstruction and dilatation of the biliary tree (Fig. 23.15). Management of cholestatic jaundice depends on the underlying cause and is discussed in the relevant sections below.

Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour (Box 23.20). The most common liver tumour in Western countries is liver metastasis, whereas primary liver cancer complicating chronic viral hepatitis is more common in the Far East. Unlike metastases, neuro-endocrine tumours typically cause massive hepatomegaly but without significant weight loss. Cirrhosis can be associated with either hepatomegaly or reduced liver size in advanced disease. Although all causes of cirrhosis can involve hepatomegaly, it is much more common in alcoholic liver disease and haemochromatosis. Hepatomegaly may resolve in patients with alcoholic cirrhosis when they stop drinking.

23.20 Causes of change in liver size

Large liver (hepatomegaly)

- Liver metastases
- Multiple or large hepatic cysts
- Cirrhosis (early): NAFLD, alcohol, haemochromatosis
- Hepatic vein outflow obstruction
- Infiltration: amyloid

Small liver

- Cirrhosis (late)

Ascites

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (> 1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill. Other features include eversion of the umbilicus, herniae, abdominal striae, divarication of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

23.21 Causes of ascites

Common causes	
• Malignant disease Hepatic Peritoneal	• Cardiac failure • Hepatic cirrhosis
Other causes	
• Hypoproteinaemia Nephrotic syndrome Protein-losing enteropathy Malnutrition • Pancreatitis • Lymphatic obstruction	• Hepatic venous occlusion (p. 976) Budd–Chiari syndrome Veno-occlusive disease • Infection Tuberculosis
Rare causes	
• Meigs' syndrome*	• Hypothyroidism

*Meigs' syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour.

Pathophysiology

Ascites has numerous causes, the most common of which are malignant disease, cirrhosis and heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease (Box 23.21). Splanchnic vasodilatation is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic vasodilatation as cirrhosis advances. This leads to activation of the renin–angiotensin system with secondary aldosteronism, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity of the kallikrein–kinin system (Fig. 23.16). These systems tend to normalise arterial pressure but produce salt and water retention. In this setting the combination of splanchnic arterial vasodilatation and portal hypertension alters intestinal capillary permeability, promoting accumulation of fluid within the peritoneum.

Investigations

Ultrasonography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can be used to obtain ascitic fluid for analysis. The appearance of ascitic fluid may point to the underlying cause (Box 23.22). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and only identified on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the protein concentration and the serum–ascites albumin gradient (SAAG) are used to distinguish a transudate from an exudate. Cirrhotic patients typically develop a transudate with a total protein concentration below 25 g/L and relatively few cells. However, in up to 30% of patients, the total protein concentration is more than 30 g/L. In these cases, it is useful to calculate the SAAG by subtracting the concentration of the ascites fluid albumin from the serum albumin. A gradient of more than 11 g/L is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a transudative ascites, as indicated by an albumin gradient above 11 g/L but, unlike in cirrhosis, the total protein content is usually above 25 g/L.

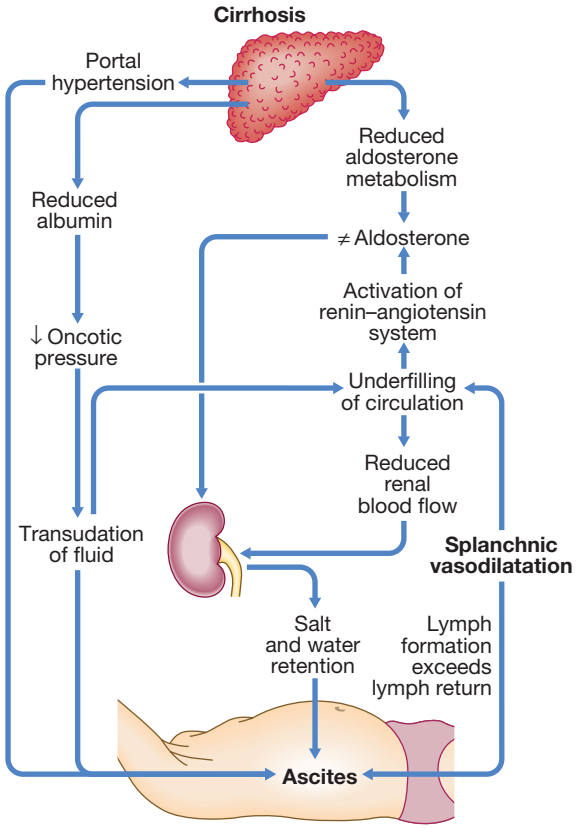

Fig. 23.16 Pathogenesis of ascites.

23.22 Ascitic fluid: appearance and analysis

Cause/appearance	
• Cirrhosis: clear, straw-coloured or light green • Malignant disease: bloody • Infection: cloudy • Biliary communication: heavy bile staining • Lymphatic obstruction: milky-white (chylous)	
Useful investigations	
• Total albumin (plus serum albumin) and protein* • Amylase	• Neutrophil count • Cytology • Microscopy and culture

*To calculate the serum–ascites albumin gradient (SAAG).

Exudative ascites (ascites protein concentration > 25 g/L or a SAAG < 11 g/L) raises the possibility of infection (especially tuberculosis), malignancy, hepatic venous obstruction, pancreatic ascites or, rarely, hypothyroidism. Ascites amylase activity above 1000 U/L identifies pancreatic ascites, and low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells (one-third of cirrhotic patients with a bloody tap have a hepatocellular carcinoma). Polymorphonuclear leucocyte counts above 250×10^6/L strongly suggest infection (spontaneous bacterial peritonitis, see below). Laparoscopy can be valuable in detecting peritoneal disease.

Management

Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid and electrolyte balance and precipitate hepatic encephalopathy (p. 941). Treatment of transudative ascites is based on restricting sodium and water intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy is treated with paracentesis, but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid daily, so body weight should not fall by more than 1 kg daily to avoid excessive fluid depletion.

Sodium and water restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance, and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/day ('no added salt diet') is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 23.23). Restriction of water intake to 1.0–1.5 L/day is necessary only if the plasma sodium falls below 125 mmol/L.

Diuretics

Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the first-line drug because it is a powerful aldosterone antagonist; it can cause painful gynaecomastia and hyperkalaemia, in which case amiloride (5–10 mg/day) can be substituted. Some patients also require loop diuretics, such as furosemide, but these can cause fluid and electrolyte imbalance and renal dysfunction. Diuresis may be improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to doses of 400 mg spironolactone and 160 mg furosemide, or who are unable to tolerate these doses due to hyponatraemia or renal impairment, are considered to have refractory or diuretic-resistant ascites and should be treated by other measures.

23.23 Some drugs containing relatively large amounts of sodium or causing sodium retention

High sodium content	
• Alginates • Antacids • Antibiotics • Phenytoin	• Sodium valproate • Effervescent preparations (e.g. aspirin, calcium, paracetamol)
Sodium retention	
• Carbenoxolone • Corticosteroids • Metoclopramide	• NSAIDs • Oestrogens

Paracentesis

First-line treatment of refractory ascites is large-volume paracentesis. Paracentesis to dryness is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% human albumin solution (HAS) for every 1.5–2 L of ascites drained) or another plasma expander. Paracentesis can be used as an initial therapy or when other treatments fail.

Transjugular intrahepatic portosystemic stent shunt

A transjugular intrahepatic portosystemic stent shunt (TIPSS) (p. 947) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. It can be used in patients awaiting liver transplantation or in those with reasonable liver function, but can aggravate encephalopathy in those with poor function.

Peritoneo-venous shunt

The peritoneo-venous shunt is a long tube with a non-return valve running subcutaneously from the peritoneum to the internal jugular vein in the neck; it allows ascitic fluid to pass directly into the systemic circulation. Complications, including infection, superior vena caval thrombosis, pulmonary oedema, bleeding from oesophageal varices and disseminated intravascular coagulopathy, limit its use and insertion of these shunts is now rare.

Complications

Renal failure

Renal failure can occur in patients with ascites. It can be pre-renal due to vasodilatation from sepsis and/or diuretic therapy, or due to hepatorenal syndrome.

Hepatorenal syndrome

This occurs in 10% of patients with advanced cirrhosis complicated by ascites. There are two clinical types; both are mediated by renal vasoconstriction due to underfilling of the arterial circulation.

- *Type 1 hepatorenal syndrome* is characterised by progressive oliguria, a rapid rise of the serum creatinine and a very poor prognosis (without treatment, median survival is less than 1 month). There is usually no proteinuria, a urine sodium excretion of less than 10 mmol/day and a urine/plasma osmolarity ratio of more than 1.5. Other non-functional causes of renal failure must be excluded before the diagnosis is made. Treatment consists of albumin infusions in combination with terlipressin and is effective in about two-thirds of patients. Haemodialysis should not be used routinely because it does not improve the outcome.

Patients who survive should be considered for liver transplantation.

- *Type 2 hepatorenal syndrome* usually occurs in patients with refractory ascites, is characterised by a moderate and stable increase in serum creatinine, and has a better prognosis.

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) may present with abdominal pain, rebound tenderness, absent bowel sounds and fever in a patient with obvious features of cirrhosis and ascites. Abdominal signs are mild or absent in about one-third of patients, and in these patients hepatic encephalopathy and fever are the main features. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count above 250×10^6/L almost invariably indicates infection. The source of infection cannot usually be determined, but most organisms isolated are of enteric origin and *Escherichia coli* is most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime or piperacillin/tazobactam). Recurrence of SBP is common but may be reduced with prophylactic quinolones such as norfloxacin or ciprofloxacin (Box 23.24).

EBM 23.24 Antibiotics and spontaneous bacterial peritonitis (SBP)

'In patients with a previous episode of SBP and continued ascites, norfloxacin 400 mg/day prevents recurrence (NNT_B 4.5).'

'In patients with cirrhosis who have had a gastrointestinal haemorrhage, prophylactic antibiotics reduce the risk of bacterial peritonitis (NNT_B 12.5) and improve survival (NNT_B 11).'

Prognosis

Only 10–20% of patients survive 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.

Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by liver disease. As it progresses, confusion is followed by coma. Confusion needs to be differentiated from delirium tremens and Wernicke's encephalopathy, and coma from subdural haematoma, which can occur in alcoholics after a fall (Box 23.25). Features include changes of intellect, personality, emotions and consciousness, with or without neurological signs. The degree of encephalopathy can be graded from 1 to 4, depending on these features, and this is useful in assessing response to therapy (see Box 23.9, p. 933). When an episode develops acutely, a precipitating factor may be found (Box 23.26). The earliest features are very mild and easily overlooked but, as the condition becomes more severe, apathy, inability to concentrate, confusion, disorientation, drowsiness, slurring of speech and eventually coma develop. Convulsions sometimes occur. Examination usually shows a flapping tremor (asterixis), inability to perform simple mental arithmetic tasks or to draw objects such as a star (constructional apraxia; p. 923), and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs; if these are present, other causes must be sought. Fetor hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

23.25 Differential diagnosis of hepatic encephalopathy

- Intracranial bleed (subdural, extradural haematoma, p. 1218)
- Drug or alcohol intoxication (pp. 252 and 254)
- Delirium tremens/alcohol withdrawal (p. 253)
- Wernicke's encephalopathy (p. 253)
- Primary psychiatric disorders (p. 242)
- Hypoglycaemia (p. 814)
- Neurological Wilson's disease (p. 1198)
- Post-ictal state

23.26 Factors precipitating hepatic encephalopathy

- Drugs (especially sedatives, antidepressants)
- Dehydration (including diuretics, paracentesis)
- Portosystemic shunting
- Infection
- Hypokalaemia
- Constipation
- ↑Protein load (including GI bleeding)

Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating neurotoxins that are normally metabolised by the liver. Accordingly, most affected patients have evidence of liver failure and portosystemic shunting of blood, but the balance between these varies from individual to individual. Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. The 'neurotoxins' causing encephalopathy are unknown, but they are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. These substances are normally metabolised by the healthy liver and excluded from the systemic circulation. Ammonia has

traditionally been considered an important factor. Recent interest has focused on γ-aminobutyric acid (GABA) as a mediator, along with octopamine, amino acids, mercaptans and fatty acids that can act as neurotransmitters. The brain in cirrhosis may also be sensitised to other factors such as drugs that can precipitate hepatic encephalopathy (see Box 23.26). Disruption of the function of the blood–brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

Investigations

The diagnosis can usually be made clinically, but when doubt exists, an electroencephalogram (EEG) shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. However, increased concentrations can occur in the absence of clinical encephalopathy, rendering this investigation of little diagnostic value.

Management

The principles are to treat or remove precipitating causes (see Box 23.26) and to suppress the production of neurotoxins by bacteria in the bowel. Dietary protein restriction is rarely needed and is no longer recommended as first-line treatment because it is unpalatable and can lead to a worsening nutritional state in already malnourished patients. Lactulose (15–30 mL 3 times daily) is increased gradually until the bowels are moving twice daily. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Rifaximin (400 mg 3 times daily) is a well-tolerated, non-absorbed antibiotic that acts by reducing the bacterial content of the bowel and has been shown to be effective. It can be used in addition, or as an alternative, to lactulose if diarrhoea becomes troublesome. Chronic or refractory encephalopathy is one of the main indications for liver transplantation.

Variceal bleeding

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices (Fig. 23.17) is common in chronic liver disease. Investigation and management are discussed on page 853 and the specific management of variceal bleeding on page 946.

CIRRHOSIS

Cirrhosis is characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. Worldwide, the most common causes are chronic viral hepatitis, prolonged excessive alcohol consumption and NAFLD. Cirrhosis is the most common cause of portal hypertension and its complications.

The causes of cirrhosis are listed in Box 23.27; any condition leading to persistent or recurrent hepatocyte death, such as chronic hepatitis C infection, alcoholic liver disease (ALD) or NAFLD may lead to cirrhosis. It may also occur in prolonged biliary damage or obstruction, as is found in primary biliary cirrhosis (PBC), primary sclerosing cholangitis and post-surgical biliary strictures. Persistent blockage of venous return from the liver, such as occurs in veno-occlusive disease and Budd–Chiari syndrome, can also result in cirrhosis.

Pathophysiology

Following liver injury, stellate cells in the space of Disse (see Fig. 23.3, p. 925) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and

23.27 Causes of cirrhosis

- Alcohol
- Chronic viral hepatitis (B or C)
- Non-alcoholic fatty liver disease
- Immune
  - Primary sclerosing cholangitis
  - Autoimmune liver disease

  - Primary biliary cirrhosis
  - Secondary biliary cirrhosis
  - Cystic fibrosis
- Genetic
  - Haemochromatosis
  - Wilson's disease
  - α_1-antitrypsin deficiency
- Cryptogenic (unknown – 15%)
- Chronic venous outflow obstruction
- Any chronic liver disease

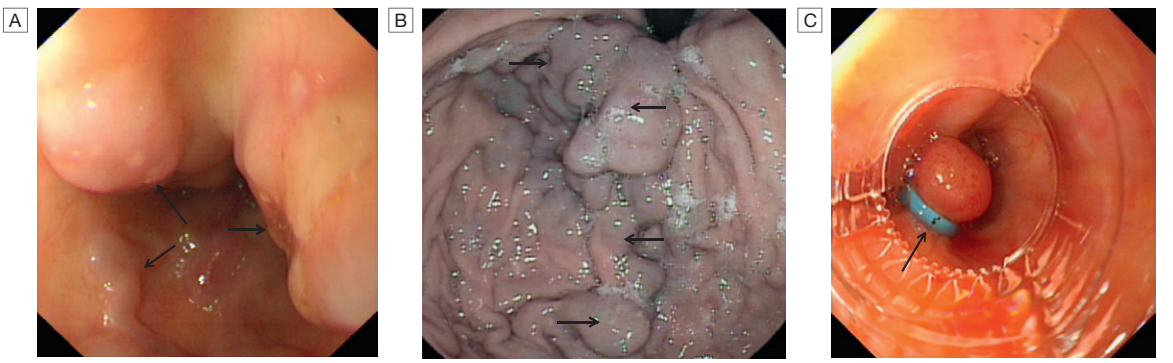

Fig. 23.17 Varices: endoscopic views. A Oesophageal varices (arrows) at the lower end of the oesophagus. B Gastric varices (arrows). C Appearance of oesophageal varices following application of strangulating bands (band ligation, arrow).

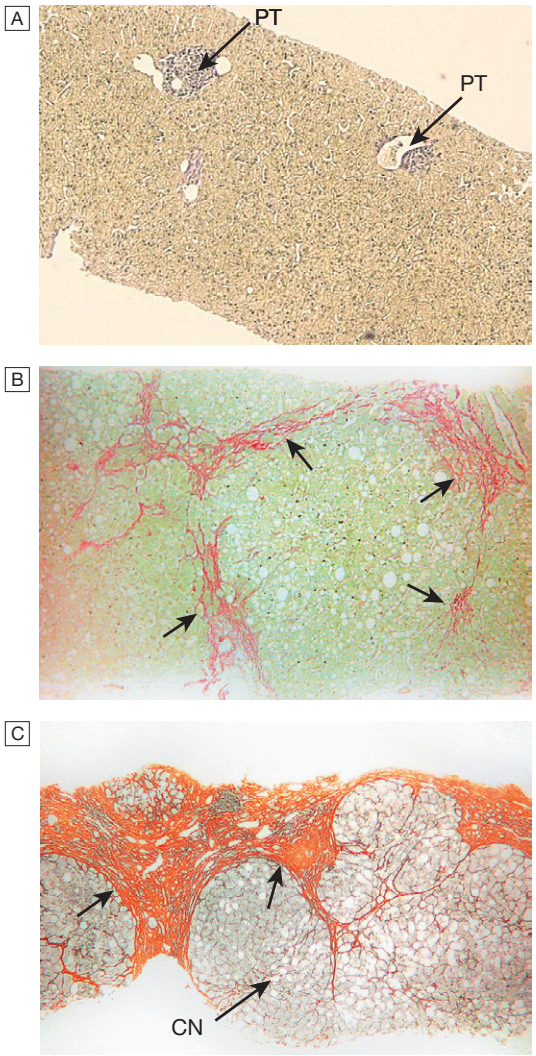

Fig. 23.18 Histological features in normal liver, hepatic fibrosis and cirrhosis. A Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intralobular bile duct branch of the hepatic artery and portal venous radical. B Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular) and linking adjacent portal tracts and hepatic veins. C A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).

other mediators that promote hepatocyte damage and tissue fibrosis (see Fig. 23.4, p. 925).

Cirrhosis is a histological diagnosis (Fig. 23.18). It evolves over years as progressive fibrosis and widespread hepatocyte loss lead to distortion of the normal liver architecture that disrupts the hepatic vasculature, causing portosystemic shunts. These changes usually affect the whole liver, but in biliary cirrhosis (e.g. PBC) they can be patchy. Cirrhosis can be classified histologically into:

- *Micronodular cirrhosis*, characterised by small nodules about 1 mm in diameter and typically seen in alcoholic cirrhosis.
- *Macronodular cirrhosis*, characterised by larger nodules of various sizes. Areas of previous collapse of the liver architecture are evidenced by large fibrous scars.

Clinical features

The clinical presentation is highly variable. Some patients are asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly, signs of portal hypertension (p. 945) or hepatic insufficiency. When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea, vomiting and upper abdominal discomfort (Box 23.28). Cirrhosis will occasionally present because of shortness of breath due to a large right pleural effusion, or with hepatopulmonary syndrome (p. 975).

Hepatomegaly is common when the cirrhosis is due to ALD or haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. A reduction in liver size is especially common if the cause is viral hepatitis or autoimmune liver disease. The liver is often hard, irregular and non-tender. Jaundice is mild when it first appears and is due primarily to a failure to excrete bilirubin. Palmar erythema can be seen early in the disease, but is of limited diagnostic value, as it occurs in many other conditions associated with a hyperdynamic circulation, including normal pregnancy, as well as being found in some healthy people. Spider telangiectasias occur and comprise a central arteriole (which occasionally raises the skin surface), from which small vessels radiate. They vary in size from 1 to 2 mm in diameter, and are usually found only above the nipples. One or two small spider telangiectasias may be present in about 2% of healthy people and may occur transiently in greater numbers in the third trimester of pregnancy, but otherwise they are a strong indicator of liver disease. Florid spider telangiectasia, gynaecomastia and parotid enlargement are most common in alcoholic cirrhosis. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Pulmonary arteriovenous shunts also develop, leading to hypoxaemia and eventually to central cyanosis, but this is a late feature.

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular

23.28 Clinical features of hepatic cirrhosis

- Hepatomegaly (although liver may also be small)
- Jaundice
- Ascites
- Circulatory changes: spider telangiectasia, palmar erythema, cyanosis
- Endocrine changes: loss of libido, hair loss
  - Men: gynaecomastia, testicular atrophy, impotence
  - Women: breast atrophy, irregular menses, amenorrhoea
- Haemorrhagic tendency: bruises, purpura, epistaxis
- Portal hypertension: splenomegaly, collateral vessels, variceal bleeding
- Hepatic (portosystemic) encephalopathy
- Other features: pigmentation, digital clubbing, Dupuytren's contracture

23.29 Features of chronic liver failure

- Worsening synthetic liver function
  - Prolonged PT
  - Low albumin
- Jaundice
- Portal hypertension
- Variceal bleeding
- Hepatic encephalopathy
- Ascites
  - Spontaneous bacterial peritonitis
  - Hepatorenal failure

atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances.

Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below). Ascites also signifies advanced disease. Evidence of hepatic encephalopathy also becomes common with disease progression. Non-specific features of chronic liver disease include clubbing of the fingers and toes. Dupuytren's contracture is traditionally regarded as a complication of cirrhosis, but the evidence for this is weak. Chronic liver failure develops when the metabolic capacity of the liver is exceeded. It is characterised by the presence of encephalopathy and/or ascites. The term 'hepatic decompensation' or 'decompensated liver disease' is often used when chronic liver failure occurs.

Other clinical and laboratory features may be present (Box 23.29); these include peripheral oedema, renal failure, jaundice, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis.

Management

This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications, including ascites, hepatic encephalopathy, portal hypertension and varices. Once the diagnosis of cirrhosis is made, endoscopy should be performed to screen for oesophageal varices (p. 946) and repeated every 2 years. As cirrhosis is associated with an increased risk of hepatocellular carcinoma (HCC), patients should be placed under regular surveillance for it (p. 967).

Chronic liver failure due to cirrhosis can also be treated by liver transplantation. This currently accounts for about three-quarters of all liver transplants (p. 978).

Prognosis

The overall prognosis in cirrhosis is poor. Many patients present with advanced disease and/or serious complications that carry a high mortality. Overall, only 25% of patients survive 5 years from diagnosis but, where liver function is good, 50% survive for 5 years and 25% for up to 10 years. The prognosis is more favourable when the underlying cause of the cirrhosis can be corrected, as in alcohol misuse, haemochromatosis or Wilson's disease.

Laboratory tests give only a rough guide to prognosis in individual patients. Deteriorating liver function, as evidenced by jaundice, ascites or encephalopathy, indicates a poor prognosis unless a treatable cause such as infection is found. Increasing bilirubin, falling albumin (or an albumin concentration < 30 g/L), marked hyponatraemia (< 120 mmol/L) not due to diuretic therapy, and a prolonged PT are all bad prognostic features (Boxes 23.30 and 23.31). The Child–Pugh score and, more recently, the MELD (Model for End-stage Liver Disease) score can be used to assess prognosis. The MELD is more difficult to calculate at the bedside but, unlike the Child–Pugh score, includes renal function; if this is impaired, it is known to be a poor prognostic feature in end-stage disease (Box 23.32). Although

23.30 Child–Pugh classification of prognosis in cirrhosis

Score	1	2	3
Encephalopathy	None	Mild	Marked
Bilirubin (μmol/L)*			
PBC/sclerosing cholangitis	< 68	68–170	> 170
Other causes of cirrhosis	< 34	34–50	> 50
Albumin (g/L)	> 35	28–35	< 28
PT (seconds prolonged)	< 4	4–6	> 6
Ascites	None	Mild	Marked

Add the individual scores: < 7 = Child's A, 7–9 = Child's B, > 9 = Child's C

*To convert bilirubin in μmol/L to mg/dL, divide by 17.

23.31 Survival in cirrhosis

Child–Pugh grade	Survival (%) 1 year	5 years	10 years	Hepatic deaths (%)
A	82	45	25	43
B	62	20	7	72
C	42	20	0	85

Based on Powell LW, Mortimer R, Harris OD. Cirrhosis of the liver: a comparative study of the four major aetiological groups. Med J Aust 1971; 1:941–950.

23.32 One-year survival rate depending on MELD score

MELD score	One-year survival (%) No complications	Complications*
< 9	97	90
10–19	90	85
20–29	70	65
30–39	70	50

MELD from SI units

10 × (0.378 [ln serum bilirubin (μmol/L) + 1.12 [ln INR] + 0.957 [ln serum creatinine (μmol/L)] + 0.643)

MELD from non-SI units

3.8 [ln serum bilirubin (mg/dL)] + 11.2 [ln INR] + 9.3 [ln serum creatinine (mg/dL)] + 6.4

ln = natural log. To calculate online, go to http://optn.transplant.hrsa.gov/resources/MeldPeldCalculator.asp?index=98.

*'Complications' means the presence of ascites, encephalopathy or variceal bleeding.

these scores give a guide to prognosis, the course of cirrhosis can be unpredictable, as complications such as variceal bleeding may occur.

PORTAL HYPERTENSION

This frequently complicates cirrhosis but has other causes. The normal hepatic venous pressure gradient (difference between the wedged hepatic venous pressure and free hepatic venous pressure, see below) is 5–6 mm Hg. Clinically significant portal hypertension is present when the gradient exceeds 10 mm Hg and risk of variceal bleeding increases beyond a gradient of 12 mm Hg. Increased vascular resistance is common. Causes are classified in accordance with the main sites of obstruction to blood flow in the portal venous system (Fig. 23.19). Extrahepatic portal vein obstruction is the usual source of portal hypertension in childhood and adolescence, while cirrhosis causes at least 90% of cases of portal hypertension in adults in developed countries. Schistosomiasis is the most common cause of portal hypertension worldwide but is infrequent outside endemic areas (e.g. Egypt; p. 376).

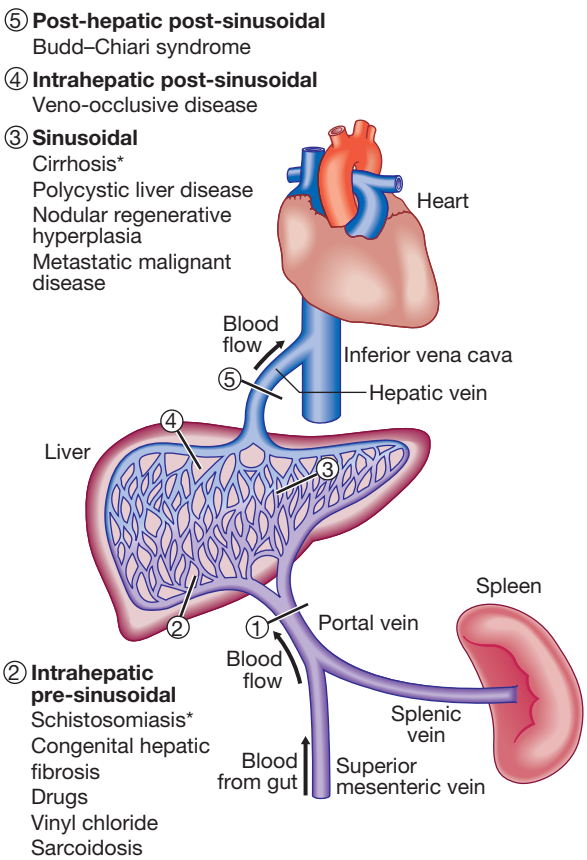

Fig. 23.19 Classification of portal hypertension according to site of vascular obstruction. *Most common cause. Note that splenic vein occlusion can also follow pancreatitis, leading to gastric varices.

23.33 Complications of portal hypertension

- Variceal bleeding: oesophageal, gastric, other (rare)
- Congestive gastropathy
- Hypersplenism
- Ascites
- Iron deficiency anaemia
- Renal failure
- Hepatic encephalopathy

Clinical features

The clinical features result principally from portal venous congestion and collateral vessel formation (Box 23.33). Splenomegaly is a cardinal finding, and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged more than 5 cm below the left costal margin in adults, but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a caput medusae. Rarely, a large umbilical collateral vessel has a blood flow sufficient to give a venous hum on auscultation (Cruveilhier–Baumgarten syndrome). The most important collateral vessel formation occurs in the oesophagus and stomach, and this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids (which are no more common in portal hypertension than in the general population). Fetor hepaticus results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

Ascites occurs as a result of renal sodium retention and portal hypertension that may be due, for example, to post-hepatic portal hypertension (hepatic outflow obstruction, p. 939) or cirrhosis.

The most important consequence of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the gastro-oesophageal junction, or from gastric varices. The size of the varices, endoscopic variceal features such as red spots and stripes, high portal pressure and liver failure are all general factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates and NSAIDs, can also precipitate bleeding. Variceal bleeding is often severe, and recurrent if preventative treatment is not given.

Pathophysiology

Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels, allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, lumbar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. As collateral vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

Investigations

The diagnosis is often made clinically. Portal venous pressure measurements are rarely needed for clinical assessment or routine management, but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements are made by using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the wedged hepatic venous pressure (WHVP). This is an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of 100×10^9/L; values below 50×10^9/L are uncommon. Leucopenia occurs occasionally but anaemia is seldom attributed directly to hypersplenism; if anaemia is found, a source of bleeding should be sought.

The most useful investigation is endoscopy to determine whether gastro-oesophageal varices are present (see Fig. 23.17, p. 942). Once the diagnosis of cirrhosis is made, endoscopy should be performed to screen for oesophageal varices (and repeated every 2 years). Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as liver disease or portal vein thrombosis. CT and MRI angiography can identify the extent of portal vein clot and are used to identify hepatic vein patency.

Management

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices is a common manifestation of chronic liver disease. In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but is still about 45% in those with poor liver function (i.e. Child–Pugh C).

The management of portal hypertension is largely focused on the prevention and/or control of variceal haemorrhage. However, it should be remembered that bleeding can also result from peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail on page 853.

Primary prevention of variceal bleeding

If non-bleeding varices are identified at endoscopy, β-adrenoceptor antagonist (β-blocker) therapy with propranolol (80–160 mg/day) or nadolol is effective in reducing portal venous pressure. Administration of these drugs at doses that reduce the heart rate by 25% has been shown to be effective in the primary prevention of variceal bleeding (Box 23.34). The efficacy of β-blockers in primary prevention is similar to that of prophylactic banding, which may also be considered, particularly in patients that are unable to tolerate β-blocker therapy. Carvedilol, a non-cardioselective vasodilating β-blocker, is also effective.

Management of acute variceal bleeding

The priority in acute bleeding is to restore the circulation with blood and plasma, not least because shock reduces liver blood flow and causes further deterioration of liver function. The source of bleeding should always be confirmed by endoscopy, because about 20% of patients are bleeding from non-variceal lesions. Management of acute variceal bleeding is described in Box 23.35 and illustrated in Figure 23.20. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as oral ciprofloxacin or intravenous cephalosporin, because sepsis is common and treatment with antibiotics has been shown to improve outcomes. The measures used to control acute variceal bleeding include vasoactive medications (e.g. terlipressin), endoscopic therapy (banding or sclerotherapy), balloon tamponade, transjugular intrahepatic portosystemic stent shunting (TIPSS) and, rarely, oesophageal transection.

Pharmacological reduction of portal venous pressure. Terlipressin is a synthetic vasopressin analogue that, in contrast to vasopressin, can be given by intermittent injection rather than continuous infusion. It reduces portal blood flow and/or intrahepatic resistance and hence reduces portal pressure. It reduces mortality in the setting of acute variceal bleeding. The dose is 2 mg IV 4 times daily until bleeding stops, and then 1 mg 4 times daily for up to 72 hours. Caution is needed in patients with severe ischaemic heart disease or peripheral vascular disease because of the drug's vasoconstrictor properties.

Banding ligation and sclerotherapy. This is the most widely used initial treatment and is undertaken if possible at the time of diagnostic endoscopy (see Fig. 23.17C, p. 942). It stops variceal bleeding in 80% of patients and can be repeated if bleeding recurs. Band ligation involves

EBM 23.34 Primary prevention of variceal bleeding

'In patients with cirrhosis, treatment with propranolol reduces variceal bleeding by 47% (NNT_B 10), death from bleeding by 45% (NNT_B 25) and overall mortality by 22% (NNT_B 16).'

- Hayes PC, et al. Lancet 1990; 336:153–156.

For further information: www.bsg.org.uk

23.35 Emergency management of bleeding

Management	Reason
IV fluids (colloid)	Extracellular volume replacement
Vasopressor (terlipressin)	Reduces portal pressure, acute bleeding and risk of early rebleeding
Prophylactic antibiotics (cephalosporin IV)	Reduces incidence of SBP
Emergency endoscopy	Confirms variceal rather than ulcer bleed
Variceal band ligation	To stop bleeding
Proton pump inhibitor	To prevent peptic ulcers
Phosphate enema and/or lactulose	To prevent hepatic encephalopathy

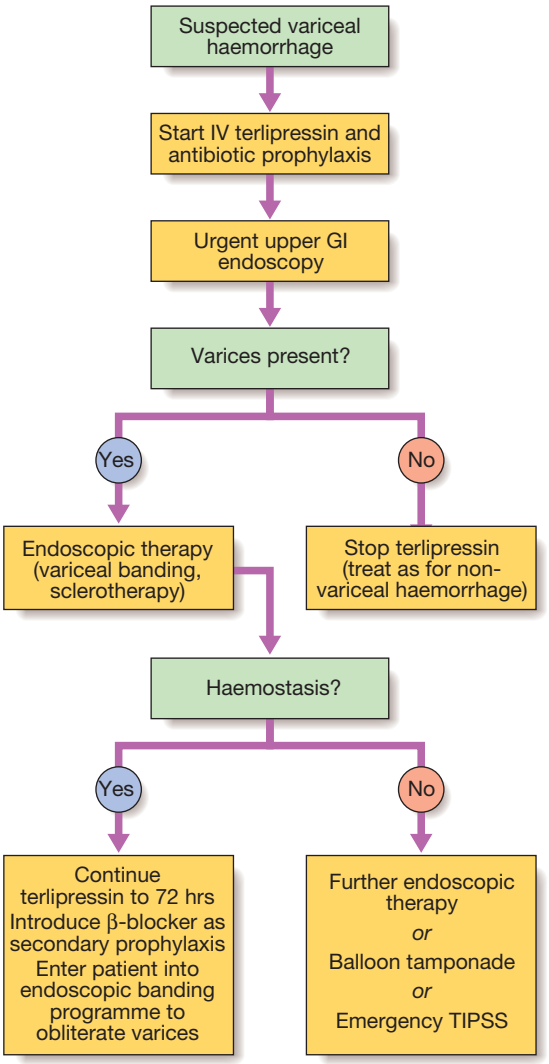

Fig. 23.20 Management of acute bleeding from oesophageal varices. (TIPSS = transjugular intrahepatic portosystemic stent shunt).

the varices being sucked into a cap placed on the end of the endoscope, allowing them to be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 4–6 weeks until the varices are obliterated. Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than, and has largely replaced, sclerotherapy, a technique in which varices are injected with a sclerosing agent. Banding is associated with a lower risk of oesophageal perforation or stricturing than sclerotherapy. Prophylactic acid suppression with proton pump inhibitors reduces the risk of secondary bleeding from banding-induced ulceration.

Active bleeding may make endoscopic therapy difficult. Protection of the patient's airway with endotracheal intubation may aid the endoscopist, facilitating endoscopic therapy, and significantly reduce the risk of pulmonary aspiration.

Balloon tamponade. This technique employs a Sengstaken–Blakemore tube possessing two balloons that exert pressure in the fundus of the stomach and in

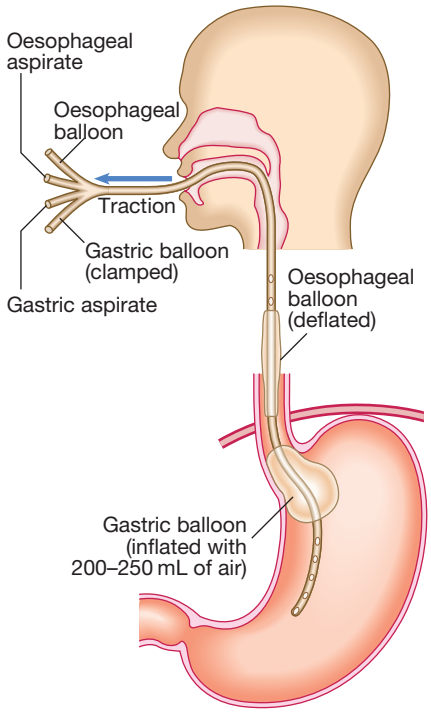

Fig. 23.21 Sengstaken–Blakemore tube.

the lower oesophagus respectively (Fig. 23.21). Additional lumens allow material to be aspirated from the stomach and from the oesophagus above the oesophageal balloon. This technique may be used in the event of life-threatening haemorrhage if early endoscopic therapy is not available or is unsuccessful.

Endotracheal intubation prior to tube insertion reduces the risk of pulmonary aspiration. The tube should be passed through the mouth and its presence in the stomach should be checked by auscultating the upper abdomen while injecting air and by radiology. The safest technique is to inflate the balloon in the stomach under direct endoscopic vision. Gentle traction is essential to maintain pressure on the varices. Initially, only the gastric balloon should be inflated, with 200–250 mL of air, as this will usually control bleeding. Inflation of the gastric balloon must be stopped if the patient experiences pain because inadvertent inflation in the oesophagus can cause oesophageal rupture. If the oesophageal balloon needs to be used because of continued bleeding, it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Pressure in the oesophageal balloon should be monitored with a sphygmomanometer, and should not exceed 40 mm Hg. Balloon tamponade will almost always stop oesophageal and gastric fundal variceal bleeding, but is only a bridge to more definitive therapy. Self-expanding removable oesophageal stents are a new alternative in patients with bleeding oesophageal, but not gastric, varices.

TIPSS. This technique uses a stent placed between the portal vein and the hepatic vein within the liver to provide a portosystemic shunt and therefore reduce portal pressure (Fig. 23.22). It is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically,

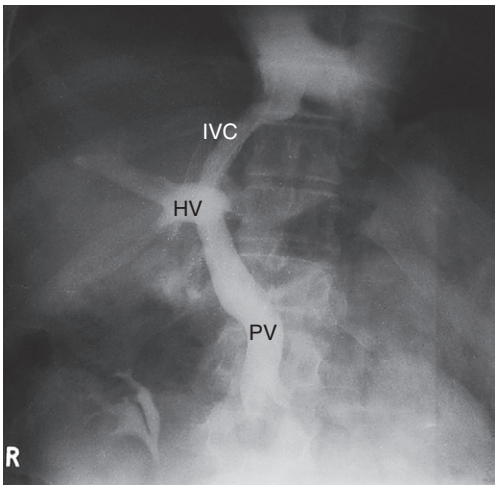

Fig. 23.22 Transjugular intrahepatic portosystemic stent shunt (TIPSS). X-ray showing placement of TIPSS within the portal vein (PV), allowing blood to flow from the portal vein into the hepatic vein (HV) and then the inferior vena cava (IVC).

EBM 23.36 Secondary prevention of variceal bleeding in patients with cirrhosis

'While TIPSS is more effective than endoscopic treatment in reducing variceal rebleeding, it does not improve survival and is associated with more encephalopathy.'

- Jalan R, et al. Gut 2000; 6:1–15.
- Laine L. Hepatology 1995; 22:663–665.

For further information: www.bsg.org.uk

coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents variceal bleeding. Further bleeding necessitates investigation and treatment (e.g. angioplasty) because it is usually associated with shunt narrowing or occlusion. Hepatic encephalopathy may occur following TIPSS and is managed by reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved (Box 23.36).

Portosystemic shunt surgery. Surgery prevents recurrent bleeding, but carries a high mortality and often leads to encephalopathy. In practice, portosystemic shunts are now reserved for patients in whom other treatments have not been successful and are offered only to those with good liver function.

Oesophageal transection. Rarely, surgical transection of the varices may be performed as a last resort when bleeding cannot be controlled by other means, but operative mortality is high.

Secondary prevention of variceal bleeding

Beta-blockers are used as a secondary measure to prevent recurrent variceal bleeding. Following successful treatment by endoscopic therapy, patients should be entered into an oesophageal banding programme with repeated sessions of therapy at 1- to 2-week intervals until the varices are obliterated. In selected individuals, TIPSS may also be considered in this setting.

Congestive gastropathy

Long-standing portal hypertension causes chronic gastric congestion recognisable at endoscopy as multiple areas of punctate erythema ('snake skin gastropathy'). Rarely, similar lesions occur more distally in the gastrointestinal tract. These areas may become eroded, causing bleeding from multiple sites. Acute bleeding can occur but repeated minor bleeding causing iron-deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using propranolol (80–160 mg/day) is the best initial treatment. If this is ineffective, a TIPSS procedure can be undertaken.

INFECTIONS AND THE LIVER

The liver may be subject to a number of different infections. These include hepatotropic viral infections, and bacterial and protozoal infections. Each has specific clinical features and requires targeted therapies.

Viral hepatitis

This must be considered in anyone presenting with hepatitic liver blood tests (high transaminases). The causes are listed in Box 23.37.

All these viruses cause illnesses with similar clinical and pathological features and which are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in Box 23.38.

Clinical features of acute infection

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow, and abdominal discomfort is common. Dark urine and pale stools may precede jaundice. There are usually few physical signs. The liver is often tender but only minimally enlarged. Occasionally, mild splenomegaly and cervical lymphadenopathy are seen. These are more frequent in children or those with Epstein–Barr virus (EBV) infection. Symptoms rarely last longer than 3–6 weeks. Complications may occur (Box 23.39) but are rare.

Investigations

A hepatitic pattern of LFTs develops, with serum transaminases typically between 200 and 2000 U/L in an

23.37 Causes of viral hepatitis

Common	
• Hepatitis A	• Hepatitis C
• Hepatitis B ± hepatitis D	• Hepatitis E
Less common	
• Cytomegalovirus	• Epstein–Barr virus
Rare	
• Herpes simplex	• Yellow fever

23.38 Features of the main hepatitis viruses

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Virus					
Group	Enterovirus	Hepadna virus	Flavivirus	Incomplete virus	Calicivirus
Nucleic acid	RNA	DNA	RNA	RNA	RNA
Size (diameter)	27 nm	42 nm	30–38 nm	35 nm	27 nm
Incubation (wks)	2–4	4–20	2–26	6–9	3–8
Spread					
Faeces	Yes	No	No	No	Yes
Blood	Uncommon	Yes	Yes	Yes	No
Saliva	Yes	Yes	Yes	Unknown	Unknown
Sexual	Uncommon	Yes	Uncommon	Yes	Unknown
Vertical	No	Yes	Uncommon	Yes	No
Chronic infection	No	Yes	Yes	Yes	No (rarely in immune-compromised)
Prevention					
Active	Vaccine	Vaccine	No	Prevented by hepatitis B vaccination	No
Passive	Immune serum globulin	Hyperimmune serum globulin	No		No

Note All body fluids are potentially infectious, although some (e.g. urine) are less infectious than others.

23.39 Complications of acute viral hepatitis

- Acute liver failure
- Cholestatic hepatitis (hepatitis A)
- Aplastic anaemia
- Chronic liver disease and cirrhosis (hepatitis B and C)
- Relapsing hepatitis

acute infection (usually lower and fluctuating in chronic infections). The plasma bilirubin reflects the degree of liver damage. The ALP rarely exceeds twice the upper limit of normal. Prolongation of the PT indicates the severity of the hepatitis but rarely exceeds 25 seconds, except in rare cases of acute liver failure. The white cell count is usually normal with a relative lymphocytosis. Serological tests confirm the aetiology of the infection.

Management

Most individuals do not need hospital care. Drugs such as sedatives and narcotics, which are metabolised in the liver, should be avoided. No specific dietary modifications are needed. Alcohol should be avoided during the acute illness. Elective surgery should be avoided in cases of acute viral hepatitis, as there is a risk of post-operative liver failure.

Liver transplantation is very rarely indicated for acute viral hepatitis complicated by liver failure, but is commonly performed for complications of cirrhosis resulting from chronic hepatitis B and C infection.

Hepatitis A

The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal–oral route. Infected individuals, who may be asymptomatic, excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and then for a further 2 weeks or so. Infection is common in children but often asymptomatic, and so up to 30% of adults will have serological evidence of past infection but give no history of jaundice. Infection is also more common in areas of overcrowding and poor sanitation. In occasional outbreaks, water and shellfish have been the vehicles of transmission. In contrast to hepatitis B, a chronic carrier state does not occur.

Investigations

Only one HAV antigen has been found and infected people make an antibody to this antigen (anti-HAV). Anti-HAV is important in diagnosis, as HAV is only present in the blood transiently during the incubation period. Excretion in the stools occurs for only 7–14 days after the onset of the clinical illness and the virus cannot be grown readily. Anti-HAV of the IgM type, indicating a primary immune response, is already present in the blood at the onset of the clinical illness and is diagnostic of an acute HAV infection. Titres of this antibody fall to low levels within about 3 months of recovery. Anti-HAV of the IgG type is of no diagnostic value, as HAV infection is common and this antibody persists for years after infection, but it can be used as a marker of previous HAV infection. Its presence indicates immunity to HAV.

Management

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated virus vaccine.

Immunisation should be considered for individuals with chronic hepatitis B or C infections. Immediate protection can be provided by immune serum globulin if this is given soon after exposure to the virus. The

protective effect of immune serum globulin is attributed to its anti-HAV content. Immunisation should be considered for those at particular risk, such as close contacts of HAV-infected patients, the elderly, those with other major disease and perhaps pregnant women.

Immune serum globulin can be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families. People travelling to endemic areas are best protected by vaccination.

Acute liver failure is rare in hepatitis A (0.1%) and chronic infection does not occur. However, HAV infection in patients with chronic liver disease may cause serious or life-threatening disease. In adults, a cholestatic phase with elevated ALP levels may complicate infection. There is no role for antiviral drugs in the therapy of HAV infection.

Hepatitis B

The hepatitis B virus consists of a core containing DNA and a DNA polymerase enzyme needed for virus replication. The core of the virus is surrounded by surface protein (Fig. 23.23). The virus, also called a Dane particle, and an excess of its surface protein (known as hepatitis B surface antigen) circulate in the blood. Humans are the only source of infection.

Hepatitis B is one of the most common causes of chronic liver disease and hepatocellular carcinoma worldwide. Approximately one-third of the world's population have serological evidence of past or current infection with hepatitis B and approximately 350–400 million people are chronic HBsAg carriers.

Hepatitis B may cause an acute viral hepatitis; however, acute infection is often asymptomatic, particularly when acquired at birth. Many individuals with chronic hepatitis B are also asymptomatic.

The risk of progression to chronic liver disease depends on the source and timing of infection (Box 23.40). Vertical transmission from mother to child in the perinatal period is the most common cause of infection worldwide and carries the highest risk of ongoing chronic infection. In this setting, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Several mechanisms contribute towards this.

- Firstly, the introduction of antigen in the neonatal period is tolerogenic.
- Secondly, the presentation of such antigen within the liver, as described above, promotes tolerance; this is particularly evident in the absence of a significant innate or inflammatory response.
- Finally, very high loads of antigen may lead to so-called 'exhaustion' of cellular immune responses. However, the state of tolerance is not permanent and may be reversed as a result of therapy, or through spontaneous changes in innate responses such as interferon-alpha and NK cells, accompanied by host-mediated immunopathology.

Chronic hepatitis can lead to cirrhosis or HCC, usually after decades of infection (Fig. 23.24). Chronic HBV infection is a dynamic process that can be divided into five phases (Box 23.41); however, these are not necessarily sequential and not all patients will go through all phases. It should be remembered that the virus is not directly cytotoxic to cells; rather it is an immune response to viral antigens displayed on infected hepatocytes that initiates liver injury. This explains why there may be very high levels of viral replication but little hepatocellular damage during the 'immune tolerant' phase.

23.40 Source of hepatitis B infection and risk of chronic infection

Horizontal transmission (10%)

- Injection drug use
- Infected unscreened blood products
- Tattoos/acupuncture needles
- Sexual (homosexual and heterosexual)
- Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)

Vertical transmission (90%)

- HBsAg-positive mother

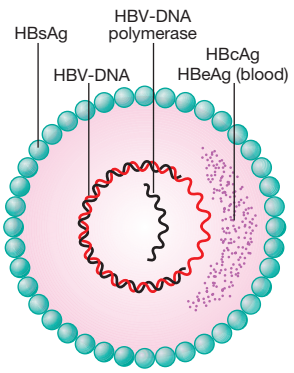

Fig. 23.23 Schematic diagram of hepatitis B virus. Hepatitis B surface antigen (HBsAg) is a protein that makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein that makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg that can be found in the blood and indicates infectivity.

Investigations

Serology

HBV contains several antigens to which infected persons can make immune responses (Fig. 23.25); these antigens and their antibodies are important in identifying HBV infection (Boxes 23.41 and 23.42), although the widespread availability of polymerase chain reaction (PCR) techniques to measure viral DNA levels in peripheral blood means that longitudinal monitoring is now also frequently guided by direct assessment of viral load.

Hepatitis B surface antigen (HBsAg). HBsAg is an indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. In acute liver failure from hepatitis B, the liver damage is mediated by viral clearance and so HBsAg is negative, with evidence of recent infection shown by the presence of hepatitis B core IgM. HBsAg appears in the blood late in the incubation period, but before the prodromal phase of acute type B hepatitis; it may be present for a few days only, disappearing even before jaundice has developed, but usually lasts for 3–4 weeks and can

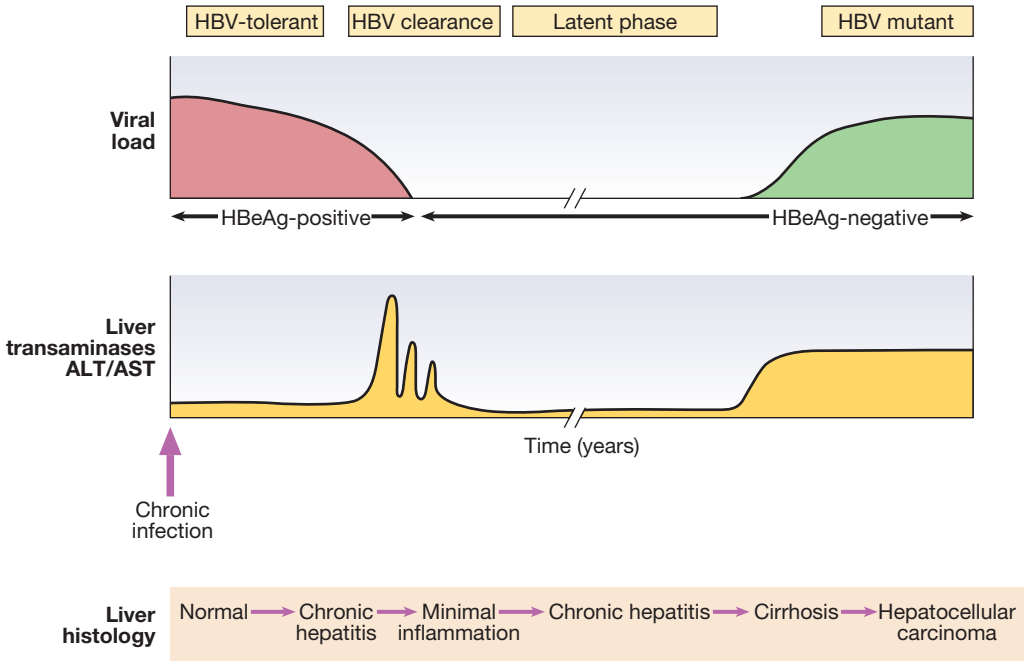

Fig. 23.24 Natural history of chronic hepatitis B infection. There is an initial immunotolerant phase with high levels of virus and normal liver biochemistry. An immunological response to the virus then occurs, with elevation in serum transaminases, which causes liver damage: chronic hepatitis. If this response is sustained over many years and viral clearance does not occur promptly, chronic hepatitis may result in cirrhosis. In individuals with a successful immunological response, viral load falls, HBe antibody develops and there is no further liver damage. Some individuals may subsequently develop HBV-DNA mutants that escape from immune regulation, and viral load again rises with further chronic hepatitis. Mutations in the core protein result in the virus's inability to secrete HBe antigen despite high levels of viral replication; such individuals have HBeAg-negative chronic hepatitis. (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

23.41 The five phases of chronic hepatitis B virus infection

Phase	HBsAg	HBeAg	Anti-HBe Ab	Viral load	ALT	Histology	Notes
'Immune tolerant' phase	+	+	–	+++	Normal/ Low	Normal/minimal necroinflammation	Prolonged in perinatally infected individuals; may be short or absent if infected as an adult. High viral load and so very infectious
'Immune reactive' HBeAg-positive chronic hepatitis phase	+	+	–	++	Raised	Moderate/severe necroinflammation	May last weeks or years. High risk of cirrhosis or HCC if prolonged. Increased chance of spontaneous loss of HBeAg with seroconversion to anti-HBe Ab-positive state
'Inactive carrier' phase	+	–	+	–/+	Normal	Normal/minimal necroinflammation	Low risk of cirrhosis or HCC in majority
HBeAg-negative chronic hepatitis phase	+	–	+	Fluctuating +/++	Raised/ Fluctuating	Moderate/severe necroinflammation	May represent late immune reactivation or presence of 'pre-core mutant' HBV. High risk of cirrhosis or HCC
HBsAg-negative phase	–	–	+	–/±	Normal	Normal	Ultrasensitive techniques may detect low-level HBV even after HBsAg loss

persist for up to 5 months. The persistence of HBsAg for longer than 6 months indicates chronic infection. Antibody to HBsAg (anti-HBs) usually appears after about 3–6 months and persists for many years or perhaps permanently. Anti-HBs implies either a previous infection, in which case anti-HBc (see below) is usually also present, or previous vaccination, in which case anti-HBc is not present.

Hepatitis B core antigen (HBcAg). HBcAg is not found in the blood, but antibody to it (anti-HBc) appears early

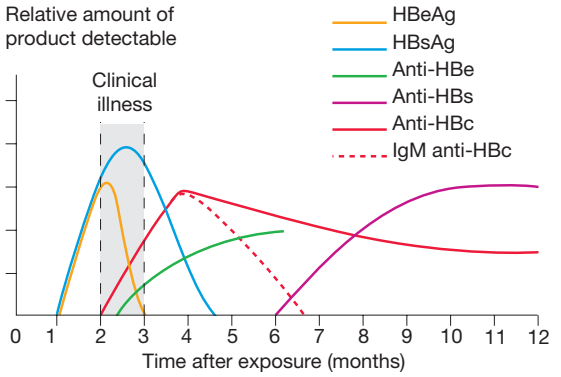

Fig. 23.25 Serological responses to hepatitis B virus infection. (HBeAg = hepatitis B e antigen; anti-HBe = antibody to HBeAg; HBsAg = hepatitis B surface antigen; anti-HBs = antibody to HBsAg; anti-HBc = antibody to hepatitis B core antigen)

23.42 How to interpret the serological tests of acute hepatitis B virus infection

Interpretation	HBsAg	Anti-HBc IgM	Anti-HBc IgG	Anti-HBs
Incubation period	+	+	–	–
Acute hepatitis				
Early	+	+	–	–
Established	+	+	+	–
Established (occasional)	–	+	+	–
Convalescence				
(3–6 months)	–	±	+	±
(6–9 months)	–	–	+	+
Post-infection	–	–	+	±
Immunisation without infection	–	–	–	+

+ Positive; – negative; ± present at low titre or absent.

in the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type, with IgG antibody appearing later. Anti-HBc (IgM) can sometimes reveal an acute HBV infection when the HBsAg has disappeared and before anti-HBs has developed (see Fig. 23.25 and Box 23.42).

Hepatitis B e antigen (HBeAg). HBeAg is an indicator of viral replication. In acute hepatitis B it may appear only transiently at the outset of the illness; its appearance is followed by the production of antibody (anti-HBe). The HBeAg reflects active replication of the virus in the liver.

Chronic HBV infection (see below) is marked by the presence of HBsAg and anti-HBc (IgG) in the blood. Usually, HBeAg or anti-HBe is also present; HBeAg indicates continued active replication of the virus in the liver. The absence of HBeAg usually implies low viral replication; the exception is HBeAg-negative chronic hepatitis B (also called 'pre-core mutant' infection, discussed below), in which high levels of viral replication, serum HBV-DNA and hepatic necroinflammation are seen, despite negative HBeAg.

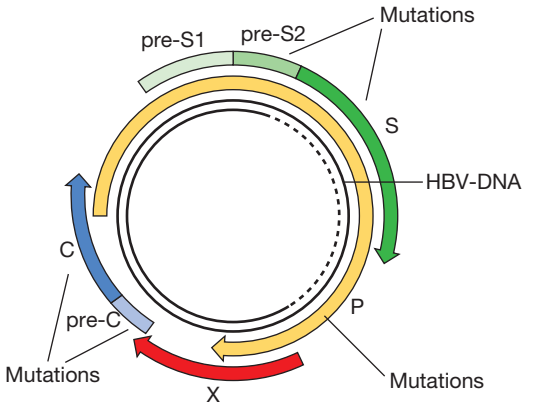

Fig. 23.26 The site of HBV-DNA mutations. HBV-DNA encodes four proteins: a DNA polymerase needed for viral replication (P), a surface protein (S), a core protein (C) and an X protein. The pre-C and C regions encode a core protein and an e antigen. Although mutations in the hepatitis B virus are frequent, certain mutations have important clinical consequences. Pre-C encodes a signal sequence needed for the C protein to be secreted from the liver cell into serum as e antigen. A mutation in the pre-core region leads to a failure of secretion of e antigen into serum, and so individuals have high levels of viral production but no detectable e antigen in the serum. Mutations can also occur in the surface protein and may lead to the failure of vaccination to prevent infection since surface antibodies are produced against the native S protein. Mutations also occur in the DNA polymerase during antiviral treatment with lamivudine.

Viral load and genotype

HBV-DNA can be measured by PCR in the blood. Viral loads are usually in excess of 10^5 copies/mL in the presence of active viral replication, as indicated by the presence of e antigen. In contrast, in those with low viral replication, HBsAg- and anti-HBe-positive, viral loads are less than 10^5 copies/mL. The exception is in patients who have a mutation in the pre-core protein, which means they cannot secrete e antigen into serum (Fig. 23.26). Such individuals will be anti-HBe-positive but have a high viral load and often evidence of chronic hepatitis. These mutations are common in the Far East, and those patients affected are classified as having e antigen-negative chronic hepatitis. They respond differently to antiviral drugs from those with classical e antigen-positive chronic hepatitis.

Measurement of viral load is important in monitoring antiviral therapy and identifying patients with pre-core mutants. Specific HBV genotypes (A–H) can also be identified using PCR. In some settings these may be useful in guiding therapy, as genotype A tends to respond better to pegylated interferon alfa, compared to genotypes C and D.

Management of acute hepatitis B

Treatment is supportive, with monitoring for acute liver failure, which occurs in less than 1% of cases. There is no definitive evidence that antiviral therapy reduces the severity or duration of acute hepatitis B.

Full recovery occurs in 90–95% of adults following acute HBV infection. The remaining 5–10% develop a chronic hepatitis B infection that usually continues for life, although later recovery occasionally occurs. Infection passing from mother to child at birth leads to chronic infection in the child in 90% of cases and recovery is rare. Chronic infection is also common

in immunodeficient individuals, such as those with Down's syndrome or human immunodeficiency virus (HIV) infection. Fulminant liver failure due to acute hepatitis B occurs in less than 1% of cases.

Recovery from acute HBV infection occurs within 6 months and is characterised by the appearance of antibody to viral antigens. Persistence of HBeAg beyond this time indicates chronic infection. Combined HBV and HDV infection causes more aggressive disease.

Management of chronic hepatitis B

Treatments are still limited, as no drug is consistently able to eradicate hepatitis B infection completely (i.e. render the patient HBsAg-negative). The goals of treatment are HBeAg seroconversion, reduction in HBV-DNA and normalisation of the LFTs. The indication for treatment is a high viral load in the presence of active hepatitis, as demonstrated by elevated serum transaminases and/or histological evidence of inflammation and fibrosis. The oral antiviral agents are more effective in reducing viral loads in patients with e antigen-negative chronic hepatitis B than in those with e antigen-positive chronic hepatitis B, as the pre-treatment viral loads are lower.

Most patients with chronic hepatitis B are asymptomatic and develop complications such as cirrhosis and hepatocellular carcinoma only after many years (see Fig. 23.24). Cirrhosis develops in 15–20% of patients with chronic HBV over 5–20 years. This proportion is higher in those who are e antigen-positive.

Two different types of drug are used to treat hepatitis B: direct-acting nucleoside/nucleotide analogues and pegylated interferon-alfa.

Direct-acting nucleoside/nucleotide antiviral agents

Orally administered nucleoside/nucleotide antiviral agents are the mainstay of therapy. These act by inhibiting the reverse transcription of pre-genomic RNA to HBV-DNA by HBV-DNA polymerase but do not directly affect the cccDNA (covalently closed circular DNA) template for viral replication, and so relapse is common if treatment is withdrawn. One major concern is the selection of antiviral-resistant mutations with long-term treatment. This is particularly important with some of the older agents, such as lamivudine, as mutations induced by previous antiviral exposure may also induce resistance to newer agents. Entecavir and tenofovir (see below) are potent antivirals with a high barrier to genetic resistance, and so are the most appropriate first-line agents.

Lamivudine. Although effective, long-term therapy is often complicated by the development of HBV-DNA polymerase mutants (e.g. the 'YMDD variant'), which may occur after 9 months and are characterised by a rise in viral load during treatment. Telbivudine is more potent but is also susceptible to viral resistance. Adefovir is associated with development of HBV-DNA mutants at a lower rate than with lamivudine; 2% are identified after 2 years of treatment but this figure increases to 18% after 3 years.

Entecavir and tenofovir. Monotherapy with entecavir or tenofovir is more effective than either lamivudine or adefovir in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis (Boxes 23.43 and 23.44). Antiviral resistance mutations occur in only 1–2% after 3 years of entecavir drug exposure. Both drugs have anti-HIV action and so their use as monotherapy is contraindicated in HIV-positive patients, as it may lead to HIV antiviral drug resistance. Current European guidelines advise that the other nucleoside/nucleotide antivirals should not be used as first-line monotherapy due to the induction of viral mutations, unless more potent drugs with a high barrier to resistance are not available or appropriate.

EBM 23.43 Entecavir and telbivudine in chronic hepatitis B infection

'In HBeAg-positive patients, 48 weeks of treatment with entecavir suppresses HBV-DNA levels in 67%, compared to 36% with lamivudine and 60% with telbivudine. Anti-HBe seroconversion occurs in 21% following a year of entecavir, lamivudine or telbivudine. In HBeAg-negative chronic hepatitis, HBV-DNA negativity is achieved in 90% with entecavir, compared to 72% with lamivudine and 88% with telbivudine at 1 year. Treatment also improves histology and liver biochemistry.'

- Chang T-T. N Engl J Med 2006; 354:1001–1010.
- Lai C-L. N Engl J Med 2007; 357:2576–2588.
- Lai C-L. N Engl J Med 2006; 354:1011–1020.

For further information: www.easl.eu/_clinical-practice-guideline/

EBM 23.44 Tenofovir for chronic hepatitis B

'Among patients with chronic HBV infection, tenofovir at a daily dose of 300 mg had superior antiviral efficacy with a similar safety profile as compared with adefovir 10 mg daily. In HBeAg-positive patients, tenofovir suppressed HBV-DNA to < 400 copies/mL in 76% of patients, compared with 13% of those given adefovir ($p < 0.001$).'

- Marcellin P, et al. NEJM 2008; 359:2442–2445.

Interferon-alfa

This is most effective in patients with a low viral load and serum transaminases greater than twice the upper limit of normal, in whom it acts by augmenting a native immune response. In HBeAg-positive chronic hepatitis, 33% lose e antigen after 4–6 months of treatment, compared to 12% of controls. Response rates are lower in HBeAg-negative chronic hepatitis, even when patients are given longer courses of treatment. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. Longer-acting pegylated interferons that can be given once weekly have been evaluated in both HBeAg-positive and HBeAg-negative chronic hepatitis (Box 23.45). Side-effects are common and include fatigue, depression, irritability, bone marrow suppression and the triggering of autoimmune thyroid disease.

Liver transplantation

Historically, liver transplantation was contraindicated in hepatitis B because infection often recurred in the graft. However, the use of post-liver transplant prophylaxis with direct-acting antiviral agents and hepatitis B immunoglobulins has reduced the re-infection rate to 10% and increased 5-year survival to 80%, making transplantation an acceptable treatment option.

EBM 23.45 Pegylated interferons in chronic hepatitis B infection

'In HBeAg-positive chronic hepatitis, treatment with pegylated interferon for 6 months eliminates HBeAg in 35% of patients, and normalises liver biochemistry in 25%. In HBeAg-negative chronic hepatitis, treatment with pegylated interferon for 12 months leads to normal liver biochemistry in 60% of patients, and sustained suppression of hepatitis B virus load below 400 copies/mL in 20%.'

23.46 At-risk groups meriting hepatitis B vaccination in low-endemic areas

- Parenteral drug users
- Men who have sex with men
- Close contacts of infected individuals
  - Newborn of infected mothers
  - Regular sexual partners
- Patients on chronic haemodialysis
- Patients with chronic liver disease
- Medical, nursing and laboratory personnel

Prevention

Individuals are most infectious when markers of continuing viral replication, such as HBeAg, and high levels of HBV-DNA are present in the blood. HBV-DNA can be found in saliva, urine, semen and vaginal secretions. The virus is about ten times more infectious than hepatitis C, which in turn is about ten times more infectious than HIV.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active immunisation in 95% of normal individuals. The vaccine should be offered to those at special risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 23.46). The vaccine is ineffective in those already infected by HBV. Infection can also be prevented or minimised by the intramuscular injection of hyperimmune serum globulin prepared from blood containing anti-HBs. This should be given within 24 hours, or at most a week, of exposure to infected blood in circumstances likely to cause infection (e.g. needlestick injury, contamination of cuts or mucous membranes). Vaccine can be given together with hyperimmune globulin (active–passive immunisation).

Neonates born to hepatitis B-infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

Hepatitis D (Delta virus)

The hepatitis D virus (HDV) is an RNA-defective virus that has no independent existence; it requires HBV for replication and has the same sources and modes of spread. It can infect individuals simultaneously with HBV, or can superinfect those who are already chronic carriers of HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals who are chronic carriers of HBV can cause acute hepatitis with spontaneous recovery, and occasionally simultaneous cessation of the chronic HBV infection occurs. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a worldwide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers who also carry HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

Investigations

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV followed by full recovery is associated with the appearance of low titres of anti-HDV of IgM type within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Superinfection of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

Management

Effective management of hepatitis B prevents hepatitis D.

Hepatitis C

This is caused by an RNA flavivirus. Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are only identified when they develop chronic liver disease. Eighty per cent of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare.

Hepatitis C is the cause of what used to be known as 'non-A, non-B hepatitis'.

Hepatitis C infection is usually identified in asymptomatic individuals screened because they have risk factors for infection, such as previous injecting drug use (Box 23.47), or have incidentally been found to have abnormal liver blood tests. Although most individuals remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and is unrelated to the degree of liver damage.

Investigations

Serology and virology

The HCV protein contains several antigens that give rise to antibodies in an infected person and these are used in diagnosis. It may take 6–12 weeks for antibodies to appear in the blood following acute infection such as a needlestick injury. In these cases, hepatitis C RNA can be identified in the blood as early as 2–4 weeks after infection. Active infection is confirmed by the presence of serum hepatitis C RNA in anyone who is antibody-positive. Anti-HCV antibodies persist in serum even after viral clearance, whether spontaneous or post-treatment.

23.47 Risk factors for the acquisition of chronic hepatitis C infection

- Intravenous drug misuse (95% of new cases in the UK)
- Unscreened blood products
- Vertical transmission (3% risk)
- Needlestick injury (3% risk)
- Iatrogenic parenteral transmission (i.e. contaminated vaccination needles)
- Sharing toothbrushes/razors

Molecular analysis

There are six common viral genotypes, the distribution of which varies worldwide. Genotype has no effect on progression of liver disease but does affect response to treatment. Genotype 1 is most common in northern Europe and is less easy to eradicate than genotypes 2 and 3 with traditional pegylated interferon alfa/ribavirin-based treatments.

Liver function tests

LFTs may be normal or show fluctuating serum transaminases between 50 and 200 U/L. Jaundice is rare and only usually appears in end-stage cirrhosis.

Liver histology

Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis and so a liver biopsy is often required to stage the degree of liver damage. The degree of inflammation and fibrosis can be scored histologically. The most common scoring system used in hepatitis C is the Metavir system, which scores fibrosis from 1 to 4, the latter equating to cirrhosis.

Management

The aim of treatment is to eradicate infection. Until recently, the treatment of choice was dual therapy with pegylated interferon-alfa given as a weekly subcutaneous injection, together with oral ribavirin, a synthetic nucleotide analogue (Box 23.48). The main side-effects of ribavirin are haemolytic anaemia and teratogenicity. Side-effects of interferon are significant and include flu-like symptoms, irritability and depression, all of which can affect quality of life. Virological relapse can occur in the first 3 months after stopping treatment, and cure is defined as loss of virus from serum 6 months after completing therapy (sustained virological response, or SVR). The length of treatment and efficacy depend on viral genotype (12 months' treatment for genotype 1 results in a 40% SVR, whereas 6 months' treatment for genotype 2 or 3 leads to an SVR in > 70%). Response to treatment is better in patients who have an early virological response, as defined by negativity of HCV-RNA in serum 1 month after starting therapy, and it may be possible to shorten the duration of therapy in this patient group.

The recent availability of triple therapy with the addition of protease inhibitors such as telaprevir and boceprevir to standard pegylated interferon/ribavirin has provided a significant advance in therapy, with SVR rates for genotype 1 individuals comparable to those previously only achieved in genotypes 2 and 3.

Liver transplantation should be considered when complications of cirrhosis occur, such as diuretic-resistant ascites. Unfortunately, hepatitis C almost always recurs in the transplanted liver and up to 15% of patients will develop cirrhosis in the liver graft within 5 years of transplantation.

EBM 23.48 Treatment of hepatitis C

'The addition of ribavirin to pegylated interferon-alfa therapy improves the overall sustained virological response from 33% to 55%.'

There is no active or passive protection against HCV. Progression from chronic hepatitis to cirrhosis occurs over 20–40 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV), prothrombotic states and heavy alcohol misuse. Not everyone with hepatitis C infection will necessarily develop cirrhosis but approximately 20% do so within 20 years. Once cirrhosis has developed, the 5- and 10-year survival rates are 95% and 81% respectively. One-quarter of people with cirrhosis will develop complications within 10 years and, once complications like ascites have arisen, the 5-year survival is around 50%. Once cirrhosis is present, 2–5% per year will develop primary hepatocellular carcinoma.

Hepatitis E

Hepatitis E is caused by an RNA virus that is endemic in India and the Middle East. An increase in prevalence has recently been noted in northern Europe and infection is no longer seen only in travellers from an endemic area.

The clinical presentation and management of hepatitis E are similar to that of hepatitis A. Disease is spread via the faecal–oral route; in most cases, it presents as a self-limiting acute hepatitis and does not usually cause chronic liver disease, although some cases have been described, usually in immunocompromised patients.

Hepatitis E differs from hepatitis A in that infection during pregnancy is associated with the development of acute liver failure, which has a high mortality. In acute infection, IgM antibodies to HEV are positive.

Other forms of viral hepatitis

Non-A, non-B, non-C (NANBNC) or non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Other viruses that affect the liver probably exist, but the viruses described above now account for the majority of hepatitis virus infections. Cytomegalovirus and EBV infection cause abnormal LFTs in most patients, and occasionally jaundice occurs. Herpes simplex is a rare cause of hepatitis in adults, and most of these patients are immunocompromised. Abnormal LFTs are also common in chickenpox, measles, rubella and acute HIV infection.

HIV infection and the liver

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 23.49. This topic is discussed in more detail on page 400.

23.49 Causes of abnormal liver blood tests in HIV infection

Hepatitic blood tests	
• Chronic hepatitis C • Chronic hepatitis B	• Antiretroviral drugs • Cytomegalovirus
Cholestatic blood tests	
• Tuberculosis • Atypical mycobacterium	• Sclerosing cholangitis due to cryptosporidia

23.50 Causes of pyogenic liver abscesses

- Biliary obstruction (cholangitis)
- Haematogenous
  - Portal vein (mesenteric infections)
  - Hepatic artery (bacteraemia)
- Direct extension
- Trauma
  - Penetrating or non-penetrating
- Infection of liver tumour or cyst

Liver abscess

Liver abscesses are classified as pyogenic, hydatid or amoebic.

Pyogenic liver abscess

Pyogenic liver abscesses are uncommon but important because they are potentially curable, carry significant morbidity and mortality if untreated, and are easily overlooked. The mortality of liver abscesses is 20–40%; failure to make the diagnosis is the most common cause of death. Older patients and those with multiple abscesses also have a higher mortality.

Pathophysiology

Infection can reach the liver in several ways (Box 23.50). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. They can also complicate dental sepsis. Abscesses complicating suppurative appendicitis used to be common in young adults but are now rare. Immunocompromised patients are particularly likely to develop liver abscesses. Single lesions are more common in the right liver; multiple abscesses are usually due to infection secondary to biliary obstruction. *E. coli* and various streptococci, particularly *Strep. milleri*, are the most common organisms; anaerobes, including streptococci and *Bacteroides*, can often be found when infection has been transmitted from large bowel pathology via the portal vein, and multiple organisms are present in one-third of patients.

Clinical features

Patients are generally ill with fever, and sometimes rigors and weight loss. Abdominal pain is the most common symptom and is usually in the right upper quadrant, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Tender hepatomegaly is found in more than 50% of patients. Mild jaundice may be present, becoming severe if large abscesses cause biliary obstruction. Atypical presentations are common and explain the frequency with which the diagnosis is made only at postmortem. This is a particular problem in patients with gradually developing illnesses or pyrexia of unknown origin without localising features. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

Investigations

Liver imaging is the most revealing investigation and shows 90% or more of symptomatic abscesses. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. A leucocytosis is frequently found, plasma ALP activity is usually increased, and the serum albumin is often low. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Blood cultures are positive in 50–80%. Abscesses caused by gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

Management

This includes prolonged antibiotic therapy and drainage of the abscess. Associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Pending the results of culture of blood and pus from the abscess, treatment should be commenced with a combination of antibiotics such as ampicillin, gentamicin and metronidazole. Aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or if it does not respond to antibiotics. Surgical drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or 'pseudotumour'.

Hydatid cysts

Hydatid cysts are caused by *Echinococcus granulosus* infection (p. 380). They have an outer layer derived from the host, an intermediate laminated layer and an inner germinal layer. They can be single (Fig. 23.27) or multiple. Chronic cysts become calcified. The cysts may

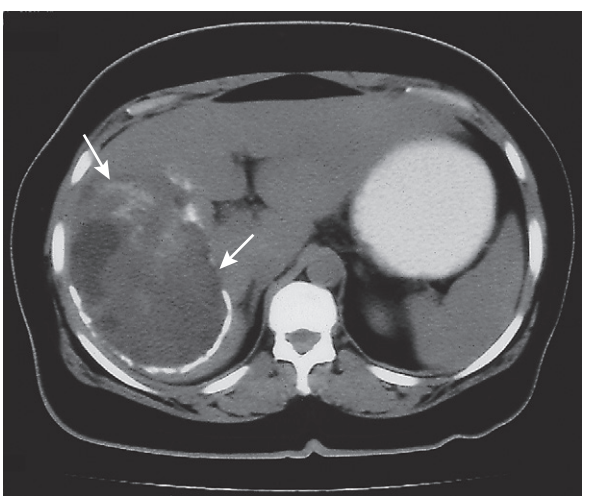

Fig. 23.27 Hydatid cyst of the liver on CT (arrows).

be asymptomatic but may present with abdominal pain or a mass. Peripheral blood eosinophilia is present in 20% of cases, whilst X-rays may show calcification of the rim of the abscess. CT reliably shows the cyst(s), and *Echinococcus* enzyme-linked immunosorbent assay (ELISA) has 90% sensitivity for hepatic hydatid cysts. Rupture or secondary infection of cysts can occur, and a communication with the intrahepatic biliary tree can then result, with associated biliary obstruction.

All patients should be treated medically with albendazole or mebendazole prior to definitive therapy. In the absence of communications with the biliary tree, treatment consists of percutaneous aspiration of the cyst followed by the injection of 100% ethanol into the cysts and then re-aspiration of the cyst contents (PAIR). Where there is communication between the cyst and biliary system, surgical removal of the intact cyst is the preferred treatment.

Amoebic liver abscesses

Amoebic liver abscesses are caused by *Entamoeba histolytica* infection (p. 367). Up to 50% of cases do not have a previous history of intestinal disease. Although amoebic liver abscesses are most often found in endemic areas, patients can present with no history of travel to these places. Abscesses are usually large, single and located in the right lobe; multiple abscesses may occur in advanced disease. Fever and abdominal pain or swelling are the most common symptoms. Diagnosis may depend on cyst aspiration revealing the classic anchovy sauce appearance of the cyst fluid. Analysis of serum for *Entamoeba* antibodies by immunoassay carries 99% sensitivity and over 90% specificity, and is more accurate than stool analysis in amoebic liver disease. Treatment is described on page 368.

ALCOHOLIC LIVER DISEASE

Alcohol is one of the most common causes of chronic liver disease worldwide, with consumption continuing to increase in many countries. Patients with alcoholic liver disease (ALD) may also have risk factors for other liver diseases (e.g. coexisting NAFLD or chronic viral hepatitis infection), and these may interact to increase disease severity.

In the UK, a unit of alcohol contains 8 g of ethanol (Box 23.51). A threshold of 14 units/week in women and 21 units/week in men is generally considered safe. The risk threshold for developing ALD is variable but begins at 30 g/day of ethanol. However, there is no clear linear relationship between dose and liver damage. For many, consumption of more than 80 g/day, for more than 5 years, is required to confer significant risk of advanced liver disease. The average alcohol consumption of a man with cirrhosis is 160 g/day for over 8 years. Some of the risk factors for ALD are:

- *Drinking pattern*. ALD and alcohol dependence are not synonymous; many of those who develop ALD are not alcohol-dependent and most dependent drinkers have normal liver function. Liver damage is more likely to occur in continuous rather than intermittent or 'binge' drinkers, as this pattern gives the liver a chance to recover. It is therefore recommended that people should have at least two alcohol-free days each week. The type of beverage does not affect risk.
- *Gender*. The incidence of alcoholic liver disease is increasing in women, who have higher blood ethanol levels than men after consuming the same amount of alcohol. This may be related to the reduced volume of distribution of alcohol.
- *Genetics*. Alcoholism is more concordant in monozygotic than dizygotic twins. Whilst polymorphisms in the genes involved in alcohol metabolism, such as aldehyde dehydrogenase, may alter drinking behaviour, they have not been linked to ALD. Recently, the patatin-like phospholipase domain-containing 3 (*PNPLA3*) gene, also known as adiponutrin, has been implicated in the pathogenesis of both ALD and NAFLD (p. 959).
- *Nutrition*. Obesity increases the incidence of liver-related mortality by over fivefold in heavy drinkers. Ethanol itself produces 7 kcal/g (29.3 kJ/g) and many alcoholic drinks also contain sugar, which further increases the calorific value and may contribute to weight gain. Excess alcohol consumption is frequently associated with nutritional deficiencies that contribute to morbidity.

23.51 Amount of alcohol in an average drink

Alcohol type	% alcohol by volume	Amount	Units*
Beer	3.5	440 mL (1 pint)	2
	9	440 mL (1 pint)	4
Wine	10	125 mL	1
	12	750 mL	9
'Alcopops'	6	330 mL	2
Sherry	17.5	750 mL	13
Vodka/rum/gin	37.5	25 mL	1
Whisky/brandy	40	700 mL	28

*1 unit = 8 g.

Pathophysiology

Alcohol reaches peak blood concentrations after about 20 minutes, although this may be influenced by stomach contents. It is metabolised almost exclusively by the liver via one of two pathways (Fig. 23.28).

Approximately 80% of alcohol is metabolised to acetaldehyde by the mitochondrial enzyme, alcohol dehydrogenase (ADH). Acetaldehyde is then metabolised to acetyl-CoA and acetate by aldehyde dehydrogenase. This generates NADH from NAD (nicotinamide adenine dinucleotide), which changes the redox potential of the cell. Acetaldehyde forms adducts with cellular proteins in hepatocytes that activate the immune system, contributing to cell injury.

The remaining 20% of alcohol is metabolised by the microsomal ethanol-oxidising system (MEOS) pathway. Cytochrome CYP2E1 is an enzyme that oxidises ethanol to acetate. It is induced by alcohol, and during metabolism of ethanol it releases oxygen free radicals, leading to lipid peroxidation and mitochondrial damage. The CYP2E1 enzyme also metabolises acetaminophen, and

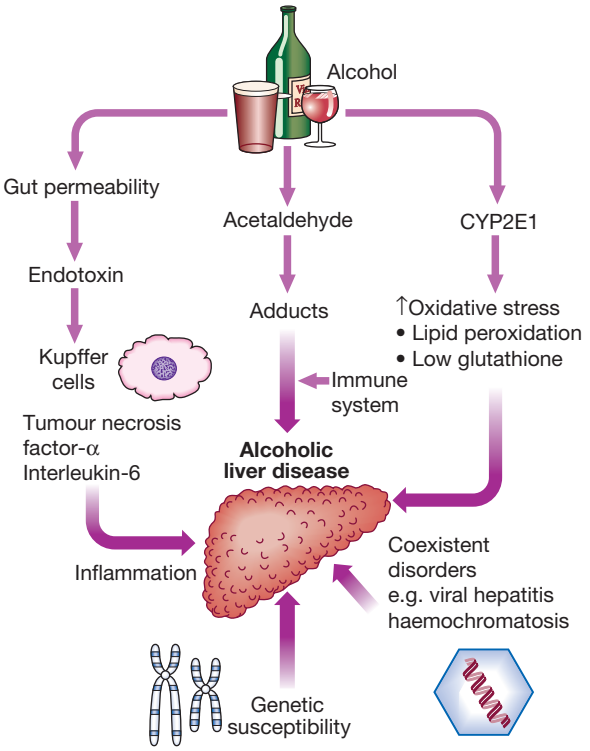

Fig. 23.28 Factors involved in the pathogenesis of alcoholic liver disease.

23.52 Pathological features of alcoholic liver disease

- Alcoholic hepatitis
  - Lipogranuloma
  - Neutrophil infiltration
  - Mallory's hyaline
  - Pericellular fibrosis
- Macrovesicular steatosis
- Fibrosis and cirrhosis
- Central hyaline sclerosis

hence chronic alcoholics are more susceptible to hepatotoxicity from low doses of paracetamol.

It is thought that pro-inflammatory cytokines may also be involved in inducing hepatic damage in alcoholic hepatitis, since endotoxin is released into the blood because of increased gut permeability, leading to release of tumour necrosis factor alpha (TNF-α), interleukin (IL)-1, IL-2 and IL-8 from immune cells. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 23.4, p. 925).

The pathological features of alcoholic liver disease are shown in Box 23.52. In about 80% of patients with severe alcoholic hepatitis, cirrhosis will coexist at presentation. Iron deposition is common and does not necessarily indicate haemochromatosis. Figure 23.30 (p. 960) shows the histological features of alcoholic liver disease, which are identical to those of non-alcoholic steatohepatitis.

Clinical features

ALD has a wide clinical spectrum ranging from mild abnormalities of LFTs on biochemical testing to advanced cirrhosis. The liver is often enlarged in ALD, even in the presence of cirrhosis. Stigmata of chronic liver disease, such as palmar erythema, are more common in alcoholic cirrhosis than in cirrhosis of other aetiologies. Alcohol misuse may also cause damage of other organs and this should be specifically looked for (see Box 10.35, p. 253). Three types of ALD are recognised (Box 23.53) but these overlap considerably, as do the pathological changes seen in the liver.

23.53 Clinical syndromes of alcoholic liver disease

Fatty liver	
• Asymptomatic abnormal liver biochemistry	• Normal/large liver
Alcoholic hepatitis	
• Jaundice • Malnutrition • Hepatomegaly	• Features of portal hypertension (e.g. ascites, encephalopathy)
Cirrhosis	
• Stigmata of chronic liver disease • Ascites/varices/ encephalopathy	• Large, normal or small liver • Hepatocellular carcinoma

Alcoholic fatty liver disease

Alcoholic fatty liver disease (AFLD) usually presents with elevated transaminases in the absence of hepatomegaly. It has a good prognosis and steatosis usually disappears after 3 months of abstinence.

Alcoholic hepatitis

This presents with jaundice and hepatomegaly; complications of portal hypertension may also be present. It has a significantly worse prognosis than AFLD. About one-third of patients die in the acute episode, particularly those with hepatic encephalopathy or a prolonged PT. Cirrhosis often coexists; if not present, it is the likely outcome if drinking continues. Patients with acute alcoholic hepatitis often deteriorate during the first 1–3 weeks in hospital. Even if they abstain, it may take up to 6 months for jaundice to resolve. In patients presenting with jaundice who subsequently abstain, the 3- and 5-year survival is 70%. In contrast, those who continue to drink have 3- and 5-year survival rates of 60% and 34% respectively.

Alcoholic cirrhosis

Alcoholic cirrhosis often presents with a serious complication, such as variceal haemorrhage or ascites, and only half of such patients will survive 5 years from presentation. However, most who survive the initial illness and who become abstinent will survive beyond 5 years.

Investigations

Investigations aim to establish alcohol misuse, to exclude alternative or additional coexistent causes of liver disease and to assess the severity of liver damage. The clinical history from patient, relatives and friends is important to establish alcohol misuse duration and severity. Biological markers, particularly macrocytosis in the absence of anaemia, may suggest and support a history of alcohol misuse. A raised GGT is not specific for alcohol misuse and may also be elevated in the

23.54 How to assess prognosis using the Glasgow alcoholic hepatitis score

Score	1	2	3
Age	< 50	> 50	
WCC ($\times 10^9$/L)	< 15	> 15	
Urea (mmol/L)	< 5	> 5	
PT ratio	< 1.5	1.5–2.0	> 2.0
Bilirubin (μmol/L)	< 125	125–250	> 250
A score ≥ 9 is associated with a 40% 28-day survival, compared to 80% for patients with a score < 9.			

(PT = prothrombin time; WCC = white cell count)

presence of other conditions, including NAFLD. The level may not therefore return to normal with abstinence if chronic liver disease is present, and GGT should not be relied on as an indicator of ongoing alcohol consumption. The presence of jaundice may suggest alcoholic hepatitis. Determining the extent of liver damage often requires a liver biopsy.

In alcoholic hepatitis, PT and bilirubin are used to calculate a 'discriminant function' (DF), also known as the Maddrey score, which enables the clinician to assess prognosis (PT = prothrombin time; serum bilirubin in μmol/L is divided by 17 to convert to mg/dL):

DF = [4.6 × Increase in PT (sec)] + Bilirubin (mg/dL)

A value over 32 implies severe liver disease with a poor prognosis and is used to guide treatment decisions (see below). A second scoring system, the Glasgow score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis with a cutoff of 9 (Box 23.54).

Management

Cessation of alcohol consumption is the single most important treatment and prognostic factor. Life-long abstinence is the best advice. General health and life expectancy are improved when this occurs, irrespective of the stage of liver disease. Abstinence is even effective at preventing progression, hepatic decompensation and death once cirrhosis is present. Treatment of alcohol dependency is discussed on page 253. In the acute presentation of ALD it is important to identify and anticipate alcohol withdrawal and Wernicke's encephalopathy, which need treating in parallel with the liver disease and any complications of cirrhosis.

Nutrition

Good nutrition is very important, and enteral feeding via a fine-bore nasogastric tube may be needed in severely ill patients.

Corticosteroids

These are of value in patients with severe alcoholic hepatitis (Maddrey's discriminative score > 32) and increase survival (Box 23.55). A similar improvement in 28-day survival from 52% to 78% is seen when steroids are given to those with a Glasgow score of more than 9. Sepsis is the main side-effect of steroids, and existing sepsis and variceal haemorrhage are the main contraindications to their use. If the bilirubin has not fallen 7 days after starting steroids, the drugs are unlikely to reduce mortality and should be stopped.

EBM 23.55 Corticosteroids in alcoholic hepatitis

'In severe alcoholic hepatitis, corticosteroids improve survival at 28 days from 65% to 85% (NNT_B 5).'

- Mathurin R, et al. J Hepatol 2002; 36:480–487.

For further information: EASL Guidelines: http://www.easl.eu/_clinical-practice-guideline/issue-9-june-2012-clinical-practice-guidelines-on-the-management-of-alcoholic-liver-disease

EBM 23.56 Pentoxifylline in alcoholic hepatitis

'In severe alcoholic hepatitis, oral pentoxifylline reduces inpatient mortality, particularly from hepatorenal failure, from 46% to 25% (NNT_B 5).'

- Akriviadis E, et al. Gastroenterology 2000; 119:1637–1648.

For further information: www.easl.eu/_clinical-practice-guideline/

Pentoxifylline

Pentoxifylline, which has a weak anti-TNF action, may be beneficial in severe alcoholic hepatitis. It reduces the incidence of hepatorenal failure and its use is not complicated by sepsis (Box 23.56). It is not known whether corticosteroids, pentoxifylline or a combination is superior in the treatment of alcoholic hepatitis.

Liver transplantation

The role of liver transplantation in the management of ALD remains controversial. In many centres, ALD is a common indication for liver transplantation. The challenge is to identify patients with an unacceptable risk of returning to harmful alcohol consumption. Many programmes require a 6-month period of abstinence from alcohol before a patient is considered for transplantation. Although this relates poorly to the incidence of alcohol relapse after transplantation, liver function may improve to the extent that transplantation is no longer necessary. The outcome of transplantation for ALD is good and, if the patient remains abstinent, there is no risk of disease recurrence. Transplantation for alcoholic hepatitis has a poorer outcome and is seldom performed.

NON-ALCOHOLIC FATTY LIVER DISEASE

Non-alcoholic fatty liver disease (NAFLD) represents a spectrum of liver disease encompassing simple fatty infiltration (steatosis), fat and inflammation (non-alcoholic steatohepatitis, NASH) and cirrhosis, in the absence of excessive alcohol consumption (typically a threshold of < 20 g/day for women and < 30 g/day for men is adopted) (Fig. 23.29). While simple steatosis has not been associated with liver-related morbidity, NASH is linked with progressive liver fibrosis, cirrhosis and liver cancer, as well as increased cardiovascular risk. The true extent of associated morbidity is not well defined;

however, in one study NASH was associated with a greater than tenfold increased risk of liver-related death (2.8% vs 0.2%) and a doubling of cardiovascular risk over a mean follow-up of 13.7 years.

NAFLD is strongly associated with obesity, dyslipidaemia, insulin resistance and type 2 (non-insulin dependent) diabetes mellitus, and so may be considered to be the hepatic manifestation of the 'metabolic syndrome' (p. 805). Increasingly sedentary lifestyles and changing dietary patterns mean that the prevalence of obesity and insulin resistance has increased, making NAFLD the leading cause of liver dysfunction in the non-alcoholic, viral hepatitis-negative population in Europe and North America. Estimates vary between populations; however, one large European study found NAFLD to be present in 94% of obese patients (body mass index (BMI) > 30 kg/m^2), 67% of overweight patients (BMI > 25 kg/m^2) and 25% of normal-weight patients. The overall prevalence of NAFLD in patients with type 2 diabetes ranges from 40% to 70%. Histological NASH was found in 3–16% of apparently healthy potential living liver-donors in Europe and 6–15% in USA.

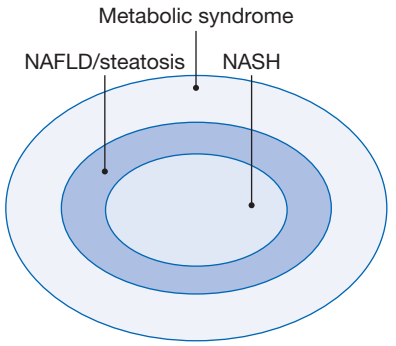

Fig. 23.29 The spectrum of non-alcoholic fatty liver disease.

Pathophysiology

Whilst the majority of patients with the metabolic syndrome develop steatosis, only a minority exhibit NASH or fibrosis. The initiating events in NAFLD are based on the development of obesity and insulin resistance, leading to increased hepatic free fatty acid flux. This imbalance between the rate of import/synthesis and the rate of export/catabolism of fatty acids in the liver leads to the development of steatosis. This may be an adaptive response through which hepatocytes store potentially toxic lipids as relatively inert triglyceride. A 'two-hit' hypothesis has been proposed to describe the pathogenesis of NAFLD, the 'first hit' causing steatosis that then progresses to steatohepatitis if a 'second hit' occurs. In reality, progression probably follows hepatocellular injury caused by a combination of several different 'hits', including:

- oxidative stress due to free radicals produced during fatty acid oxidation
- direct lipotoxicity
- gut-derived endotoxin
- cytokine release (TNF-α etc.)
- endoplasmic reticulum stress.

Cellular damage triggers a mixture of immune-mediated hepatocellular injury and cell death, which leads to stellate cell activation and hepatic fibrosis (Fig. 23.30).

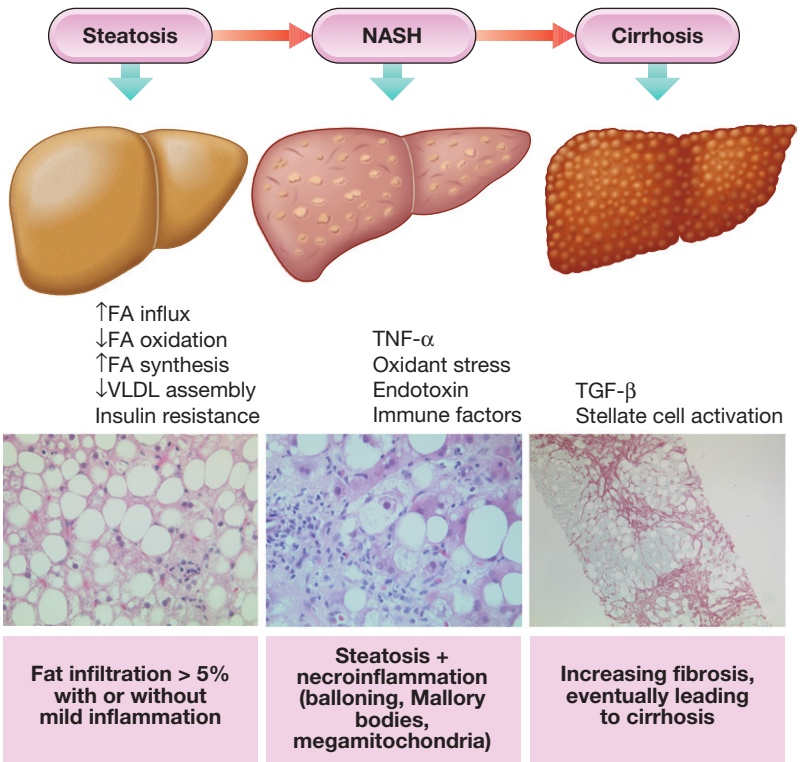

Fig. 23.30 Features of non-alcoholic fatty liver disease and non-alcoholic steatohepatitis. Rate of progression is determined by environmental (dietary) and genetic factors. (FA = fatty acids; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha; VLDL = very low-density lipoproteins)

As with many other liver diseases, subtle inter-patient genetic variations and environmental factors interact to determine disease progression. *PNPLA3* and its product, adiponutrin, may influence disease severity.

Clinical features

NAFLD is frequently asymptomatic, although it may be associated with fatigue and mild right upper quadrant discomfort. It is commonly identified as an incidental biochemical abnormality during routine blood tests. Alternatively, patients with progressive NASH may present late in the natural history of the disease with complications of cirrhosis and portal hypertension, such as variceal haemorrhage, or HCC.

The average age of NASH patients is 40–50 years (50–60 years for NASH–cirrhosis); however, the emerging epidemic of childhood obesity means that NASH is present in increasing numbers of younger patients. Most patients with NAFLD have insulin resistance and exhibit features of the metabolic syndrome (p. 805). Recognised independent risk factors for disease progression are age over 45 years, presence of diabetes (or severity of insulin resistance), obesity (BMI > 30 kg/m^2) and hypertension. These factors help with identification of 'high-risk' patient groups. NAFLD is also associated with polycystic ovary syndrome, obstructive sleep apnoea and small-bowel bacterial overgrowth.

Investigations

Investigation of patients with suspected NAFLD should be directed first towards exclusion of excess alcohol consumption and other liver diseases (including viral, autoimmune and other metabolic causes), and then at confirming the presence of NAFLD, discriminating simple steatosis from NASH and determining the extent of any hepatic fibrosis that is present.

Biochemical tests

There is no single diagnostic blood test for NAFLD. Elevations of serum ALT and AST are modest, and usually less than twice the upper limit of normal. ALT levels fall as hepatic fibrosis increases and the characteristic AST : ALT ratio of less than 1 seen in NASH reverses (AST : ALT > 1) as disease progresses towards cirrhosis, meaning that steatohepatitis with advanced disease may be present even in those with normal-range ALT levels. Other laboratory abnormalities that may be present include non-specific elevations of GGT, low-titre ANA in 20–30% of patients and elevated ferritin levels.

Imaging

Ultrasound is most often used and provides a qualitative assessment of hepatic fat content, as the liver appears 'bright' due to increased echogenicity; however, sensitivity is limited when fewer than 33% of hepatocytes are steatotic. Alternatives include CT, MRI or MR spectroscopy, which offer greater sensitivity for detecting lesser degrees of steatosis, but these are resource-intensive and not widely used in routine practice. Currently, no routine imaging modality can distinguish simple steatosis from steatohepatitis or accurately quantify hepatic fibrosis short of cirrhosis.

Liver biopsy

Liver biopsy remains the 'gold standard' investigation for diagnosis and assessment of degree of inflammation and extent of liver fibrosis. The histological definition of NASH is based on a combination of three lesions (steatosis, hepatocellular injury and inflammation; see Fig. 23.30) with a mainly centrilobular, acinar zone 3, distribution. Specific features include hepatocyte ballooning degeneration with or without acidophil bodies or spotty necrosis and a mild, mixed inflammatory infiltrate. These may be accompanied by Mallory–Denk bodies. Perisinusoidal fibrosis is a characteristic feature of NASH. Histological scoring systems are widely used to assess disease severity semi-quantitatively.

It is important to note that hepatic fat content tends to diminish as cirrhosis develops and so NASH is likely to be under-diagnosed in the setting of advanced liver disease, where it is thought to be the underlying cause of 30–75% of cases in which no specific aetiology is readily identified (so-called 'cryptogenic cirrhosis').

Management

As a marker of the metabolic syndrome, identification of NAFLD should prompt screening for and treatment of cardiovascular risk factors in all patients. However, in recognition of the greater morbidity associated with NASH as opposed to simple steatosis, liver-targeted treatment should be focused particularly on those patients with NASH.

Non-pharmacological treatment

Current treatment comprises lifestyle interventions to promote weight loss and improve insulin sensitivity through dietary changes and physical exercise. Sustained weight reduction of 7–10% is associated with significant improvement in histological and biochemical NASH severity.

Pharmacological treatment

No pharmacological agents are currently licensed specifically for NASH therapy. Treatment directed at coexisting metabolic disorders, such as dyslipidaemia and hypertension, should be given. Although use of HMG-CoA reductase inhibitors (statins) does not ameliorate NAFLD, there does not appear to be any increased risk of hepatotoxicity or other side-effects from these agents, and so they may be used to treat dyslipidaemia. Specific insulin-sensitising agents, in particular glitazones, may help selected patients, while positive results with high-dose vitamin E (800 U/day) have been tempered by evidence that high doses may be associated with an increased risk of prostate cancer and all-cause mortality, which has limited its use.

AUTOIMMUNE LIVER AND BILIARY DISEASE

The liver is an important target for autoimmune injury. The clinical picture is dictated by the nature of the autoimmune process and, in particular, the target cell for immune injury. The disease patterns are quite distinctive for primary hepatocellular injury (in the context of autoimmune hepatitis) and biliary epithelial cell injury (primary biliary cirrhosis and primary sclerosing cholangitis).

Autoimmune hepatitis

Autoimmune hepatitis is a disease of immune-mediated liver injury characterised by the presence of serum antibodies and peripheral blood T lymphocytes reactive with self-proteins, a strong association with other autoimmune diseases (Box 23.57), and high levels of serum immunoglobulins – in particular, elevation of IgG. Although most commonly seen in women, particularly in the second and third decades of life, it can develop in either sex at any age. The reasons for the breakdown in immune tolerance in autoimmune hepatitis remain unclear, although cross-reactivity with viruses such as HAV and EBV in immunogenetically susceptible individuals (typically those with human leucocyte antigen (HLA)-DR3 and DR4, particularly HLA-DRB3*0101 and HLA-DRB1*0401) has been suggested as a mechanism.

Pathophysiology

Several subtypes of this disorder have been proposed that have differing immunological markers. Although the different patterns can be associated with variation in disease aspects such as response to immunosuppressive therapy, histological patterns are similar in the different settings and the basic approach to treatment (complete control of liver injury using immunosuppressive drugs and maintained with appropriate therapy) is the same. The formal classification into disease types has fallen out of favour in recent years.

The most frequently seen autoantibody pattern is high titre of antinuclear and anti-smooth muscle antibodies, typically associated with IgG hyperglobulinaemia (type I autoimmune hepatitis in the old classification), frequently seen in young adult females. Disease characterised by the presence of anti-LKM (liver–kidney microsomal) antibodies, recognising cytochrome P450-IID6 expressed on the hepatocyte membrane, is typically seen in paediatric populations and can be more resistant to treatment than ANA-positive disease. Adult onset of anti-LKM can be seen in chronic HCV infection. This was classified as type II disease in the old system. More recently, a pattern of antibody reactivity with anti-soluble liver antigen has been described in typically adult patients, often with aggressive disease and usually lacking autoantibodies of other specificities.

23.57 Conditions associated with autoimmune hepatitis

- Migrating polyarthritis
- Urticarial rashes
- Lymphadenopathy
- Hashimoto's thyroiditis
- Thyrotoxicosis
- Myxoedema
- Pleurisy
- Coombs-positive haemolytic anaemia
- Transient pulmonary infiltrates
- Ulcerative colitis
- Glomerulonephritis
- Nephrotic syndrome

Clinical features

The onset is usually insidious, with fatigue, anorexia and jaundice. In about one-quarter of patients, the onset is acute, resembling viral hepatitis, but resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Other features include fever, arthralgia, vitiligo and epistaxis. Amenorrhoea can occur. Jaundice is mild to moderate or occasionally absent, but signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, can be present. Associated autoimmune disease, such as Hashimoto's thyroiditis or rheumatoid arthritis, is often present and can modulate the clinical presentation.

Investigations

Serological tests for autoantibodies are often positive (Box 23.58), but low titres of these antibodies occur in some healthy people and in patients with other inflammatory liver diseases. ANA also occur in connective tissue diseases and other autoimmune diseases (with an identical pattern of homogenous nuclear staining) while anti-smooth muscle antibody has been reported in infectious mononucleosis and a variety of malignant diseases. Anti-microsomal antibodies (anti-LKM) occur particularly in children and adolescents. Elevated serum IgG levels are an important diagnostic and treatment response feature if present, but the diagnosis is still possible in the presence of normal IgG levels. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed. It typically shows interface hepatitis, with or without cirrhosis.

Management

Treatment with corticosteroids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone 40 mg/day is given orally; the dose is then gradually reduced as the patient and LFTs improve. Maintenance therapy should only be instituted once LFTs are normal (as well as IgG if elevated). Approaches to maintenance include reduced-dose prednisolone (ideally below 5–10 mg/day), usually in the context of azathioprine 1.0–1.5 mg/kg/day (Box 23.59). Azathioprine can also be used as the sole maintenance immunosuppressive

23.58 Frequency of autoantibodies in chronic non-viral liver diseases and in healthy people

Disease	Antinuclear antibody (%)	Anti-smooth muscle antibody (%)	Antimitochondrial antibody*
Healthy controls	5	1.5	0.01
Autoimmune hepatitis	80	70	15
Primary biliary cirrhosis	25	35	95
Cryptogenic cirrhosis	40	30	15

*Patients with antimitochondrial antibody frequently have cholestatic LFTs and may have primary biliary cirrhosis (see text).

EBM 23.59 Immunosuppression in autoimmune hepatitis

'In autoimmune hepatitis, treatment with prednisolone ± azathioprine improves serum biochemistry and hepatic histology. It also improves survival at 10 years from 27% to 63% (NNT_B 2.7).'

'In patients who have been in remission for more than 1 year, increasing the dose of azathioprine (from 1 to 2 mg/kg) and withdrawing prednisolone reduces steroid side-effects and does not increase the risk of relapse.'

- Kirk AP, et al. Gut 1980; 21:78–83.
- Johnson PJ, et al. N Engl J Med 1995; 333:958–963.

agent in patients with low-activity disease. Newer agents such as mycophenolate mofetil (MMF) are increasingly being used but formal evidence to inform practice in this area is lacking. Patients should be monitored for acute exacerbations (LFT and IgG screening with patients alerted to the possible symptoms) and such exacerbations should be treated with corticosteroids. Although treatment can significantly reduce the rate of progression to cirrhosis, end-stage disease can be seen in patients despite treatment.

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a chronic, progressive cholestatic liver disease that predominantly affects middle-aged women. It is strongly associated with the presence of antimitochondrial antibodies (AMA), which are diagnostic, and is characterised by a granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This in turn leads to fibrosis and cirrhosis of the liver. The condition typically presents with an insidious onset of itching and/or tiredness; it may also be found incidentally as the result of routine blood tests.

Epidemiology

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America but is rare in Africa and Asia. There is a strong female-to-male predominance of 9:1; it is also more common amongst cigarette smokers. Clustering of cases has been reported, suggesting an environmental trigger in susceptible individuals.

Pathophysiology

Immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a genetic association with HLA-DR8, together with polymorphisms in a number of other genes regulating the nature of the immune response (e.g. IL-12 and its receptor). AMA are directed at pyruvate dehydrogenase complex, a mitochondrial enzyme complex that plays a key role in cellular energy generation. PBC-specific ANA (such as those directed at the nuclear pore antigen gp210) have a characteristic staining pattern in immunofluorescence assays (selectively binding to the nuclear rim or nuclear dots), which means that they should not be mistaken for the homogenously staining ANA seen in autoimmune hepatitis. Elevations in serum immunoglobulin levels are frequent but, unlike in autoimmune hepatitis, elevation is typically of IgM.

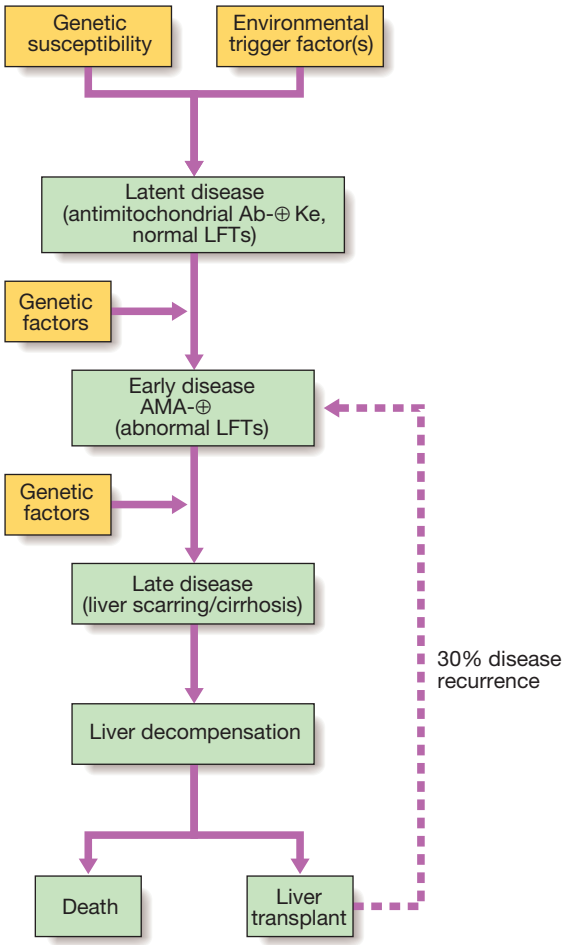

Fig. 23.31 Natural history of primary biliary cirrhosis.

Pathologically, chronic granulomatous inflammation destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis. A model of the natural history of the disease process is shown in Figure 23.31.

Clinical features

Systemic symptoms such as fatigue are common and may precede diagnosis for years. Pruritus, which can be a feature of any cholestatic disease, is a common presenting complaint and may precede jaundice by months or years. Jaundice is rarely a presenting feature. The itching is usually worse on the limbs. Although there may be right upper abdominal discomfort, fever and rigors do not occur. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis (hepatic osteodystrophy).

Initially, patients are well nourished but weight loss can occur as the disease progresses. Scratch marks may be found in patients with severe pruritus.

Jaundice is only prominent late in the disease and can become intense. Xanthomatous deposits occur in a minority, especially around the eyes. Mild hepatomegaly is common and splenomegaly becomes increasingly common as portal hypertension develops. Liver failure may supervene.

Associated diseases

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly the sicca syndrome (p. 1114), systemic sclerosis, coeliac disease (p. 879) and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

Diagnosis and investigations

The LFTs show a pattern of cholestasis (see Box 23.2, p. 929). Hypercholesterolaemia is common and worsens as disease progresses; however, it is of no diagnostic value. AMA is present in over 95% of patients, and when it is absent the diagnosis should not be made without obtaining histological evidence and considering cholangiography (MRCP or ERCP) to exclude other biliary disease. ANA and anti-smooth muscle antibodies are present in around 15% of patients (see Box 23.58); autoantibodies found in associated diseases may also be present. Ultrasound examination shows no sign of biliary obstruction. Liver biopsy is only necessary if there is diagnostic uncertainty. The histological features of PBC correlate poorly with the clinical features; portal hypertension can develop before the histological onset of cirrhosis.

Management

The hydrophilic bile acid, ursodeoxycholic acid (UDCA), at a dose of 13–15 mg/kg/day improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool, and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects (Box 23.60); it is therefore widely used in the treatment of PBC and should be regarded as the optimal first-line treatment. A significant minority of patients either fail to normalise their LFTs with UDCA or show an inadequate response, and such patients have an increased risk of developing end-stage liver disease compared to patients showing a full response. There is currently no consensus as to how to treat such patients. Immunosuppressants, such as corticosteroids, azathioprine, penicillamine and ciclosporin, have all been trialled in PBC. None shows overall benefit when given to unselected patients. Whether they offer benefit to the specific subgroup of UDCA non-responding patients requiring second-line approaches to treatment is not clear.

Liver transplantation should be considered once liver failure has developed and may be indicated in patients with intractable pruritus. Serum bilirubin remains the most reliable marker of declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease will recur in over one-third of patients at 10 years.

Pruritus

This is the main symptom requiring treatment. The cause is unknown but up-regulation of opioid receptors and increased levels of endogenous opioids may play a role. First-line treatment is with the anion-binding resin colestyramine, which probably acts by binding potential pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16 g/day orally is used. The powder is mixed in orange juice and the main dose (8 g) taken before and after breakfast, when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (most obviously UDCA), and adequate spacing should be used between drugs. Colestyramine is sometimes ineffective, especially in complete biliary obstruction, and can be difficult for some patients to tolerate. Alternative treatments include rifampicin (150 mg/day, titrated up to a maximum of 600 mg/day as required and contingent on there being no deterioration in LFTs), naltrexone (an opioid antagonist; 25 mg/day initially, increasing up to 300 mg/day), plasmapheresis and a liver support device (e.g. a molecular adsorbent recirculating system (MARS)).

Fatigue

Fatigue affects about one-third of patients with PBC. The cause is unknown but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression, hypothyroidism and coeliac disease have been excluded, there is currently no specific treatment. The impact on patients' lives can be substantial.

Malabsorption

Prolonged cholestasis is associated with steatorrhoea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

Bone disease

Osteopenia and osteoporosis are common, and normal post-menopausal bone loss is accelerated. Baseline bone density should be measured (p. 1122) and treatment started with replacement calcium and vitamin D_3. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia is rare.

EBM 23.60 Ursodeoxycholic acid (UDCA) in primary biliary cirrhosis

'In primary biliary cirrhosis, UDCA therapy (13–15 mg/kg/day) improves biochemical markers of cholestasis and jaundice. Some randomised trials have shown that UDCA treatment significantly slows disease progression, but whether it affects mortality or transplantation rates remains controversial.'

Overlap syndromes

AMA-negative PBC ('autoimmune cholangitis')

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable AMA in the serum. Serum transaminases, serum Ig levels and titres of ANA tend to be higher than in AMA-positive PBC. However, the clinical course mirrors classical PBC and these patients should be considered to have a variant of PBC.

PBC/autoimmune hepatitis overlap

A few patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulins and interface hepatitis on liver histology; in such individuals a trial of corticosteroid therapy may be beneficial.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a cholestatic liver disease caused by diffuse inflammation and fibrosis; it can involve the entire biliary tree and leads to the gradual obliteration of intrahepatic and extrahepatic bile ducts, and ultimately biliary cirrhosis, portal hypertension and hepatic failure. Although considered as an autoimmune disease, evidence for an autoimmune pathophysiology is weaker than is the case for PBC and autoimmune hepatitis. The incidence is about 6.3/100 000 in Caucasians. Cholangiocarcinoma develops in about 10–30% of patients during the course of the disease.

PSC is twice as common in young men. Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography (Fig. 23.32)
- absence of choledocholithiasis (or history of bile duct surgery)
- exclusion of bile duct cancer, by prolonged follow-up.

The term 'secondary sclerosing cholangitis' is used to describe the typical bile duct changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in Box 23.61.

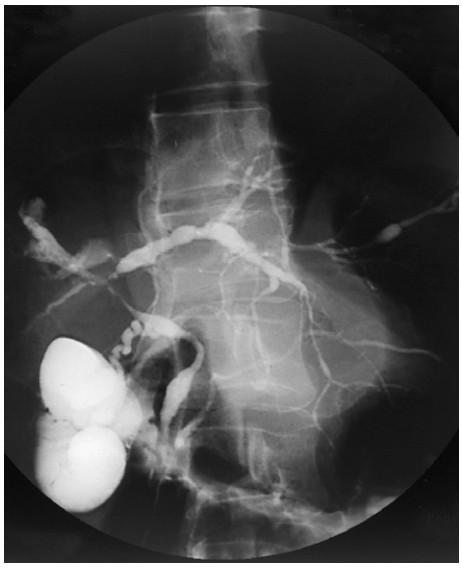

Fig. 23.32 A percutaneous cholangiogram in sclerosing cholangitis, showing characteristic irregularity of the biliary tree.

23.61 Causes of secondary sclerosing cholangitis

- Previous bile duct surgery with stricturing and cholangitis
- Bile duct stones causing cholangitis
- Intrahepatic infusion of 5-fluorodeoxyuridine
- Insertion of formalin into hepatic hydatid cysts
- Insertion of alcohol into hepatic tumours
- Parasitic infections (e.g. *Clonorchis*)
- Autoimmune pancreatitis/IgG4-associated cholangitis
- Acquired immunodeficiency syndrome (AIDS; probably infective as a result of cytomegalovirus or *Cryptosporidium*)

23.62 Diseases associated with primary sclerosing cholangitis

- Ulcerative colitis
- Crohn's colitis
- Chronic pancreatitis
- Retroperitoneal fibrosis
- Riedel's thyroiditis
- Retro-orbital tumours
- Immune deficiency states
- Sjögren's syndrome
- Angio-immunoplastic lymphadenopathy
- Histiocytosis X
- Autoimmune haemolytic anaemia
- Autoimmune pancreatitis/IgG4-associated cholangitis

Pathophysiology

The cause of PSC is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis (Box 23.62). About two-thirds of patients have coexisting ulcerative colitis, and PSC is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop PSC, particularly those with extensive colitis or pancolitis. The prevalence of primary sclerosing cholangitis is lower in patients with Crohn's colitis (about 1%). Patients with PSC and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and those who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

It is currently believed that PSC is an immunologically mediated disease, triggered in genetically susceptible individuals by toxic or infectious agents, which may gain access to the biliary tract through a leaky, diseased colon. A close link with HLA haplotype A1 B8 DR3 DRW52A has been identified. This haplotype is commonly found in association with other organ-specific autoimmune diseases (e.g. autoimmune hepatitis).

The importance of immunological factors has been emphasised by reports showing humoral and cellular abnormalities in PSC. Perinuclear antineutrophil cytoplasmic antibodies (ANCA) have been detected in the sera of 60–80% of patients with PSC with or without ulcerative colitis, and in 30–40% of patients with ulcerative colitis alone. The antibody is not specific for PSC and is found in other chronic liver diseases (e.g. 50% of patients with autoimmune hepatitis).

Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Common symptoms include

fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation. Physical examination is abnormal in about 50% of symptomatic patients; the most common findings are jaundice and hepatomegaly/splenomegaly. The condition may be associated with many other diseases (see Box 23.62).

Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy, and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found only at a late stage. In addition to ANCA, low titres of serum ANA and anti-smooth muscle antibodies may be found in PSC but have no diagnostic significance; serum AMA is absent.

The key investigation is now MRCP, which is usually diagnostic, revealing multiple irregular stricturing and dilatation (see Fig. 23.32). ERCP should be reserved for patients in whom therapeutic intervention is likely to be necessary and should follow MRCP.

On liver biopsy the characteristic early features of PSC are periductal 'onion-skin' fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts (Fig. 23.33). Later, fibrosis spreads, progressing inevitably to biliary cirrhosis; obliterative cholangitis leads to the so-called 'vanishing bile duct syndrome'.

Management

There is no cure for PSC, but management of cholestasis and its complications and specific treatment of the disease process are indicated. UDCA is widely used, although the evidence to support this is limited. UDCA may have benefit in terms of reducing colon carcinoma risk.

The course of PSC is variable. In symptomatic patients, median survival from presentation to death or liver transplantation is about 12 years. About 75% of asymptomatic patients survive 15 years or more. Most patients die from liver failure, about 30% die from bile duct carcinoma, and the remainder die from colonic cancer or complications of colitis. Immunosuppressive agents, including prednisolone, azathioprine, methotrexate and ciclosporin, have been tried; generally, results have been disappointing.

Symptomatic patients often have pruritus. Management is as for PBC. Fatigue appears to be less prominent than in PBC, although it is still present in some patients.

Management of complications

Broad-spectrum antibiotics (e.g. ciprofloxacin) should be given for acute attacks of cholangitis but have no proven value in preventing attacks. If cholangiography shows a well-defined obstruction to the extrahepatic bile ducts ('dominant stricture'), mechanical relief can be obtained by placement of a plastic stent or by balloon dilatation performed at ERCP. It is important, in this situation, actively to consider the possibility of cholangiocarcinoma (the differential diagnosis for dominant extrahepatic stricture). Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that requires treatment (p. 1120).

Surgical treatment

Surgical resection of the extrahepatic bile duct and biliary reconstruction have a limited role in the management of non-cirrhotic patients with dominant extrahepatic disease. Orthotopic transplantation is the only surgical option in patients with advanced liver disease; 5-year survival is 80–90% in most centres. Unfortunately, the condition may recur in the graft and there are no identified therapies able to prevent this. Cholangiocarcinoma is a contraindication to transplantation. Colon carcinoma risk can be increased in patients following transplant because of the effects of immune suppression and enhanced surveillance should be instituted.

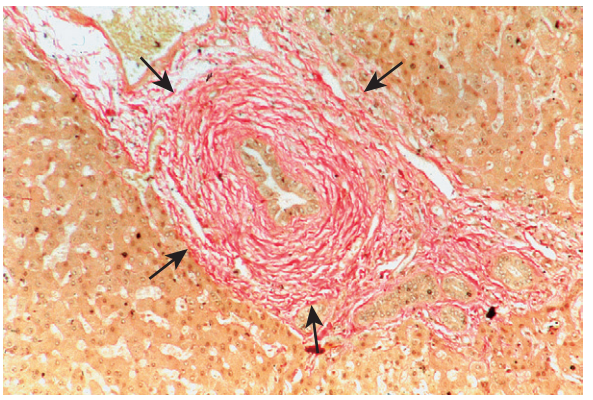

Fig. 23.33 Primary sclerosing cholangitis. Note onion-skin scarring (arrows) surrounding a bile duct.

IgG4-associated cholangitis

This recently reported disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in more than 90% of the patients; p. 894). IgG4-associated cholangitis (IAC) often presents with obstructive jaundice (due to either hilar stricturing/intrahepatic sclerosing cholangitis or a low bile duct stricture), and cholangiographic appearances suggest PSC with or without hilar cholangiocarcinoma. The serum IgG4 is often raised and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. An important observation is that, compared to PSC, IAC appears to respond well to steroid therapy.

LIVER TUMOURS AND OTHER FOCAL LIVER LESIONS

Identification of a hepatic mass lesion is common, both in patients with known pre-existing liver disease and as a primary presentation. Although primary and secondary malignant tumours are important potential

diagnoses, benign disease is frequent. The finding of a liver mass, with its association in the minds of patients with metastatic malignant disease, creates a high level of anxiety, a factor that should always be borne in mind. The critical steps to be taken in diagnosing hepatic mass lesions are:

- determining the presence, nature and severity of any underlying chronic liver disease, as the differential diagnosis is very different in patients with and without chronic liver disease
- use of optimal (usually multiple) imaging modalities.

Primary malignant tumours

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the most common primary liver tumour, and the sixth most common cause of cancer worldwide. Cirrhosis is present in 75–90% of individuals with HCC and is an important risk factor for the disease. The risk is between 1% and 5% in cirrhosis caused by hepatitis B and C. There is also an increased risk in cirrhosis due to haemochromatosis, alcohol, NASH and α_1-antitrypsin deficiency. In northern Europe, 90% of those with HCC have underlying cirrhosis, compared with 30% in Taiwan, where hepatitis B is the main risk factor. The age-adjusted incidence rates vary from 28 per 100 000 in South-east Asia (reflecting the prevalence of hepatitis B) to 10 per 100 000 in southern Europe and 5 per 100 000 in northern Europe. Chronic hepatitis B infection increases the risk of HCC 100-fold and is the major risk factor worldwide. The risk of HCC is 0.4% per year in the absence of cirrhosis and 2–6% in cirrhosis. The risk is four times higher in HBeAg-positive individuals than in those who are HBeAg-negative. Hepatitis B vaccination has led to a fall in HCC in countries with a high prevalence of hepatitis B. The incidence in Europe and North America has risen recently, probably related to the increased prevalence of hepatitis C and NASH cirrhosis. The risk is higher in men and rises with age.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single nodule or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, while lung and bone metastases are rare. Well-differentiated tumours can resemble normal hepatocytes and can be difficult to distinguish from normal liver.

Clinical features

Patients typically present with HCC in one of two ways. Commonly, those with underlying cirrhosis develop a deterioration in their liver function, with worsening ascites and/or jaundice or variceal haemorrhage. Other characteristic symptoms can include weight loss, anorexia and abdominal pain. This often-rapid deterioration can, however, be the event that leads to previously occult cirrhosis becoming clinically apparent, meaning that absence of an established diagnosis of cirrhosis does not preclude a diagnosis of HCC complicating cirrhosis. Examination may reveal hepatomegaly or a right hypochondrial mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur. The advanced nature of the disease that presents in this way makes curative therapy unlikely.

The second presentation is through screening of patients at risk of HCC. The disease is typically detected much earlier in its natural history, significantly increasing the treatment options.

Investigations

Serum markers

Alpha-fetoprotein (AFP) is produced by 60% of HCCs. Levels increase with the size of the tumour and are often normal or only minimally elevated in small tumours detected by ultrasound screening. Serum AFP can also rise in the presence of active hepatitis B and C viral replication; very high levels are seen in acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to be interpreted with caution. Nevertheless, in the absence of a marked hepatic flare of disease, a progressively rising AFP, or AFP over 400 ng/mL (normal is < 10 ng/mL), warrants an aggressive search for HCC. In HCC patients with elevated AFP levels, serial measurements can be a useful biomarker of disease progression/response to treatment.

Imaging

Ultrasound will detect focal liver lesions as small as 2–3 cm. The use of ultrasound contrast agents has increased sensitivity and specificity, but is highly user-dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. Multidetector row CT, following intravenous contrast, identifies HCC by its classical hypervascular appearance (Fig. 23.34). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. MRI can be used instead of CT. Angiography is now seldom performed and has been superseded by the above techniques. Combination of imaging modalities more accurately diagnoses and stages the extent of disease, and using at least two modalities

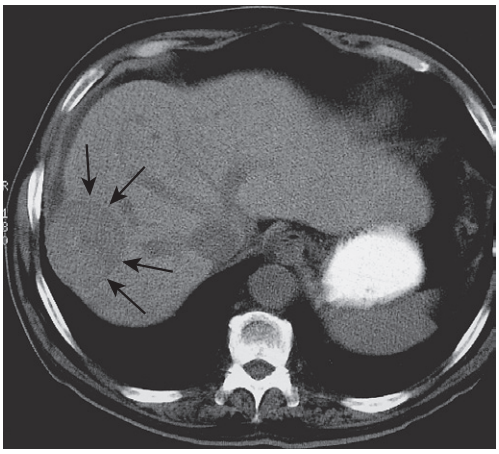

Fig. 23.34 CT showing a large hepatocellular carcinoma (arrows).

(typically, CT or MRI following initial screening ultrasound identification of a mass lesion) is recommended.

Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided in patients who may be eligible for transplantation or surgical resection because there is a small (< 2%) risk of tumour seeding along the needle tract. In all cases of potential HCC where biopsy is being considered, the impact that a confirmed diagnosis will have on therapy must be weighed against the risks of bleeding. If biopsy will not change management, then its appropriateness should be considered carefully.

Role of screening

Screening for HCC, by ultrasound scanning and AFP measurements at 6-month intervals, is indicated in high-risk patients, such as those with cirrhosis due to hepatitis B and C, haemochromatosis, alcohol, NASH and α_1-antitrypsin deficiency. It may also be indicated in individuals with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although no randomised controlled studies of outcome have been undertaken, screening identifies smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation (Box 23.63). The role of screening in other forms of chronic liver disease, such as autoimmune hepatitis and PBC, is unclear. This is compounded by the fact that disease staging by biopsy is no longer standard practice in conditions such as PBC, so formal documentation of the presence of cirrhosis, which might be the trigger for commencement of HCC screening, rarely takes place.

Management

This is different for patients with cirrhosis and those without (see Box 23.63). In the presence of cirrhosis, tumour size, multicentricity, extent of liver disease (Child–Pugh score) and performance status dictate appropriate therapy. An algorithm for managing those with cirrhosis is shown in Figure 23.35.

Prognosis depends on tumour size, the presence of vascular invasion, and liver function in those with cirrhosis. Screening has improved the outlook through early detection.

EBM 23.63 Guidelines for screening and management of hepatocellular carcinoma

'Cirrhotic patients who would be suitable for curative therapy if diagnosed with hepatocellular carcinoma should be offered screening with 6-monthly ultrasound and AFP testing.'

'Curative therapies for hepatocellular carcinoma include liver transplantation, hepatic resection and ablative therapy. Treatment depends on the presence/absence of cirrhosis, underlying liver function, tumour size and tumour multicentricity.'

- European Association for the Study of the Liver Clinical Guidelines. J Hepatol 2012; 56:908–943.

For further information: www.aasld.org/practiceguidelines/

Hepatic resection

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. However, there is a 50% recurrence rate at 5 years; this may be due to a second de novo tumour or recurrence of the original tumour. Few patients with cirrhosis are suitable for hepatic resection because of the high risk of hepatic failure; nevertheless, surgery is offered, particularly in the Far East, to some cirrhotic patients with small tumours and good liver function (Child–Pugh A with no portal hypertension).

Liver transplantation

Transplantation has the benefit of curing underlying cirrhosis and removing the risk of a second, de novo tumour in an at-risk patient. The requirement for immunosuppression creates its own risks of reactivation, however, if residual or metastatic disease is present, and assessment of patients for suitability for liver transplantation focuses on the exclusion of extrahepatic and vascular-invading disease. The 5-year survival following liver transplantation is 75% for patients with single tumours less than 5 cm in size or three tumours smaller than 3 cm (the Milan criteria). Unfortunately, the underlying liver disease, in particular hepatitis C, may recur in the transplanted liver and can result in recurrent cirrhosis giving rise to de novo HCC risk, now complicated by the presence of immunosuppression.

Percutaneous therapy

Percutaneous ethanol injection into the tumour under ultrasound guidance is efficacious (80% cure rate) for tumours of 3 cm or smaller. Recurrence rates (50% at 3 years) are similar to those following surgical resection. Radiofrequency ablation, using a single electrode inserted into the tumour under radiological guidance, is an alternative that takes longer to perform but may cause more complete tumour necrosis. Improvements in percutaneous therapy, with the combination of low patient impact, relative efficacy and capacity for repeat treatment, are making these approaches attractive, particularly in patients in whom major surgery would be inappropriate. Their role in primary therapy as an alternative to curative resection or transplantation remains to be established.

Trans-arterial chemo-embolisation

Hepatocellular cancers are not radiosensitive and the response rate to chemotherapy with drugs such as doxorubicin is only around 30%. In contrast, hepatic artery embolisation with Gelfoam and doxorubicin is more effective, with survival rates of 60% in cirrhotic patients with unresectable HCC and good liver function (compared with 20% in untreated patients) at 2 years. Unfortunately, any survival benefit is lost at 4 years. Trans-arterial chemo-embolisation (TACE) is contraindicated in decompensated cirrhosis and multifocal HCC. TACE is now most frequently used as a holding first intervention whilst the tumour is being assessed and the definitive management plan is being developed.

Chemotherapy

Sorafenib improves survival from 7.9 to 10.7 months in cirrhotic patients. The drug is a multikinase inhibitor with activity against Raf, vascular endothelial growth

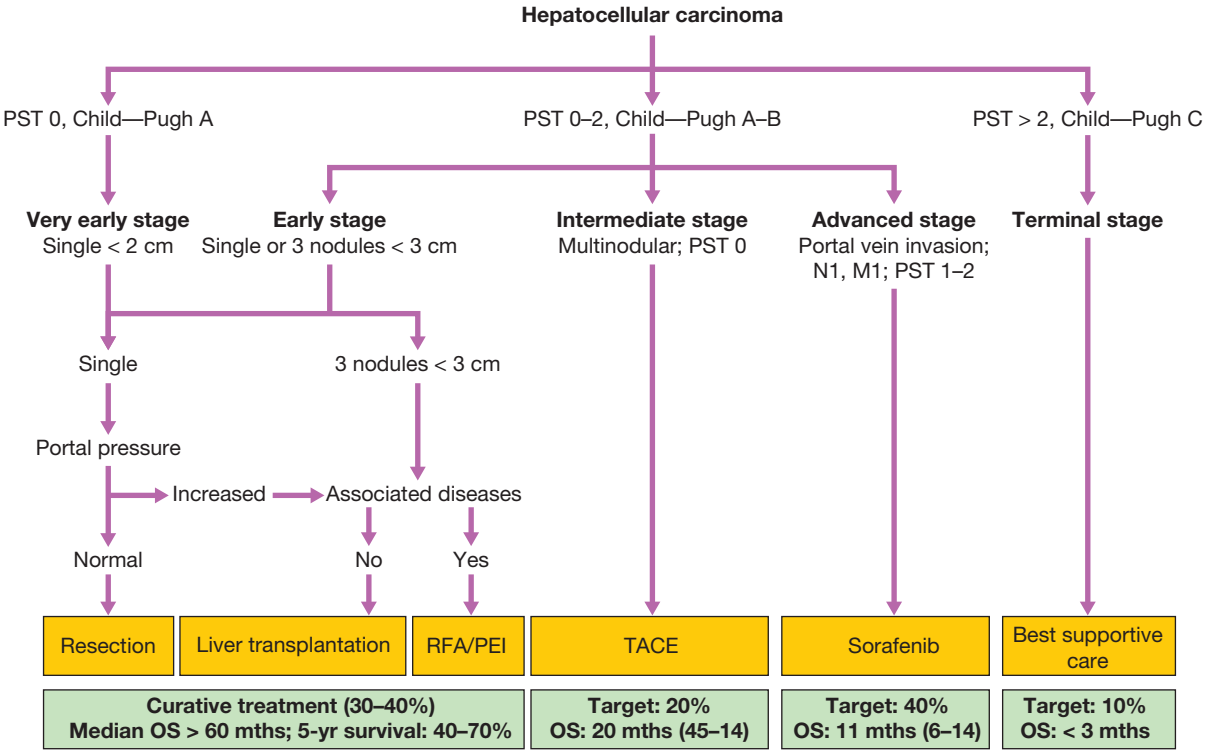

Fig. 23.35 Management of hepatocellular carcinoma complicating cirrhosis. Performance status (PST; see Box 11.3, p. 268): 0 = fully active, no symptoms; > 2 = limited self-care, confined to bed or chair for 50% of waking hours. Child–Pugh score: see Box 23.30, p. 944. N1, M1: lymph node involvement and metastases (for TNM classification, see Box 11.4, p. 268) (OS = overall survival; PEI = percutaneous ethanol injection; RFA = radiofrequency ablation; TACE = trans-arterial chemo-embolisation). Based on EASL–EORTC Clinical Practice Guidelines 2012 – see p. 988.

factor (VEGF) and platelet-derived growth factor (PDGF) signalling, and is the first systemic therapy to prolong survival in HCC. The ultimate role of sorafenib in HCC – in particular, when and how best to use it – remains to be established.

Fibrolamellar hepatocellular carcinoma

This rare variant differs from HCC in that it occurs in young adults, equally in males and females, in the absence of hepatitis B infection and cirrhosis. The tumours are often large at presentation and the AFP is usually normal. Histology of the tumour reveals malignant hepatocytes surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. This variant of HCC has a better prognosis following surgery than an equivalent-sized HCC, two-thirds of patients surviving beyond 5 years.

Other primary malignant tumours

These are rare but include haemangio-endothelial sarcomas. Cholangiocarcinoma (bile duct cancer) typically presents with bile duct obstruction rather than as a hepatic mass lesion, although the latter occasionally occurs.

Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

Clinical features

The primary neoplasm is asymptomatic in 50% of patients, being detected on either radiological, endoscopic or blood biochemistry screening. There is liver enlargement and weight loss; jaundice may be present.

Investigations

A raised ALP activity is the most common biochemical abnormality but LFTs may be normal. Ascitic fluid, if present, has a high protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging shows filling defects (Fig. 23.36); laparoscopy may reveal the tumour and facilitates liver biopsy.

Management

Hepatic resection can improve survival for slow-growing tumours such as colonic carcinomas, and is an approach that should be actively explored in patients who are fit for liver resection, have had the primary tumour resected and in whom extrahepatic disease has been excluded. Patients with neuro-endocrine tumours, such as gastrinomas, insulinomas and glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients; this may include arterial embolisation of the tumour masses.

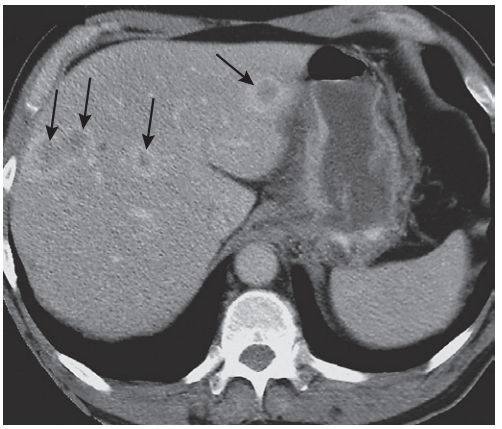

Fig. 23.36 CT showing multiple liver metastases (arrows).

Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

Hepatic adenomas

These are rare vascular tumours that may present as an abdominal mass, or with abdominal pain or intraperitoneal bleeding. They are more common in women and may be caused by oral contraceptives, androgens and anabolic steroids. Resection is indicated for the relief of symptoms. Hepatic adenomas can increase in size during pregnancy. Large or rapidly growing adenomas can, rarely, rupture, causing intraperitoneal bleeding.

Haemangiomas

These are the most common benign liver tumours and are present in 1–20% of the population. Most are smaller than 5 cm and rarely cause symptoms (Fig. 23.37). The diagnosis is usually made by ultrasound, but CT may show a low-density lesion with delayed arterial filling. Surgery is only needed for very large symptomatic lesions or where the diagnosis is in doubt.

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is common in women under the age of 40. The lesions are usually asymptomatic but can be up to 10 cm in diameter; they can be differentiated from adenoma because of a focal central scar seen on CT or MRI. Histologically, they consist of nodular regeneration of hepatocytes but without fibrosis. They may be multiple but only rarely need resection.

Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 23.38). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, percutaneous or surgical debulking can be attempted but recurrence is typical. Liver abscesses are discussed on page 956.

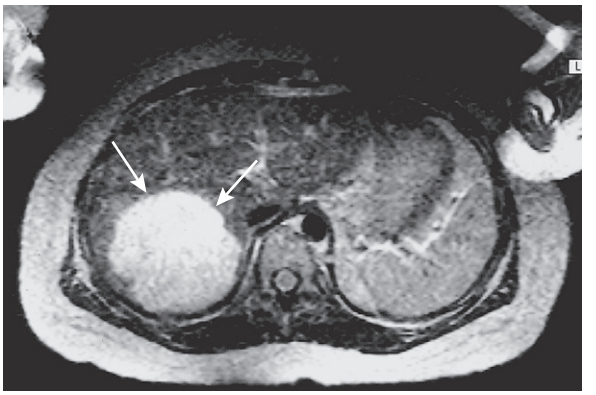

Fig. 23.37 MRI showing a haemangioma (arrows) in the liver.

Fig. 23.38 CT showing multiple cysts in the liver and kidneys in polycystic disease.

DRUGS AND THE LIVER

The liver is the primary site of drug metabolism and an important target for drug-induced injury. Pre-existing liver disease may affect the capacity of the liver to metabolise drugs, and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses. Box 23.64 also shows drugs that should be avoided in patients with cirrhosis, as they can exacerbate known complications of cirrhosis. The possibility of undiagnosed underlying liver injury should always be considered in patients exhibiting unexpected effects following drug exposure.

Drug-induced liver injury

Drug toxicity should always be considered in the differential diagnosis of patients presenting with acute liver failure, jaundice or abnormal liver biochemistry. Some typical patterns of drug toxicity are listed in Box 23.65; the most common picture is of a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to

23.64 Drugs to be avoided in cirrhosis

Drug	Problem	Toxicity
NSAIDs	Reduced renal blood flow Mucosal ulceration	Hepatorenal failure Bleeding varices
ACE inhibitors	Reduced renal blood flow	Hepatorenal failure
Codeine	Constipation	Hepatic encephalopathy
Narcotics	Constipation, drug accumulation	Hepatic encephalopathy
Anxiolytics	Drug accumulation	Hepatic encephalopathy

(ACE = angiotensin-converting enzyme)

23.65 Examples of common causes of drug-induced hepatotoxicity

Pattern	Drug
Cholestasis	Chlorpromazine High-dose oestrogens
Cholestatic hepatitis	NSAIDs Co-amoxiclav Statins
Acute hepatitis	Rifampicin Isoniazid
Non-alcoholic steatohepatitis	Amiodarone
Venous outflow obstruction	Busulfan Azathioprine
Fibrosis	Methotrexate

normalise following a drug-induced hepatitis, and it may take months for them to normalise following a cholestatic hepatitis. Occasionally, permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

The key to diagnosing acute drug-induced liver disease is to take a detailed drug history (Box 23.66), looking for temporal relationships between drug exposure and onset of liver abnormality (bearing in mind the fact that liver injury can frequently take weeks or even months to develop following exposure). A liver biopsy should be considered if there is suspicion of pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Where drug-induced liver injury is suspected or cannot be excluded, the potential culprit drug should be discontinued unless it is impossible to do so safely.

Types of liver injury

Different histological patterns of liver injury may occur with drug injury.

Cholestasis

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was common when high concentrations of oestrogens (50 μg/day) were used as contraceptives. Both the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canalicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic steroids used by body-builders may also cause a cholestatic hepatitis. In some cases (e.g. NSAIDs and cyclo-oxygenase (COX)-2 inhibitors) there is overlap with acute hepatocellular injury.

23.66 The diagnosis of acute drug-induced liver disease

- Tabulate the drugs taken
  - Prescribed
  - Self-administered
- Establish whether hepatotoxicity is reported in the literature
- Relate the time at which the drugs were taken to the onset of illness
  - 4 days to 8 weeks (usual)
- Establish the effect of stopping the drugs on normalisation of liver biochemistry
  - Hepatitic LFTs (2 months)
  - Cholestatic/mixed LFTs (6 months)
- Exclude other causes
  - Viral hepatitis
  - Biliary disease
- Consider liver biopsy

N.B. Challenge tests with drugs should be avoided.

Hepatocyte necrosis

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granulomas may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies, including germander, comfrey and jin bu huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

Steatosis

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate (see Box 23.69, p. 978). Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone toxicity can produce a similar histological picture to NASH.

Vascular/sinusoidal lesions

Drugs such as the alkylating agents used in oncology can damage the vascular endothelium and lead to hepatic venous outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

Hepatic fibrosis

Most drugs cause reversible liver injury and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

INHERITED LIVER DISEASES

The inherited diseases are an important and probably under-diagnosed group of liver diseases. In addition to the 'classical' conditions such as haemochromatosis and Wilson's disease, the important role played by the liver in the expression of the inborn errors of metabolism should be remembered, as should the potential for genetic underpinning for intrahepatic cholestasis.

Haemochromatosis

Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 23.67).

Hereditary haemochromatosis

In hereditary haemochromatosis (HHC), iron is deposited throughout the body and total body iron may reach 20–60 g (normally 4 g). The important organs involved are the liver, pancreatic islets, endocrine glands and heart. In the liver, iron deposition occurs first in the periportal hepatocytes, extending later to all hepatocytes. The gradual development of fibrous septa leads to the formation of irregular nodules, and finally regeneration results in macronodular cirrhosis. An excess of liver iron can occur in alcoholic cirrhosis but this is mild by comparison with haemochromatosis.

23.67 Causes of haemochromatosis

Primary haemochromatosis

- Hereditary haemochromatosis
- Congenital acaeruloplasminaemia
- Congenital atransferrinaemia

Secondary iron overload

- Parenteral iron-loading (e.g. repeated blood transfusion)
- Iron-loading anaemia (thalassaemia, sideroblastic anaemia, pyruvate kinase deficiency)
- Liver disease

Complex iron overload

- Juvenile haemochromatosis
- Neonatal haemochromatosis
- Alcoholic liver disease
- Porphyria cutanea tarda
- African iron overload (Bantu siderosis)

Pathophysiology

The disease is caused by increased absorption of dietary iron and is inherited as an autosomal recessive trait. Approximately 90% of patients are homozygous for a single-point mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein, which has structural and functional similarity to the HLA proteins. The mechanisms by which HFE regulates iron absorption are unclear. However, it is believed that HFE normally interacts with the transferrin receptor in the basolateral membrane of intestinal epithelial cells. In HHC, it is thought that the lack of functional HFE causes a defect in uptake of transferrin-associated iron, leading to up-regulation of enterocyte iron-specific divalent metal transporters and excessive iron absorption. A histidine to aspartic acid mutation at position 63 (H63D) in HFE causes a less severe form of haemochromatosis that is most commonly found in patients who are compound heterozygotes also carrying a C282Y mutated allele. Fewer than 50% of C282Y homozygotes will develop clinical features of haemochromatosis; therefore other factors must also be important. HHC may promote accelerated liver disease in patients with alcohol excess or hepatitis C infection. Iron loss in menstruation and pregnancy can delay the onset of HHC in females.

Clinical features

Symptomatic disease usually presents in men over 40 years with features of liver disease (often with hepatomegaly), diabetes mellitus or heart failure. Fatigue and arthropathy are early symptoms but are frequently absent. Leaden-grey skin pigmentation due to excess melanin occurs, especially in exposed parts, axillae, groins and genitalia: hence the term 'bronzed diabetes'. Once again, absence of this feature does not preclude the diagnosis. Impotence, loss of libido, testicular atrophy and arthritis with chondrocalcinosis secondary to calcium pyrophosphate deposition are also common. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.

Investigations

Serum iron studies show a greatly increased ferritin, a raised plasma iron and saturated plasma iron-binding capacity. Transferrin saturation of more than 45% is suggestive of iron overload. Significant liver disease is unusual in patients with ferritin lower than 1000 μg/L. The differential diagnoses for elevated ferritin are inflammatory disease or excess ethanol consumption for modest elevations (< 1000 μg/L). Very significant ferritin elevation can be seen in adult Still's disease. In terms of imaging techniques, MRI has high specificity for iron overload, but poor sensitivity. Liver biopsy allows assessment of fibrosis and distribution of iron (hepatocyte iron characteristic of haemochromatosis). The Hepatic Iron Index (HII) provides quantification of liver iron (μmol of iron per g dry weight of liver/age in years). HII of more than 1.9 suggests genetic haemochromatosis (Fig. 23.39). Both the C282Y and the H63D mutations can be identified by genetic testing, which is now in routine clinical use.

Management

Treatment consists of weekly venesection of 500 mL blood (250 mg iron) until the serum iron is normal;

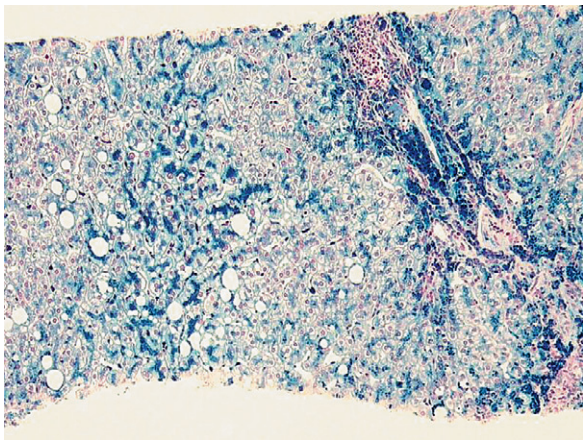

Fig. 23.39 Liver histology: haemochromatosis. This Perls stain shows accumulating iron within hepatocytes, which is stained blue. There is also accumulation of large fat globules in some hepatocytes (macrovesicular steatosis). Iron also accumulates in Kupffer cells and biliary epithelial cells.

this may take 2 years or more. The aim is to reduce ferritin to under 50 µg/L. Thereafter, venesection is continued as required to keep the serum ferritin normal. Liver and cardiac problems improve after iron removal, but joint pain is less predictable and can improve or worsen after iron removal. Diabetes mellitus does not resolve after venesection. Other therapy includes that for cirrhosis and diabetes mellitus. First-degree family members should be investigated, preferably by genetic screening and also by checking the plasma ferritin and iron-binding saturation. Liver biopsy is only indicated in asymptomatic relatives if the LFTs are abnormal and/or the serum ferritin is greater than 1000 µg/L because these features are associated with significant fibrosis or cirrhosis. Asymptomatic disease should also be treated by venesection until the serum ferritin is normal.

Pre-cirrhotic patients with HHC have a normal life expectancy, and even cirrhotic patients have a good prognosis compared with other forms of cirrhosis (three-quarters of patients are alive 5 years after diagnosis). This is probably because liver function is well preserved at diagnosis and improves with therapy. Screening for hepatocellular carcinoma (p. 967) is mandatory because this is the main cause of death, affecting one-third of patients with cirrhosis irrespective of therapy. Venesection reduces but does not abolish the risk of hepatocellular carcinoma in the presence of cirrhosis.

Secondary haemochromatosis

Many conditions, including chronic haemolytic disorders, sideroblastic anaemia, other conditions requiring multiple blood transfusion (generally over 50 L), porphyria cutanea tarda, dietary iron overload and occasionally alcoholic cirrhosis, are associated with widespread secondary siderosis. The features are similar to primary haemochromatosis, but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for the *HFE* gene and this may contribute to the development of iron overload.

Wilson's disease

Wilson's disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism caused by a variety of mutations in the *ATP7B* gene on chromosome 13. Total body copper is increased, with excess copper deposited in, and causing damage to, several organs.

Pathophysiology

Normally, dietary copper is absorbed from the stomach and proximal small intestine, and is rapidly taken into the liver, where it is stored and incorporated into caeruloplasmin, which is secreted into the blood. The accumulation of excessive copper in the body is ultimately prevented by its excretion, the most important route being via bile. In Wilson's disease, there is almost always a failure of synthesis of caeruloplasmin; however, some 5% of patients have a normal circulating caeruloplasmin concentration and this is not the primary pathogenic defect. The amount of copper in the body at birth is normal, but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

The *ATP7B* gene encodes a member of the copper-transporting P-type adenosine triphosphatase family, which functions to export copper from various cell types. At least 200 different mutations have been described. Most cases are compound heterozygotes with two different mutations in *ATP7B*. Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns. The large number of culprit mutations means that, in contrast to haemochromatosis, genetic diagnosis is not routine in Wilson's disease, although it may have a role in screening families following identification of the genotype in an index patient.

Clinical features

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence, although it can present in adults in their fifties. Neurological damage causes basal ganglion syndromes and dementia, which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

Liver disease

Episodes of acute hepatitis, sometimes recurrent, can occur, especially in children, and may progress to fulminant liver failure. The latter is characterised by the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. Chronic hepatitis can also develop insidiously and eventually present with established cirrhosis; liver failure and portal hypertension may supervene. The possibility of Wilson's disease should be considered in any patient under the age of 40 presenting with recurrent acute hepatitis or chronic liver disease of unknown cause, especially when accompanied by haemolysis.

Neurological disease

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia (Ch. 26). Unusual clumsiness for age may be an early symptom. Neurological disease typically develops after the onset of liver disease and can be prevented by effective treatment started following diagnosis in the liver disease phase. This increases the importance of diagnosis in the liver phase beyond just allowing effective management of liver disease.

Kayser–Fleischer rings

These constitute the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson's disease (less often in children but almost always in neurological Wilson's disease), albeit sometimes only by slit-lamp examination. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery (see p. 922). They disappear with treatment.

Investigations

A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. However, advanced liver failure from any cause can reduce the serum caeruloplasmin, and occasionally it is normal in Wilson's disease. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than 0.6 μmol/24 hrs (38 μg/24 hrs) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion whilst giving D-penicillamine is a useful confirmatory test; more than 25 μmol/24 hrs is considered diagnostic of Wilson's disease.

Management

The copper-binding agent, penicillamine, is the drug of choice. The dose given must be sufficient to produce cupriuresis and most patients require 1.5 g/day (range 1–4 g). The dose can be reduced once the disease is in remission but treatment must continue for life, even through pregnancy. Care must be taken to ensure that re-accumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these do occur, trientine dihydrochloride (1.2–2.4 g/day) and zinc (50 mg 3 times daily) are potential alternatives.

Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson's disease is unclear. Prognosis is excellent, provided treatment is started before there is irreversible damage. Siblings and children of patients with Wilson's disease must be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

Alpha$_1$-antitrypsin deficiency

Alpha$_1$-antitrypsin (α_1-AT) is a serine protease inhibitor (Pi) produced by the liver. The mutated form of α_1-AT (PiZ) cannot be secreted into the blood by liver cells because it is retained within the endoplasmic reticulum of the hepatocyte. Homozygous individuals (PiZZ) have low plasma α_1-AT concentrations, although globules containing α_1-AT are found in the liver, and these people may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously, chronic hepatitis and cirrhosis in adults, and, in the long term, HCC. Alpha$_1$-AT deficiency is a not uncommon exacerbating factor for liver disease of other aetiologies, and the possibility of dual pathology should be considered in patients in whom severity of disease, such as ALD, appears disproportionate to the level of underlying insult.

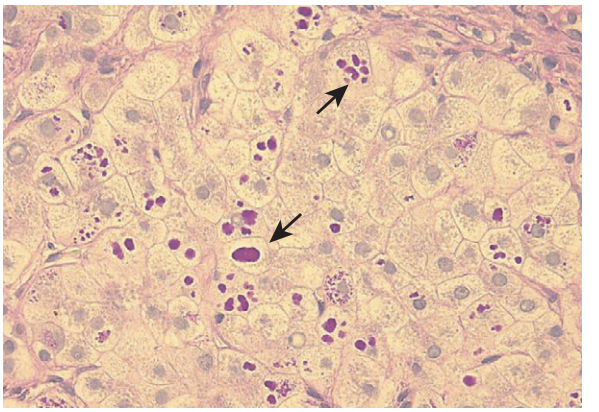

Fig. 23.40 Liver histology in α_1-antitrypsin deficiency. Accumulation of periodic acid–Schiff-positive granules (arrows) within individual hepatocytes is shown in this section from a patient with α_1-AT deficiency.

There are no clinical features distinguishing liver disease due to α_1-AT deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma α_1-AT concentration and genotyping for the presence of the mutation. Alpha$_1$-AT-containing globules can be demonstrated in the liver (Fig. 23.40) but this is not necessary to make the diagnosis. Occasionally, patients with liver disease and minor reductions of plasma α_1-AT concentrations have α_1-AT variants other than PiZZ, but the relationship of these to liver disease is uncertain.

There is no specific treatment; the risk of severe and early-onset emphysema means that all patients should be advised to stop smoking.

Gilbert's syndrome

Gilbert's syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 23.17, p. 937). It is an autosomal dominant trait caused by a mutation in the promoter region of the UDP-glucuronyl transferase enzyme, which leads to reduced enzyme expression. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronyl transferase.

Clinical features

The typical presentation is with isolated elevation of bilirubin, typically, although not exclusively, in the setting of physical stress or illness. There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence stercobilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed. In the presence of haemolysis, pallor due to anaemia and splenomegaly due to excessive reticulo-endothelial activity are usually present.

Investigations

The plasma bilirubin is usually less than 100 µmol/L (~6 mg/dL) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Hepatic histology is normal and liver biopsy is not recommended for the investigation of patients with possible Gilbert's syndrome. The condition is not associated with liver injury and thus has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.

VASCULAR LIVER DISEASE

Metabolically, the liver is highly active and has large oxygen requirements. This places it at risk of ischaemic injury in settings of impaired perfusion. The risk is mitigated, however, by the dual perfusion of the liver (via portal vein as well as hepatic artery), with the former representing a low-pressure perfusion system that offers protection against the potential effects of arterial hypotension. The single outflow through the hepatic vein and the low-pressure perfusion system of the portal vein make the liver vulnerable to venous thrombotic ischaemia in the context of Budd–Chiari syndrome and portal vein thrombosis, respectively.

Hepatic arterial disease

Liver ischaemia

Liver ischaemic injury is relatively common during hypotensive or hypoxic events and is under-diagnosed. The characteristic pattern is one of rising transaminase values in the days following such an event (e.g. prolonged seizures). Liver synthetic dysfunction and encephalopathy are uncommon but can occur. Liver failure is very rare. Diagnosis typically rests on clinical suspicion and exclusion of other potential aetiologies. Treatment is aimed at optimising liver perfusion and oxygen delivery. Outcome is dictated by the morbidity and mortality associated with the underlying disease, given that liver ischaemia frequently occurs in the context of other organ ischaemia in high-risk patients.

Liver arterial disease

Hepatic arterial disease is rare outside the setting of liver transplantation and is difficult to diagnose. It can cause significant liver damage. Hepatic artery occlusion may result from inadvertent injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually > 1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic artery aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis and surgical or biopsy trauma are the main causes. They usually lead to bleeding into the biliary tree, peritoneum or intestine, and are best diagnosed by angiography. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery but this rarely causes symptoms.

Hepatic artery thrombosis is a recognised complication of liver transplantation and typically occurs in the early post-transplant period. Clinical features are often related to bile duct rather than liver ischaemia because of the dominant role of the hepatic artery in extrahepatic bile duct perfusion. Manifestations can include bile duct anastomotic failure with bile leak or the development of late bile duct strictures. Diagnosis and initial intervention are radiological in the first instance, with ERCP and biliary stenting being the principal approaches to the treatment of bile duct injury.

Portal venous disease

Portal hypertension

See page 945.

Portal vein thrombosis

Portal venous thrombosis as a primary event is rare, but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease, and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may rarely lead to bowel infarction, requiring surgery. Treatment is otherwise based on anticoagulation, although there are no randomised data on efficacy. An underlying thrombophilia needs to be excluded. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension (p. 945). Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low.

Portal vein thrombosis can arise as a secondary event in patients with cirrhosis and portal hypertension, and is a recognised cause of decompensation in patients with previously stable cirrhosis. In patients showing such decompensation, portal vein patency should be assessed by ultrasound with Doppler flow studies.

Hepatopulmonary syndrome

This condition is characterised by resistant hypoxaemia (PaO_2 < 9.3 kPa or 70 mm Hg), intrapulmonary vascular dilatation in patients with cirrhosis, and portal hypertension. Clinical features include finger clubbing, cyanosis, spider naevi and a characteristic reduction in arterial oxygen saturation on standing. The hypoxia is due to intrapulmonary shunting through direct arteriovenous

communications. Nitric oxide (NO) overproduction may be important in pathogenesis. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe (PaO_2 < 6.7 kPa or 50 mm Hg), is associated with an increased operative risk.

Portopulmonary hypertension

This unusual complication of portal hypertension is similar to 'primary pulmonary hypertension' (p. 724). It is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. The condition is caused by vasoconstriction and obliteration of the pulmonary arterial system, and leads to breathlessness and fatigue.

Hepatic venous disease

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart (see Fig. 23.19, p. 945). The clinical features depend on the cause and on the speed with which obstruction develops, and can mimic many other forms of chronic liver disease, sometimes leading to delayed diagnosis. Congestive hepatomegaly and ascites are, however, the most consistent features. The possibility of hepatic venous obstruction should always be considered in patients with an atypical liver presentation.

Budd–Chiari syndrome

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Many patients have haematological disorders such as myelofibrosis, primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria, or antithrombin III, protein C or protein S deficiencies (Ch. 24). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena caval stenosis are the other main causes. The underlying cause cannot be found in about 50% of patients, although this percentage is falling as molecular diagnostic tools (such as the JAK2 mutation in myelofibrosis) increase our capacity to diagnose underlying haematological disorders. Hepatic congestion affecting the centrilobular areas is followed by centrilobular fibrosis, and eventually cirrhosis supervenes in those who survive long enough.

Clinical features

Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and, often, upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.

Investigations

The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis. Ascitic fluid analysis shows a protein concentration above 25 g/L (exudate) in the early stages; however, this often falls later in the disease. Doppler ultrasound may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as it often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is only needed if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

Management

Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, thrombolysis with streptokinase, followed by heparin and oral anticoagulation, should be considered. Ascites is initially treated medically but often with only limited success. Short hepatic venous strictures can be treated with angioplasty. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPSS, followed by anticoagulation. Surgical shunts, such as portacaval shunts, are less commonly performed now that TIPSS is available. Occasionally, a web can be resected or an inferior vena caval stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

Prognosis without transplantation or shunting is poor, particularly following an acute presentation with liver failure. A 3-year survival of 50% is reported in those who survive the initial event. The 1- and 10-year survival following liver transplantation is 85% and 69% respectively, and this compares with a 5- and 10-year survival of 87% and 37% following surgical shunting.

Veno-occlusive disease

Veno-occlusive disease (VOD) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in *Senecio* and *Heliotropium* plants used to make teas, as well as cytotoxic drugs and hepatic irradiation, are all recognised causes. VOD may develop in 10–20% of patients following haematopoietic stem cell transplantation (usually within the first 20 days), and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting, VOD is thought to relate to preconditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous outflow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may make the diagnosis. Traditionally, treatment has been supportive, but defibrotide shows promise (the drug binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation).

Cardiac disease

Hepatic damage, due primarily to congestion, may develop in all forms of right heart failure (p. 548);

usually, the clinical features are predominantly cardiac. Very rarely, long-standing cardiac failure and hepatic congestion give rise to cardiac cirrhosis. Cardiac causes of acute and chronic liver disease are under-diagnosed. Treatment is that of the underlying heart disease.

Nodular regenerative hyperplasia of the liver

This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. It is believed to be due to damage to small hepatic arterioles and portal venules. It occurs in older people and is associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs, such as azathioprine. The condition is usually asymptomatic, but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis is very favourable. Management is based on treatment of the portal hypertension.

PREGNANCY AND THE LIVER

The inter-relationship between liver disease and pregnancy can be a complex one and a source of real anxiety for both patient and clinicians. Three possibilities need to be borne in mind when faced with a pregnant woman with a liver abnormality:

- that this represents a worsening of pre-existing chronic liver or biliary disease (although pregnancy may be the first time a woman's liver biochemistry has been tested, so this may not have previously been diagnosed)
- that this represents a genuine first presentation of liver disease that is not intrinsically related to pregnancy
- that this represents a genuine pregnancy-associated liver injury process.

It is critical to obtain information relating to liver disease risk factors and pre-pregnancy liver status to establish whether any abnormality was present before pregnancy. In general, the earlier in pregnancy that liver abnormality presents, the more likely it is to represent either pre-existing liver disease or non-pregnancy-related acute liver disease. Equally, the best outcome for both mother and baby results from optimising the physical condition of the mother, and in situations of deteriorating liver function (which can be steep in late pregnancy) consideration should always be given to early delivery if the fetus is viable. Joint management between hepatologists and obstetricians is essential.

Intercurrent and pre-existing liver disease

Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases, and there is no convincing evidence that the mode of delivery affects this. Hepatitis E is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with either worsening or improvement of autoimmune hepatitis, although improvement during pregnancy and rebound post-partum is the most common pattern seen. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones (p. 981) are more common during pregnancy, and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made with ultrasound. In biliary obstruction due to gallstones, therapeutic ERCP can be safely performed, but lead protection for the fetus is essential and X-ray screening must be kept to a minimum.

Pregnancy-associated liver disease

The following conditions occur only during pregnancy, may recur in subsequent pregnancies and resolve after delivery of the baby. The causes of abnormal LFTs in pregnancy, which include pregnancy-associated liver disease, are shown in Box 23.68.

Acute cholestasis of pregnancy

This accounts for 20% of cases of jaundice in pregnancy; it usually occurs in the third trimester of pregnancy but can arise earlier. It may be linked with intrauterine growth retardation and premature birth, but is most

23.68 Abnormal liver function tests in pregnancy

- **Liver function tests**: ALT levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- **Pre-existing liver disease**: pregnancy is uncommon in cirrhosis because cirrhosis causes relative infertility. Variceal bleeding can occur if varices present prior to conception, and ascites or polyhydramnios should be treated with amiloride rather than spironolactone. Penicillamine for Wilson's disease and azathioprine for autoimmune liver disease should be continued during pregnancy. Autoimmune liver disease can flare up post-partum.
- **Unrelated liver disease**: viral- and drug-induced hepatitis must be excluded in the presence of an elevated ALT. Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post-partum, and are a cause of a raised ALP level. Biliary imaging with ultrasound and MRCP is safe. ERCP to remove stones can be performed safely with shielding of the fetus from radiation.
- **Pregnancy-related liver diseases**: occur predominantly in the third trimester and resolve post-partum. Maternal and fetal mortality and morbidity are prevented by early delivery.

characteristically associated with intrauterine fetal death if the pregnancy goes beyond 36 weeks of gestation. The condition characteristically presents with itching and cholestatic LFTs. A normal bilirubin and hepatitic LFTs do not, however, preclude the diagnosis. Bile salts are elevated in the serum and this represents a useful clinical test. Delivery leads to resolution and should be considered from 36 weeks onwards. Pregnancy should not be allowed to continue beyond term because of a steep rise in the risk of intrauterine death. UDCA (15 mg/kg daily) effectively controls itching and probably prevents premature birth. The major issue with UDCA in acute cholestasis of pregnancy is the relatively long time required to achieve effective levels within the bile pool, which renders it of little use in patients presenting in the very end stages of pregnancy. Cholestasis recurs in 60% of future pregnancies and the opportunities available for screening based on previous risk make UDCA a much more viable therapy in this setting.

Acute fatty liver of pregnancy

This is more common in twin and first pregnancies, and may arise more frequently when the fetus is male. It occurs in 1 in 14000 pregnancies in the USA. It typically presents between 31 and 38 weeks of pregnancy with vomiting and abdominal pain followed by jaundice. In severe cases, this may be followed by lactic acidosis, coagulopathy, encephalopathy and renal failure. Hypoglycaemia can also occur. The features are characteristic of a defect in beta-oxidation of fatty acids in the mitochondria that leads to the formation of small fat droplets in liver cells (known as microvesicular fatty liver). Some women are heterozygous for loss-of-function mutations in the long-chain 3-hydroxyacyl-CoA dehydrogenase (*LCHAD*) gene. Other causes of microvesicular steatosis that have a similar clinical presentation outside pregnancy are shown in Box 23.69. Differentiation from toxaemia of pregnancy (which is more common) can be achieved by the finding of high serum uric acid levels and the absence of haemolysis. Overlap between acute fatty liver of pregnancy, HELLP (see below) and toxaemia of pregnancy can occur. Early diagnosis, specialist care and delivery of the fetus have led to a fall in maternal and perinatal mortality to 1% and 7% respectively.

23.69 Hepatic mitochondrial cytopathies

- Acute fatty liver of pregnancy
- Drugs: sodium valproate, tetracyclines
- Reye's syndrome (aspirin toxicity in childhood)
- Toxins: *Bacillus cereus*

Toxaemia of pregnancy and HELLP

The HELLP syndrome (haemolysis, elevated liver enzymes and low platelets) is a variant of pre-eclampsia that tends to affect multiparous women. It usually presents at 27–36 weeks of pregnancy with hypertension, proteinuria and fluid retention, although, as with all liver diseases of pregnancy, the presentation can be highly variable and all potential diagnoses should be considered in all patients. Jaundice only occurs in 5% of cases. Blood tests may show low haemoglobin, with fragmented red cells, markedly elevated serum transaminases and raised D-dimers. The condition can be complicated by hepatic infarction and rupture. Maternal complications also include disseminated intravascular coagulation and placental abruption. Maternal mortality is 1% and perinatal mortality can be up to 30%. Delivery usually leads to prompt resolution, and disease recurs in fewer than 5% of subsequent pregnancies.

LIVER TRANSPLANTATION

The outcome following liver transplantation has improved significantly over the last decade so that elective transplantation in low-risk individuals now has a 1-year survival rate of more than 90% and is an effective treatment for end-stage liver disease. The number of procedures is limited by cadaveric donor availability, and in many parts of the world this has led to living donor transplant programmes. Despite this, 10% of those listed for liver transplantation will die while awaiting a donor liver. The main complications of liver transplantation relate to rejection, complications of long-term immunosuppression and disease recurrence in the liver graft.

Indications and contraindications

Currently, around 9500 liver transplants are undertaken in Europe and the USA annually. About 10% are performed for acute liver failure, 6% for metabolic diseases, 71% for cirrhosis and 11% for hepatocellular carcinoma. Most patients are under 60 years of age, and only 10% are aged between 60 and 70 years. Indications for elective transplant assessment are listed in Box 23.70. In North America the most common indication is hepatitis C cirrhosis, about 10–20% of transplants being for alcoholic cirrhosis (Fig. 23.41). Patients with alcoholic liver disease need to show a capacity for abstinence.

The main contraindications to transplantation are sepsis, extrahepatic malignancy, active alcohol or other substance misuse, and marked cardiorespiratory dysfunction.

Patients are matched for ABO blood group and size, but do not require HLA-matching with donors, as the

23.70 Indications for liver transplant assessment for cirrhosis

Complications

- First episode of bacterial peritonitis
- Diuretic-resistant ascites
- Recurrent variceal haemorrhage
- Hepatocellular carcinoma < 5 cm
- Persistent hepatic encephalopathy

Poor liver function

- Bilirubin > 100 μmol/L (5.8 mg/dL) in primary biliary cirrhosis
- MELD score > 12
- Child–Pugh grade C

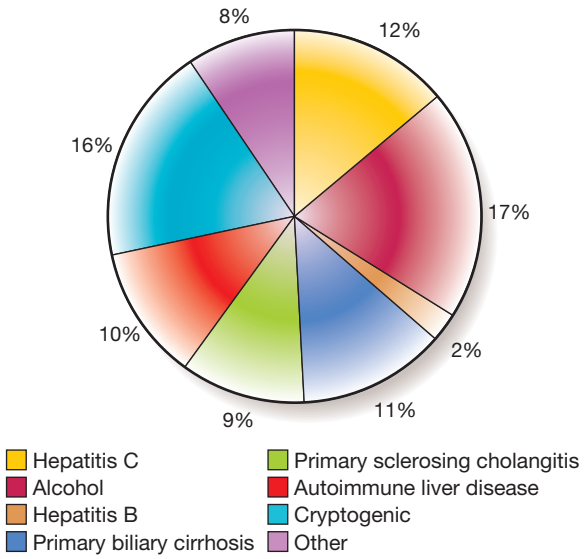

Fig. 23.41 Indications for liver transplantation in the UK between 2001 and 2005.

liver is a relatively immune-privileged organ compared with heart or kidney.

In many parts of the world, the MELD score (see Box 23.32, p. 944) is used to identify and prioritise patients for transplantation. In the UK, a similar score that also incorporates serum sodium, the United Kingdom End-Stage Liver Disease score (UKELD), is used to guide recipient selection. To be listed for elective (non-super-urgent) transplantation in the UK, patients must have a greater than 50% projected post-transplant 5-year survival and fall into one of three categories:

- *Category 1*: estimated 1-year mortality without transplantation of more than 9% (equivalent to a UKELD score of more than 49 points)
- *Category 2*: HCC diagnosed radiologically by two concordant modalities; based on CT, a single lesion of less than 5 cm maximum diameter or fewer than three lesions each less than 3 cm in diameter without macrovascular invasion or metastases.
- *Category 3*: 'variant syndromes', including diuretic-resistant ascites, hepatopulmonary syndrome, chronic hepatic encephalopathy, intractable pruritus, familial amyloidosis, primary hyperlipidaemia, polycystic liver disease and recurrent cholangitis.

Super-urgent listing is reserved for patients with acute liver failure according to specific criteria.

Two types of transplant are increasingly used because of insufficient cadaveric donors:

- *Split liver transplantation.* A cadaveric donor liver can be split into two, with the larger right lobe used in an adult and the smaller left lobe used in a child. This practice has led to an increase in procedures despite a shortage of donor organs.
- *Living donor transplantation.* This is normally performed using the left lateral segment or the right lobe. The donor mortality is significant at 0.5–1%. Pre-operative assessment includes looking at donor liver size and psychological status.

Complications

Early complications

Primary graft non-function

This is a state of hepatocellular dysfunction arising as a consequence of liver paresis that results from ischaemia following removal from the donor and prior to reperfusion in the recipient. Factors that increase the likelihood of primary non-function include increasing donor age, degree of steatosis in the liver, and the length of ischaemia. Treatment is supportive until recovery of function. Occasionally, recovery is not seen and re-transplant is necessary.

Technical complications

These include hepatic artery thrombosis, which may necessitate re-transplantation. Anastomotic biliary strictures can also occur; these may respond to endoscopic balloon dilatation and stenting, or require surgical reconstruction. Portal vein thrombosis is rare.

Rejection

Less immunosuppression is needed following liver transplantation than with kidney or heart/lung grafting. Initial immunosuppression is usually with tacrolimus or ciclosporin, prednisolone and azathioprine or mycophenolate. Some patients can eventually be maintained on a single agent. Acute cellular rejection occurs in 60–80% of patients, commonly at 5–10 days post transplant and usually within the first 6 weeks, but can arise at any point. This normally responds to 3 days of high-dose intravenous methylprednisolone.

Infections

Bacterial infections, such as pneumonia and wound infections, can occur in the first few weeks after transplantation. Cytomegalovirus (primary infection or reactivation) is a common infection in the 3 months after transplantation and can cause hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk of infection, and are usually given prophylactic antiviral therapy such as valganciclovir. Herpes simplex virus reactivation or, rarely, primary infection may occur. Prophylaxis is given to recipients who have had previous exposure to tuberculosis for the first 6 months after transplantation to prevent reactivation.

Late complications

These include recurrence of the initial disease in the graft and complications due to the immunosuppressive therapy, such as renal impairment from ciclosporin. Metabolic syndrome is common, being described in about 50% of transplant recipients within 6 months in the USA. Chronic vascular rejection is rare, occurring in only 5% of cases.

Prognosis

The outcome following transplantation for acute liver failure is worse than for chronic liver disease because

23.71 Liver disease in old age

- **Alcoholic liver disease**: 10% of cases present over the age of 70 years, when disease is more likely to be severe and has a worse prognosis.
- **Hepatitis A**: causes more severe illness and runs a more protracted course.
- **Primary biliary cirrhosis**: one-third of cases are over 65 years.
- **Liver abscess**: more than 50% of all cases in the UK are over 60 years.
- **Hepatocellular carcinoma**: approximately 50% of cases present over the age of 65 years in the UK.
- **Surgery**: older people are less likely to survive liver surgery (including transplantation) because comorbidity is more prevalent.

most patients have multi-organ failure at the time of transplantation. The 1-year survival is 65% and falls only a little to 59% at 5 years. The 1-year survival for patients with cirrhosis is over 90%, falling to 70–75% at 5 years.

CHOLESTATIC AND BILIARY DISEASE

The concepts of biliary and cholestatic disease, and the important distinctions between them, can be a source of confusion. 'Cholestasis' relates to a biochemical abnormality (typically elevation of ALP and, if the process is significant, elevation in serum bile acid levels and bilirubin) resulting from an abnormality in bile flow. The cause can range from inherited or acquired dysfunction of transporter molecules responsible for the production of canalicular bile to physical obstruction of the extrahepatic bile duct. 'Biliary disease' relates to pathology at any level from the small intrahepatic bile ducts to the sphincter of Oddi. Although there is very significant overlap between cholestatic and biliary disease, there are scenarios where cholestasis can exist without biliary disease (transporter disease or pure drug-induced cholestasis) and where biliary disease can exist without cholestasis (when disease of the bile duct does not impact on bile flow). These anomalies should always be borne in mind, and cholestasis and biliary disease always effectively distinguished.

Chemical cholestasis

Pure cholestasis can occur as an inherited condition (see p. 972), as a consequence of cholestatic drug reactions (p. 971) or as acute cholestasis of pregnancy (p. 977). A more frequent, but less recognised, acquired biochemical cholestasis occurs in sepsis ('cholangitis lente'). This biochemical phenomenon is one of the causes of LFT abnormality in sepsis, does not require specific treatment, and has a prognostic significance conferred by the underlying septic process.

Mutations in the biliary transporter proteins on the hepatocyte canalicular membrane (familial intrahepatic cholestasis 1, FIC1), illustrated in Figure 23.7 (p. 927), have been shown to cause an inherited intrahepatic biliary disease in childhood, characterised by raised ALP levels and progression to a biliary cirrhosis. It is also becoming increasingly clear that these proteins contribute to intrahepatic biliary disease in adulthood.

Benign recurrent intrahepatic cholestasis

This rare condition usually presents in adolescence and is characterised by recurrent episodes of cholestasis, lasting 1–6 months. It is now known to be mediated by mutations in the *ATP8B1* gene, which lies on chromosome 18 and encodes FIC1.

Episodes start with pruritus, while painless jaundice develops later. LFTs show a cholestatic pattern. Liver biopsy shows cholestasis during an episode but is normal between episodes. Treatment is required to relieve the symptoms of cholestasis, such as pruritus, and the long-term prognosis is good.

Intrahepatic biliary disease

Inflammatory and immune disease

The small intrahepatic bile ducts appear to be specifically vulnerable to immune injury, and ductopenic injury ('vanishing bile duct syndrome') can be a feature of a number of chronic conditions, including graft-versus-host disease (GVHD), sarcoidosis and, in the setting of liver transplantation, ductopenic rejection. Intrahepatic small bile duct injury occurs most frequently in PBC, an autoimmune cholestatic disease, and less frequently in PSC (Box 23.72).

Caroli's disease

This is very rare and is characterised by segmental saccular dilatations of the intrahepatic biliary tree. The

23.72 Comparison of primary biliary cirrhosis and primary sclerosing cholangitis

	PBC	PSC
Gender (F:M)	10:1	1:3
Age	Older: median age 50–55 yrs	Younger: median age 20–40 yrs
Disease associations	Non-organ-specific autoimmune disease (e.g. Sjögren's syndrome) and autoimmune thyroid disease	Ulcerative colitis
Autoantibody profile	90% AMA +ve	65–85% pANCA +ve (but this is non-specific and not diagnostic)
Predominant bile-duct injury	Intrahepatic	Extrahepatic > intrahepatic

(AMA = antimitochondrial antibodies; pANCA = perinuclear antineutrophil cytoplasmic antibodies)

whole liver is usually affected, and extrahepatic biliary dilatation occurs in about one-quarter of patients. Recurrent attacks of cholangitis (see Box 23.18, p. 937) may cause hepatic abscesses. Complications include biliary stones and cholangiocarcinoma. Antibiotics are required for episodes of cholangitis. Occasionally, localised disease can be treated by segmental liver resection, and liver transplantation may sometimes be required.

Congenital hepatic fibrosis

This is characterised by broad bands of fibrous tissue linking the portal tracts in the liver, abnormalities of the interlobular bile ducts, and sometimes a lack of portal venules. The renal tubules may show cystic dilatation (medullary sponge kidney, p. 506), and eventually renal cysts may develop. The condition can be inherited as an autosomal recessive trait. Liver involvement causes portal hypertension with splenomegaly and bleeding from oesophageal varices that usually presents in adolescence or in early adult life. The prognosis is good because liver function is preserved. Treatment may be required for variceal bleeding and occasionally cholangitis. Patients can present during childhood with renal failure if the kidneys are severely affected.

Cystic fibrosis

Cystic fibrosis (p. 680) is associated with a biliary cirrhosis in about 5% of individuals. Splenomegaly and an elevated ALP are characteristic. Complications do not normally arise until late adolescence or early adulthood, when bleeding due to variceal haemorrhage may occur. UDCA improves liver blood tests but it is not known whether the drug can prevent progression of liver disease. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of both biliary and pancreatic disease.

Extrahepatic biliary disease

Diseases of the extrahepatic biliary tree typically present with the clinical features of impaired bile flow (obstructive jaundice and fat malabsorption). Obstructive disease is frequently a consequence of stricturing following gallstone passage and associated infection and inflammation or post-surgical intervention. PSC frequently involves the extrahepatic biliary tree, and its differential, IgG4 disease, is an important and potentially treatable cause of disease (p. 966). Malignant diseases (cholangiocarcinoma or carcinoma of the head of pancreas should be considered in all patients with extrahepatic biliary obstruction.

Choledochal cysts

This term applies to cysts anywhere in the biliary tree (Fig. 23.42). The great majority cause diffuse dilatation of the common bile duct (type I), but others take the form of biliary diverticula (type II), dilatation of the intraduodenal bile duct (type III) and multiple biliary cysts (type IV). The last type merges with Caroli's disease (see above). In the neonate, they may present with jaundice or biliary peritonitis. Recurrent jaundice, abdominal pain and cholangitis may arise in the adult.

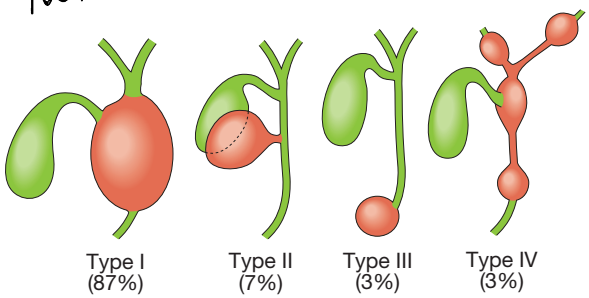

Fig. 23.42 Classification and frequency of choledochal cysts.
From Shearman and Finlayson 1989 – see p. 988.

Liver abscess and biliary cirrhosis may develop, and there is an increased incidence of cholangiocarcinoma. Excision of the cyst with hepatico-jejunostomy is the treatment of choice.

Secondary biliary cirrhosis

Secondary biliary cirrhosis develops after prolonged large duct biliary obstruction due to gallstones, benign bile duct strictures or sclerosing cholangitis (see below). Carcinomas rarely cause secondary biliary cirrhosis because few patients survive long enough. The clinical features are those of chronic cholestasis with episodes of ascending cholangitis or even liver abscess (p. 956). Cirrhosis, ascites and portal hypertension are late features. Relief of biliary obstruction may require endoscopic or surgical intervention. Cholangitis requires treatment with antibiotics, which can be given continuously if attacks recur frequently.

Gallstones

Gallstone formation is the most common disorder of the biliary tree and it is unusual for the gallbladder to be diseased in the absence of gallstones. In developed countries, gallstones occur in 7% of males and 15% of females aged 18–65 years, with an overall prevalence of 11%. In individuals under 40 years there is a 3:1 female preponderance, whereas in the elderly the sex ratio is about equal. In developed countries, the incidence of symptomatic gallstones appears to be increasing and they occur at an earlier age. Gallstones are less frequent in India, the Far East and Africa. There has been much debate over the role of diet in cholesterol gallstone disease; an increase in dietary cholesterol, fat, total calories and refined carbohydrate or lack of dietary fibre has been implicated. At present, the best data support an association between simple refined sugar in the diet and gallstones.

Pathophysiology

Gallstones are conveniently classified into cholesterol or pigment stones, although the majority are of mixed composition. Cholesterol stones are most common in developed countries, whereas pigment stones are more frequent in developing countries. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which

23.73 Risk factors and mechanisms for cholesterol gallstones

↑ Cholesterol secretion

23.75 Pathogenic factors leading to the production of lithogenic bile

- Defective bile salt synthesis
- Excessive intestinal loss of bile salts
- Over-sensitive bile salt feedback
- Excessive cholesterol secretion
- Abnormal gallbladder function

are radio-opaque. Gallstone formation is multifactorial, and the factors involved are related to the type of gallstone (Boxes 23.73 and 23.74).

Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease the liver produces bile that contains an excess of cholesterol, because there is either a relative deficiency of bile salts or a relative excess of cholesterol ('lithogenic' bile). Disorders with the potential to induce lithogenic bile are shown in Box 23.75. Factors initiating crystallisation of cholesterol in lithogenic bile (nucleation factors) are also important in determining the rate at which crystals form from saturated bile. Factors favouring nucleation (mucus, calcium, fatty acids, other proteins) and antinucleating factors (apolipoproteins) have been described.

Pigment stones

Brown crumbly pigment stones are almost always the consequence of bacterial or parasitic biliary infection. They are common in the Far East, where infection allows bacterial β-glucuronidase to hydrolyse conjugated bilirubin to its free form, which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in developed countries is not satisfactorily explained. Haemolysis is important, as these stones occur in chronic haemolytic disease.

Biliary sludge

This describes gelatinous bile that contains numerous microspheroliths of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions, but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

Clinical features

Only 10% of individuals with gallstones develop clinical evidence of gallstone disease. Symptomatic stones within the gallbladder (Box 23.76) manifest as either biliary pain ('biliary colic') or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term 'biliary colic' is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic. Typically, the pain occurs suddenly and persists for about 2 hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20%), and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrathoracic disease, oesophagitis, myocardial infarction or dissecting aneurysm.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as 'gallstone dyspepsia'. These symptoms are not now recognised as being caused by

23.76 Clinical features and complications of gallstones

Clinical features	
• Asymptomatic (80%)	• Acute cholecystitis
• Biliary colic	• Chronic cholecystitis
Complications	
• Empyema of the gallbladder	• Pressure on/inflammation of the common bile duct by a gallstone in the cystic duct (Mirizzi's syndrome)
• Porcelain gallbladder	• Gallstone ileus
• Choledocholithiasis	• Cancer of the gallbladder
• Acute pancreatitis	
• Fistulae from gallbladder to duodenum/colon	

gallstones and are best regarded as functional dyspepsia (p. 852).

Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing 'limey' bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of 'porcelain' gallbladder results.

Gallstones in the gallbladder (cholecystolithiasis) migrate to the common bile duct (choledocholithiasis, p. 984) in approximately 15% of patients and cause biliary colic. Rarely, fistulae develop between the gallbladder and the duodenum, colon or stomach. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may impact either at the terminal ileum or occasionally in the duodenum or sigmoid colon. The resultant intestinal obstruction may be followed by 'gallstone ileus'. Gallstones impacted in the cystic duct may cause stricturing of the common hepatic duct and the clinical picture of extrahepatic biliary diseases (with its important differential of malignant bile duct stricture). The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due (it is thought) to oedema at the ampulla as the stone passes into the duodenum (no stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage). Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease (it may present with jaundice, obstructive LFTs with biliary dilatation, post-cholecystectomy pain or acute pancreatitis).

Cancer of the gallbladder is uncommon (p. 985) but in over 95% of cases is associated with gallstones. The diagnosis is usually made as an incidental histological finding following cholecystectomy for gallstone disease.

Investigations

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has a greater than 92% sensitivity and 99% specificity for gallbladder stones (see Fig. 23.8, p. 930). CT (Fig. 23.43) and MRCP are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema), but are inferior to ultrasound in defining their presence in the gallbladder. When recurrent attacks of otherwise unexplained acute pancreatitis occur, this may result from 'microlithiasis' in the gallbladder or common bile duct, and this is best assessed by endoscopic ultrasound (EUS).

Management

Asymptomatic gallstones found incidentally should not be treated because the majority will never cause symptoms. Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy, with the severity of symptoms being balanced against the individual patient surgical risk in deciding whether surgery is warranted.

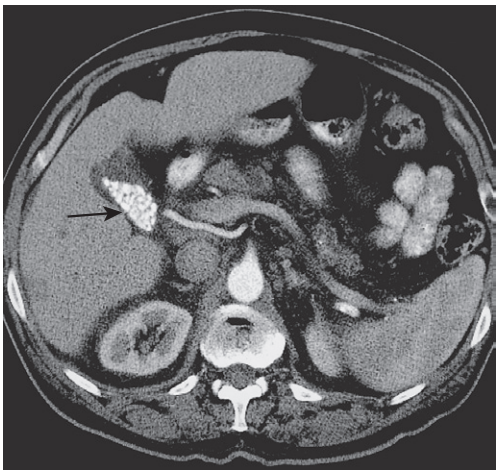

Fig. 23.43 CT showing gallstones within the gallbladder (arrow).

23.77 Treatment of gallstones

Gallbladder stones

- Cholecystectomy: open or laparoscopic
- Oral bile acids: chenodeoxycholic or ursodeoxycholic (low rate of stone dissolution)

Bile duct stones

- Lithotripsy (endoscopic or extracorporeal shock wave, ESWL)
- Endoscopic sphincterotomy and balloon trawl
- Surgical bile duct exploration

Various techniques can be used to treat common bile duct stones (Box 23.77).

Cholecystitis

Acute cholecystitis

Pathophysiology

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a bile tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage, which releases phospholipase, converting biliary lecithin to lysolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in elderly patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

Clinical features

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic (p. 982) and acute cholecystitis may be difficult;

features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness, rigidity worse on inspiration (Murphy's sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual. Jaundice occurs in less than 10% of patients and is usually due to passage of stones into the common bile duct, or compression or even stricturing of the common bile duct following stone impaction in the cystic duct (Mirizzi's syndrome). Gallbladder perforation occurs in 10–15% of cases, and gallbladder empyema may arise.

Investigations

Peripheral blood leucocytosis is common, except in the elderly patient, in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis (p. 889), which may be a potentially serious complication of gallstones. Only when the amylase is higher than 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur in many other causes of abdominal pain. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intrabiliary gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis, but gallbladder empyema or perforation is best assessed by CT.

Management

Medical

This consists of bed rest, pain relief, antibiotics and intravenous fluids. Moderate pain can be treated with NSAIDs but more severe pain should be managed with opiates. A cephalosporin (such as cefuroxime) or piperacillin/tazobactam is the usual antibiotic of choice, but metronidazole is normally added in severely ill patients and local prescribing practice may vary. Nasogastric aspiration is only needed for persistent vomiting. Cholecystitis usually resolves with medical treatment, but the inflammation may progress to an empyema or perforation and peritonitis.

Surgical

Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. Operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. When cholecystectomy may be difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

Chronic cholecystitis

Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often at night and following a heavy meal. The clinical features are similar to those of acute calculous cholecystitis but milder. The patient may recover spontaneously or following analgesia and antibiotics. Patients are usually advised to undergo elective laparoscopic cholecystectomy.

Acute cholangitis

Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems, such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, fever (with or without rigors) and right upper quadrant pain are the main presenting features ('Charcot's triad'). Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.

Choledocholithiasis

Stones in the common bile duct (choledocholithiasis) occur in 10–15% of patients with gallstones (Fig. 23.44), which have usually migrated from the gallbladder. Primary bile duct stones are rare but can develop within the common bile duct many years after a cholecystectomy, and are sometimes related to biliary sludge arising from dysfunction of the sphincter of Oddi. In Far Eastern countries, primary common bile duct stones are thought to follow bacterial infection secondary to parasitic infections with *Clonorchis sinensis*, *Ascaris lumbricoides* or *Fasciola hepatica* (pp. 377, 371 and 379). Common bile duct stones can cause bile duct obstruction and may be complicated by cholangitis due to secondary bacterial infection, septicaemia, liver abscess and biliary stricture.

Clinical features

Choledocholithiasis may be asymptomatic, may be found incidentally by operative cholangiography at

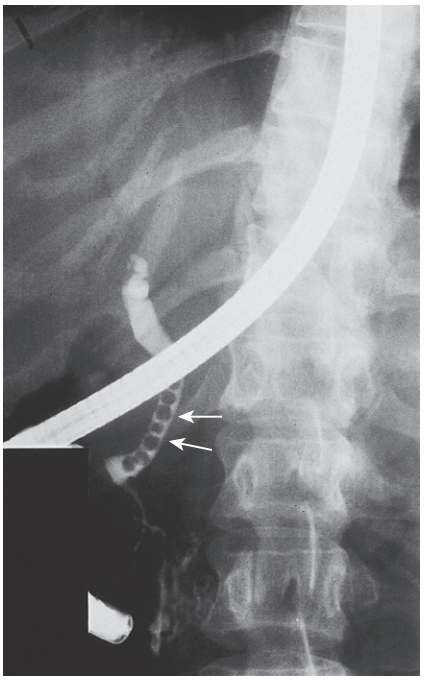

Fig. 23.44 ERCP showing common duct stones (arrows).

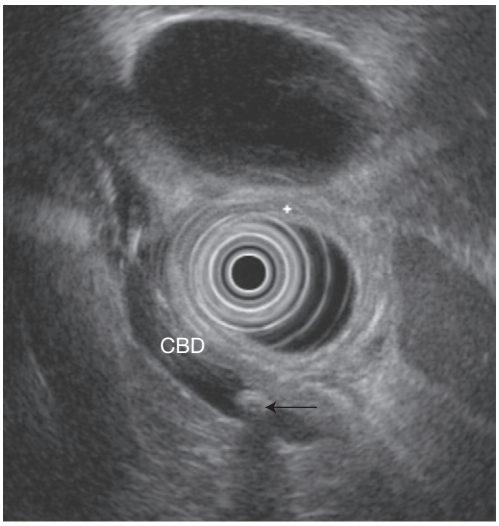

Fig. 23.45 Endoscopic ultrasound (EUS) image in a patient with cholangitis. The dilated common bile duct (CBD) contains a small stone (arrow), which causes acoustic shadowing.

cholecystectomy, or may manifest as recurrent abdominal pain with or without jaundice. The pain is usually in the right upper quadrant, and fever, pruritus and dark urine may be present. Rigors may be a feature; jaundice is common and usually associated with pain. Physical examination may show the scar of a previous cholecystectomy; if the gallbladder is present, it is usually small, fibrotic and impalpable.

Investigations

The LFTs show a cholestatic pattern and there is bilirubinuria. If cholangitis is present, the patient usually has a leucocytosis. The most convenient method of demonstrating obstruction to the common bile duct is by transabdominal ultrasound. This shows dilated extrahepatic and intrahepatic bile ducts, together with gallbladder stones (Fig. 23.45), but does not always reveal the cause of the obstruction in the common bile duct; 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. EUS is extremely accurate at identifying bile duct stones. MRCP is non-invasive, and is indicated when intervention is not necessarily mandatory (e.g. the patient with possible bile duct stones but no jaundice or sepsis).

Management

Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics, such as cefuroxime and metronidazole (local prescribing practice may vary). Blood cultures should be taken before the antibiotics are administered. Patients also require urgent decompression of the biliary tree and stone removal. ERCP with biliary sphincterotomy and stone extraction is the treatment of choice and is successful in about 90% of patients. If ERCP fails, other approaches include percutaneous transhepatic drainage and combined ('rendezvous') endoscopic procedures, extracorporeal shock wave lithotripsy (ESWL) and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP because it carries higher morbidity and mortality. Before the common bile duct is explored, the diagnosis of choledocholithiasis should be confirmed by intraoperative cholangiography. If gallstones are found, the bile duct is explored, all stones are removed, stone clearance is checked by cholangiography or choledochoscopy, and a T-tube is inserted into the common bile duct. It is now possible to achieve these goals laparoscopically in specialist centres.

Recurrent pyogenic cholangitis

This disease occurs predominantly in South-east Asia. Biliary sludge, calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage, and requires drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.

Tumours of the gallbladder and bile duct

Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually in those over the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder ('porcelain gallbladder', p. 983) are at high risk of malignant change, and gallbladder polyps over 1 cm in size are associated with increased risk of malignancy; preventative cholecystectomy should be considered in such patients. Chronic infection with *Salmonella*, especially in areas where typhoid is endemic, is also a risk factor.

Carcinoma of the gallbladder may be diagnosed incidentally and is found in 1–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and later persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and porcelain gallbladder may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision, but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is invariable and palliative management is usually all that can be offered. Survival is generally short, death typically occurring within 1 year in patients presenting with symptoms.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is an uncommon tumour that can arise anywhere in the biliary tree, from the intrahepatic bile ducts (20–25% of cases) and the confluence of the right and left hepatic ducts at the liver

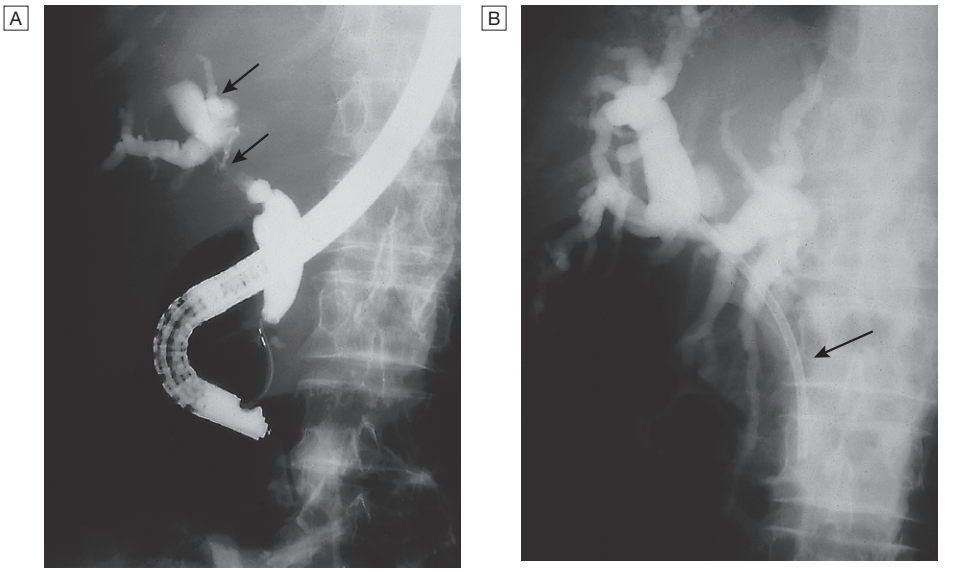

Fig. 23.46 Cholangiocarcinoma. A ERCP showing malignant biliary stricture (bottom arrow) and dilated intrahepatic bile ducts above (top arrow). B Post-ERCP stenting showing plastic endobiliary stent (arrow), which will drain bile from the dilated ducts above the stricture into the duodenum.

hilum (50–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the incidence is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli's disease and choledochal cysts (see Fig. 23.42, p. 981). In the Far East, particularly northern Thailand, chronic liver fluke infection (*Clonorchis sinensis*) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of approximately 20%, although only 5% of CCAs relate to primary sclerosing cholangitis. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths. The presentation is usually with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made by a combination of CT and MRI but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19–9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. Endoscopic ultrasound-fine needle aspiration (EUS-FNA) of bile duct masses is sometimes possible, and in specialist centres single-operator cholangioscopy with biopsy is now established. CCAs can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. However, most patients are treated by stent insertion across the malignant biliary stricture, using endoscopic or transhepatic techniques (Fig. 23.46). Combination chemotherapy is increasingly used and palliation with endoscopic photodynamic therapy has provided encouraging results.

Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relationship to the ampulla of Vater, and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour, but staging by CT/MRI is essential. Ampullary carcinoma must be differentiated from carcinoma of the head of the pancreas and a cholangiocarcinoma because these latter conditions both have a worse prognosis. Imaging may show a 'double duct sign' with stricturing of both the common bile duct and pancreatic duct at the ampulla and upstream dilatation of the ducts. EUS is the most sensitive method of assessing and staging ampullary or periampullary tumours.

Curative surgical treatment can be undertaken by pancreaticoduodenectomy, and the 5-year survival may be as high as 50%. If resection is impossible, palliative surgical bypass or stenting may be necessary.

Benign gallbladder tumours

These are uncommon, often asymptomatic and usually found incidentally at operation or postmortem. Cholesterol polyps, sometimes associated with cholesterolosis, papillomas and adenomas, are the main types.

Miscellaneous biliary disorders

Post-cholecystectomy syndrome

Dyspeptic symptoms following cholecystectomy (post-cholecystectomy syndrome) occur in about 30% of patients, depending on how the condition is defined, how actively symptoms are sought and the original indication for cholecystectomy. The syndrome occurs most frequently in women, in patients who have had symptoms for more than 5 years before cholecystectomy, and when the operation was undertaken for non-calculous

23.78 Causes of post-cholecystectomy symptoms

Immediate post-surgical	
• Bleeding • Biliary peritonitis • Abscess	• Bile duct trauma/transection • Fistula
Biliary	
• Common bile duct stones • Benign stricture • Tumour • Cystic duct stump syndrome	• Disorders of the ampulla of Vater (e.g. benign papillary fibrosis; sphincter of Oddi dysfunction)
Extrabiliary	
• Non-ulcer dyspepsia • Peptic ulcer • Pancreatic disease	• Gastro-oesophageal reflux • Irritable bowel syndrome • Functional abdominal pain

gallbladder disease. An increase in bowel habit resulting from bile acid diarrhoea occurs in about 5–10% of patients after cholecystectomy, and often responds to colestyramine 4–8 g daily. Severe post-cholecystectomy syndrome occurs in only 2–5% of patients. The main causes are listed in Box 23.78.

The usual symptoms include right upper quadrant pain, flatulence, fatty food intolerance, and occasionally jaundice and cholangitis. The LFTs may be abnormal and sometimes show cholestasis. Ultrasonography is used to detect biliary obstruction, and EUS or MRCP is used to seek common bile duct stones. If retained bile duct stones are excluded, sphincter of Oddi dysfunction should be considered (see below). Other investigations that may be required include upper gastrointestinal endoscopy, small bowel radiology and pancreatic function tests. The possibility of a functional illness should also be considered.

Sphincter of Oddi dysfunction

The sphincter of Oddi is a small smooth muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. Sphincter of Oddi dysfunction (SOD) is characterised by an increase in contractility that produces a benign non-calculous obstruction to the flow of bile or pancreatic juice. This may cause pancreaticobiliary pain, deranged LFTs or recurrent pancreatitis. A clinical classification system, based on clinical history, laboratory results and ERCP findings, is widely used (Boxes 23.79 and 23.80).

Clinical features

Patients with SOD, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease.

- *Patients with biliary-type SOD* experience recurrent, episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.
- *Patients with pancreatic SOD* usually present with unexplained recurrent attacks of pancreatitis.

Investigations

The diagnosis is established by excluding gallstones, including microlithiasis, and demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry. This is not, however, widely available and is associated with a high rate of procedure-related pancreatitis.

23.79 Classification of biliary sphincter of Oddi dysfunction

Biliary type I
• Biliary-type pain • Abnormal liver enzymes (ALT/AST > twice normal on two or more occasions) • Dilated common bile duct (> 12 mm diameter) • Delayed drainage of ERCP contrast beyond 45 mins
Biliary type II
• Biliary-type pain with one or two of the above criteria
Biliary type III
• Biliary-type pain with no other abnormalities

23.80 Classification of pancreatic sphincter of Oddi dysfunction

Pancreatic type I
• Pancreatic-type pain • Twice normal amylase or lipase • Pancreatic duct > 6 mm in the head or 5 mm in the body
Pancreatic type II
• Pancreatic-type pain with only one of the above criteria
Pancreatic type III
• Pancreatic-type pain with no other abnormalities

Management

All biliary SOD patients with type I disease are treated with endoscopic sphincterotomy. The results are good but patients should be warned that there is a high risk of complications, particularly acute pancreatitis. Manometry should ideally be performed in all suspected SOD type II and III patients, and 'speculative' sphincterotomy should be avoided. In type III patients without documented evidence of sphincter hypertension, medical therapy with nifedipine and/or low-dose amitriptyline may be tried. The role of botulinum toxin ('botox') injection into the sphincter to improve sphincter function remains unclear.

Pancreatic SOD can be treated with pancreatic stenting followed by pancreatic sphincterotomy, carried out in specialised units. Emerging evidence suggests that all patients being investigated by ERCP for suspected SOD should also undergo prophylactic pancreatic duct stenting, because this significantly reduces the rate of procedure-related acute pancreatitis.

Cholesterolosis of the gallbladder

In this condition, lipid deposits in the submucosa and epithelium appear as multiple yellow spots on the pink mucosa, giving rise to the description 'strawberry gallbladder'. Cholesterolosis of the gallbladder is usually asymptomatic but may occasionally present with right upper quadrant pain. Small, fixed filling defects may be visible on ultrasonography; the radiologist can usually differentiate between gallstones and cholesterolosis.

23.81 Gallbladder disease in old age

- **Gallstones**: by the age of 70 years, prevalence is around 30% in women and 19% in men.
- **Acute cholecystitis**: tends to be severe, may have few localising signs, and is associated with a high frequency of empyema and perforation. If such complications supervene, mortality may reach 20%.
- **Cholecystectomy**: mortality after urgent cholecystectomy for acute uncomplicated cholecystitis is not significantly higher than in younger patients.
- **Endoscopic sphincterotomy and removal of common duct stones**: well tolerated by older patients, with lower mortality than surgical common bile duct exploration.
- **Cancer of the gallbladder**: a disease of old age, with a 1-year survival of 10%.

The condition is usually diagnosed at cholecystectomy; if the diagnosis is made radiologically, cholecystectomy may be indicated, depending on symptoms.

Adenomyomatosis of the gallbladder

In this condition, there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitansky–Aschoff sinuses. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It may be diagnosed by oral cholecystography, when a halo or ring of opacified diverticula can be seen around the gallbladder. Other appearances include deformity of the body of the gallbladder or marked irregularity of the outline. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a 'Phrygian cap'. Most patients are treated by cholecystectomy but only after excluding other diseases in the upper gastrointestinal tract.

IgG4-associated cholangitis

This recently reported disease often presents with obstructive jaundice and is discussed fully on page 966.

CLINICAL EXAMINATION IN BLOOD DISEASE

 Insets (*Glossitis*) From Hoffbrand, et al. 2010; (*Petechiae*) Young, et al. 2006 – see p. 1056.

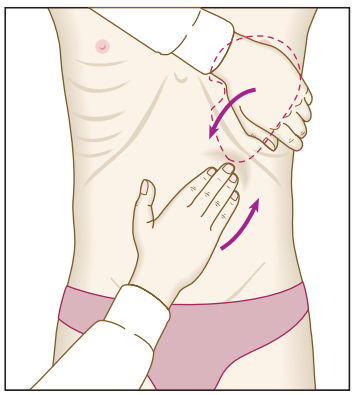
Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems, but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities must include a general history and examination, as well as a search for symptoms and signs of abnormalities of red cells, white cells, platelets, haemostatic systems, lymph nodes and lymphoreticular tissues.

6 Lymphadenopathy

Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.

Lymphadenopathy

History



- Speed of onset, rate of enlargement
- Painful or painless
- Associated symptoms: weight loss, night sweats, itch

Examination

- Sites: localised, generalised
- Size (cm)
- Character: hard, soft, rubbery
- Fixed, mobile
- Search area that node drains for abnormalities (e.g. dental abscess)
- Other general examination (e.g. joints, rashes, finger clubbing)

8 Examination of the spleen

- Move hand up from right iliac fossa, towards left upper quadrant on expiration.
- Keep hand still and ask patient to take a deep breath through the mouth to feel spleen edge being displaced downwards.
- Place your left hand around patient's lower ribs and approach costal margin to pull spleen forwards.
- To help palpate small spleens, roll the patient on to the right side and examine as before.

Characteristics of the spleen

- Notch
- Superficial
- Dull to percussion
- Cannot get examining hand between ribs and spleen
- Moves well with respiration

Anaemia

Symptoms and signs help to indicate the clinical severity of anaemia. A full history and examination is needed to identify the underlying cause.

Anaemia

Non-specific symptoms

- Tiredness
- Lightheadedness
- Breathlessness
- Development/worsening of ischaemic symptoms, e.g. angina or claudication

Non-specific signs

- Mucous membrane pallor
- Tachypnoea
- Raised jugular venous pressure
- Tachycardia
- Flow murmurs
- Ankle oedema
- Postural hypotension

Bleeding

Bleeding can be due to congenital or acquired abnormalities in the clotting system. History and examination help to clarify the severity and underlying cause of the bleeding.

Bleeding

History

- Site of bleed
- Duration of bleed
- Precipitating causes, including previous surgery or trauma
- Family history
- Drug history
- Age at presentation
- Other medical conditions, e.g. liver disease

Examination

There are two main patterns of bleeding:

1. **Mucosal bleeding**
   Reduced number or function of platelets (e.g. bone marrow failure or aspirin) or von Willebrand factor (e.g. von Willebrand disease)
   Skin: petechiae, bruises
   Gum and mucous membrane bleeding
   Fundal haemorrhage
   Post-surgical bleeding
2. **Coagulation factor deficiency**
   (e.g. haemophilia or warfarin)
   Bleeding into joints (haemarthrosis) or muscles
   Bleeding into soft tissues
   Retroperitoneal haemorrhage
   Intracranial haemorrhage
   Post-surgical bleeding

Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting mankind (anaemias) to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur as a consequence of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Blood flows throughout the body in the vascular system, and consists of:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which defend against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding
- plasma, which contains proteins with many functions, including antibodies and coagulation factors.

Haematopoiesis

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the liver and spleen, and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow), so that, in adults, normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red marrow can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made up of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 24.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and also phagocytoses nuclei from red cells prior to their release into the circulation. Megakaryocytes are large cells which produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells which normally represent less than 5% of the marrow population and are scattered throughout the intertrabecular spaces.

Stem cells

All blood cells are derived from pluripotent haematopoietic stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e. make more stem cells) or differentiate to produce a hierarchy of lineage-committed stem cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU–GM (colony-forming unit – granulocyte, monocyte) are stem cells that produce granulocytic and monocytic lines, CFU–E produce erythroid cells, and CFU–Meg produce megakaryocytes and ultimately platelets (Fig. 24.2).

Growth factors, produced in bone marrow stromal cells and elsewhere, control the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as interleukin-3 (IL-3), stem cell factor (SCF) and granulocyte, macrophage–colony-stimulating factor (GM–CSF), act on a wide number of cell types at various stages of differentiation. Others,

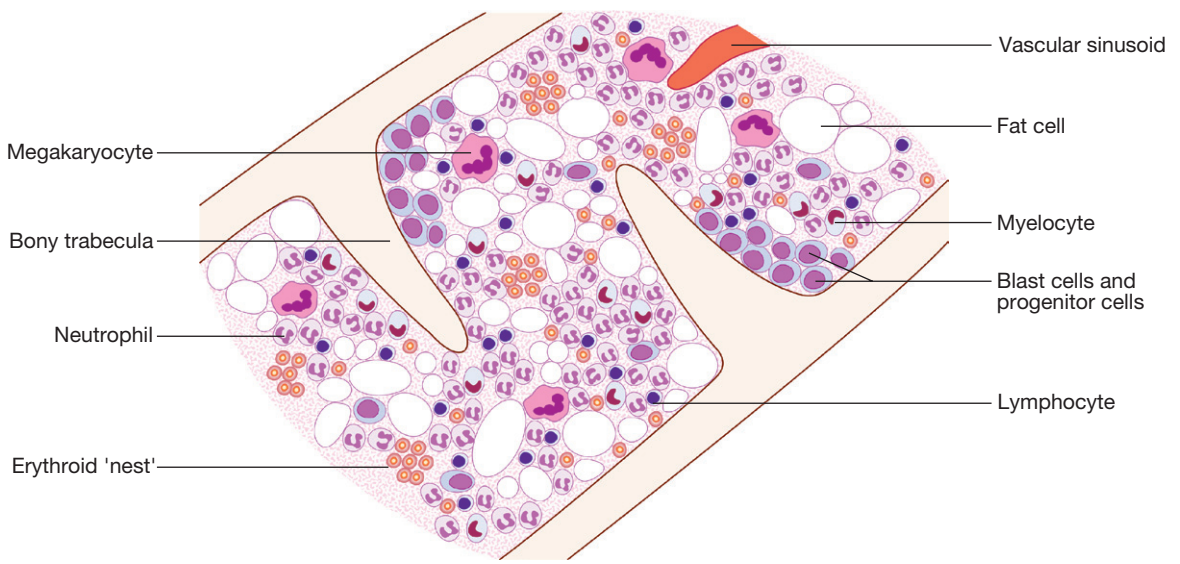


Fig. 24.1 Structural organisation of normal bone marrow.

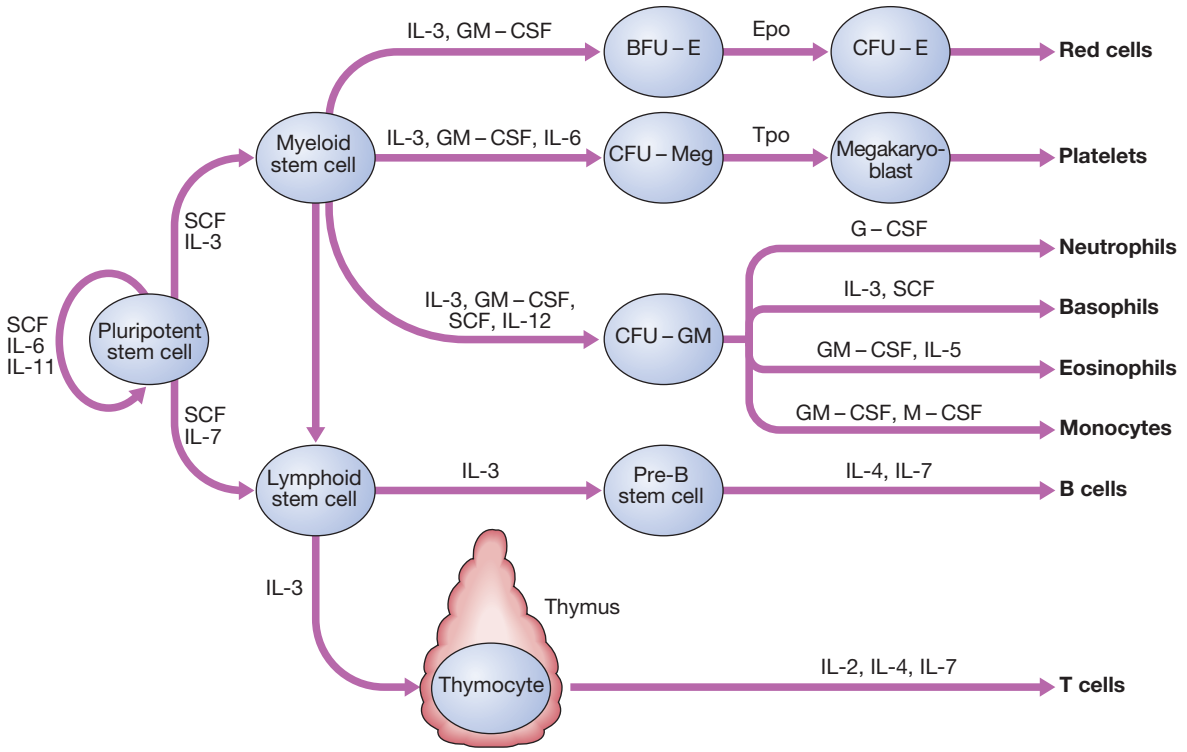

Fig. 24.2 Stem cells and growth factors in haematopoietic cell development. (BFU-E = burst-forming unit – erythroid; CFU–E = colony-forming unit – erythroid; CFU–GM = colony-forming unit – granulocyte, monocyte; CFU–Meg = colony-forming unit – megakaryocyte; Epo = erythropoietin; G–CSF = granulocyte–colony-stimulating factor; GM–CSF = granulocyte, macrophage–colony-stimulating factor; IL = interleukin; M–CSF = macrophage–colony-stimulating factor; SCF = stem cell factor; Tpo = thrombopoietin)

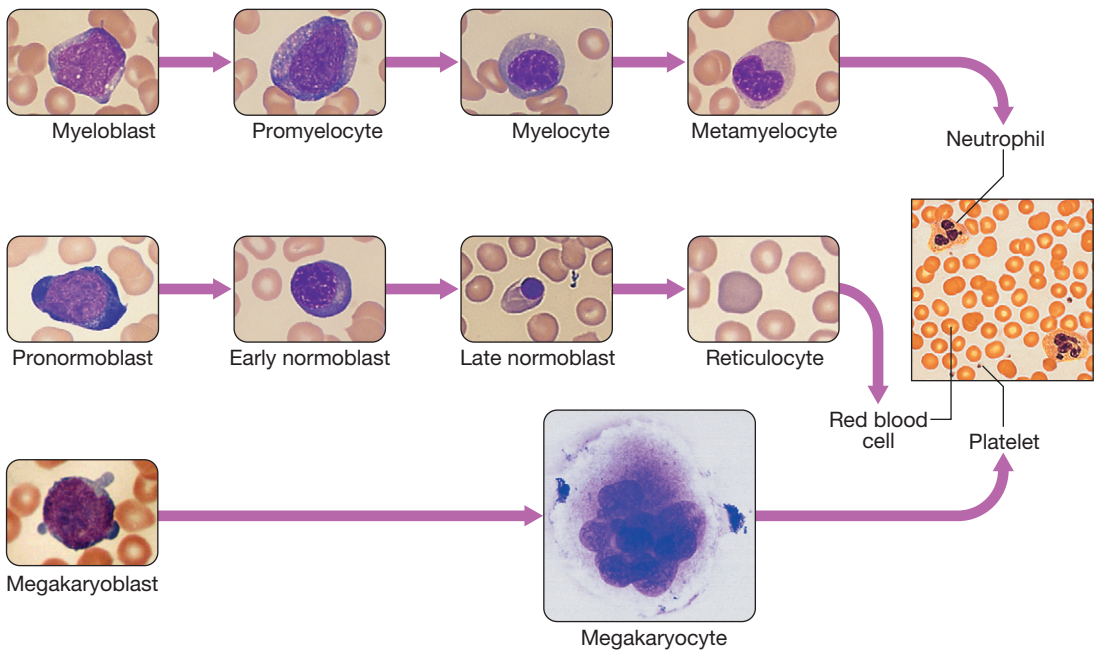

Fig. 24.3 Maturation pathway of red cells, granulocytes and platelets. The image on the right is normal blood film.

such as erythropoietin (Epo), granulocyte–colony-stimulating factor (G–CSF) and thrombopoietin (Tpo), are lineage-specific. Many of these growth factors are now synthesised by recombinant DNA technology and used as treatments: for example, Epo to correct renal anaemia and G–CSF to hasten neutrophil recovery after chemotherapy.

The bone marrow also contains stem cells which can differentiate into non-haematological cells, such as nerve, skeletal muscle, cardiac muscle, liver and blood

vessel endothelium. This is termed stem-cell plasticity and may have exciting clinical applications in the future (Ch. 3).

Blood cells and their functions

Red cells

Red cell precursors formed in the bone marrow from the erythroid (CFU–E) progenitor cells are called erythroblasts or normoblasts (Fig. 24.3). These divide and acquire haemoglobin, which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte, which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge ('polychromasia'). Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by erythropoietin, a polypeptide hormone produced by renal interstitial peritubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure (p. 478) causes anaemia, which can be treated with exogenous recombinant erythropoietin.

Normal mature red cells circulate for about 120 days. They are 8 µm biconcave discs lacking a nucleus but filled with haemoglobin, which delivers oxygen to the tissues. In order to pass through the smallest capillaries, the red cell membrane is deformable, with a lipid bilayer to which a 'skeleton' of filamentous proteins is attached via special linkage proteins (Fig. 24.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 24.8D, p. 999). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 24.4). The ABO and Rhesus systems are the most commonly recognised (p. 1012), but over 400 blood group antigens have been described.

Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A ($\alpha\alpha/\beta\beta$) represents over 90% of adult haemoglobin, whereas haemoglobin F ($\alpha\alpha/\gamma\gamma$) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe^{2+}), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains 'swing' closer together; they move apart as oxygen is lost. In the 'open' deoxygenated state, 2,3 diphosphoglycerate (DPG), a product of red cell metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 24.5). The position of this curve depends upon the concentrations of 2,3 DPG, H^+ ions and CO_2; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g. when

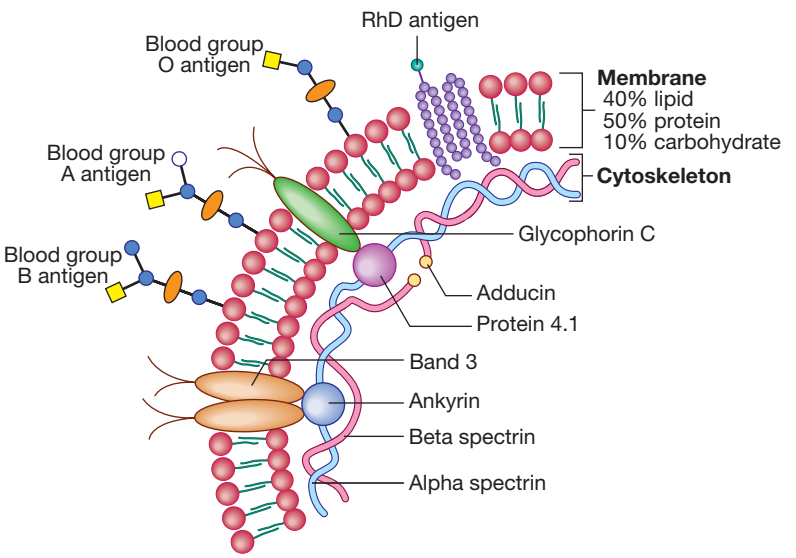

Fig. 24.4 Normal structure of red cell membrane. Red cell membrane flexibility is conferred by attachment of cytoskeletal proteins. Important transmembrane proteins include band 3 (an ion transport channel) and glycophorin (involved in cytoskeletal attachment and gas exchange, and a receptor for *Plasmodium falciparum* in malaria). Antigens on the red blood cell determine an individual's blood group. There are about 22 blood group systems (groups of carbohydrate or protein antigens controlled by a single gene or by multiple closely linked loci); the most important clinically are the ABO and Rhesus (Rh) systems (p. 1012). The ABO genetic locus has three main allelic forms: A, B and O. The A and B alleles encode glycosyltransferases that introduce N-acetylgalactosamine (open circle) and D-galactose (blue circle), respectively, on to antigenic carbohydrate molecules on the membrane surface. People with the O allele produce an O antigen, which lacks either of these added sugar groups. Rh antigens are transmembrane proteins.

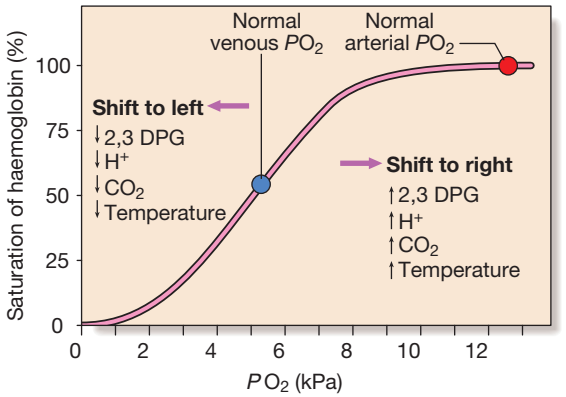

Fig. 24.5 The haemoglobin oxygen dissociation curve. Factors are listed which shift the curve to the right (more oxygen released from blood) and to the left (less oxygen released) at given PO_2. (To convert kPa to mmHg, multiply by 7.5.)

red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3 DPG and has a left-shifted oxygen dissociation curve, which, together with the low pH of fetal blood, ensures fetal oxygenation.

Genetic mutations affecting the haem-binding pockets of globin chains or the 'hinge' interactions between globin chains result in haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16, and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains results in the thalassaemias (p. 1034). Defects in haem synthesis cause the porphyrias (p. 458).

Destruction

Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for re-use in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

White cells

White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 24.12, p. 1004). Granulocytes and monocytes are formed from bone marrow CFU-GM progenitor cells during myelopoiesis. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleoli. As the cells divide and mature, the nucleus segments and the cytoplasm acquires specific neutrophilic, eosinophilic or basophilic granules (see Fig. 24.3). This takes about 14 days. The cytokines G-CSF, GM-CSF and M-CSF are involved in the production of myeloid cells, and G-CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally found only in the marrow but may appear in the circulation in infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a 'leucoerythroblastic' picture; this indicates a serious disturbance of marrow function.

Neutrophils

Neutrophils, the most common white blood cells in the blood of adults, are 10–14 μm in diameter, with a multilobular nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (p. 72). A large storage pool of mature neutrophils exists in the bone marrow. Every day, some 10^{11} neutrophils enter the circulation, where cells may be circulating freely or attached to endothelium in the marginating pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in the circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

Eosinophils

Eosinophils represent 1–6% of the circulating white cells. They are a similar size to neutrophils but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (p. 311). They are also involved in allergic reactions (e.g. atopic asthma, p. 666; see also p. 89).

Basophils

These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules which obscure the nucleus. Mast cells resemble basophils but are found only in the tissues. These cells are involved in hypersensitivity reactions (p. 75).

Monocytes

Monocytes are the largest of the white cells, with a diameter of 12–20 μm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into tissue, where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1, p. 74).

Lymphocytes

Lymphocytes are derived from pluripotent haematopoietic stem cells in the bone marrow. There are two main types: T cells (which mediate cellular immunity) and B cells (which mediate humoral immunity) (p. 77). Lymphoid cells that migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow.

The majority (about 80%) of lymphocytes in the circulation are T cells. Lymphocytes are heterogeneous, the smallest being the size of red cells and the largest the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm but larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations have specific functions and lifespan can vary from a few days to many years. Cell surface antigens ('cluster of differentiation' (CD) antigens), which appear at different points of lymphocyte maturation, are used to classify lymphomas and lymphoid leukaemias.

Haemostasis

Blood must be maintained in a fluid state in order to function as a transport system, but must be able to solidify to form a clot following vascular injury in order to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets, coagulation factors, natural anticoagulants and fibrinolytic enzymes (Fig. 24.6). Dysfunction of any of these components may result in haemorrhage or thrombosis.

Platelets

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic stem cells (CFU–Meg) divide to form megakaryoblasts, which undergo a process called 'endomitotic reduplication', in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Large numbers of platelets then fragment off from each megakaryocyte into the circulation. The formation and maturation of megakaryocytes are stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the

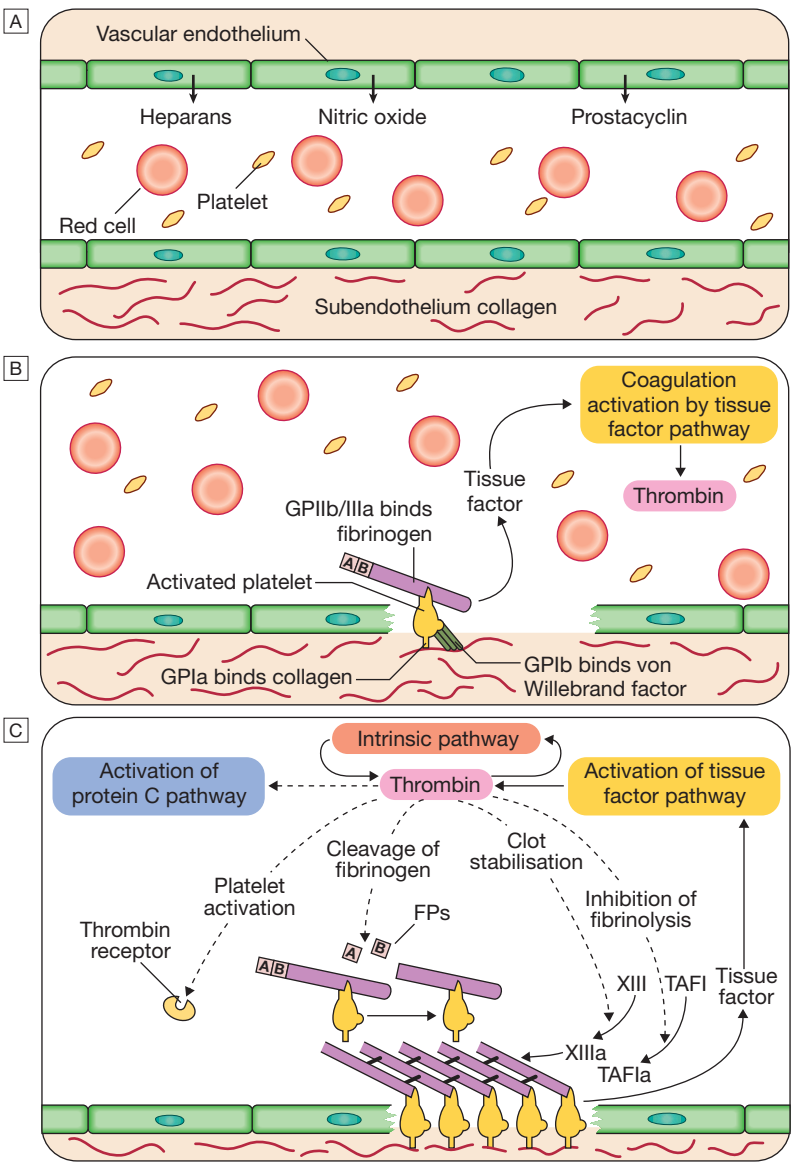

Fig. 24.6 The stages of normal haemostasis.

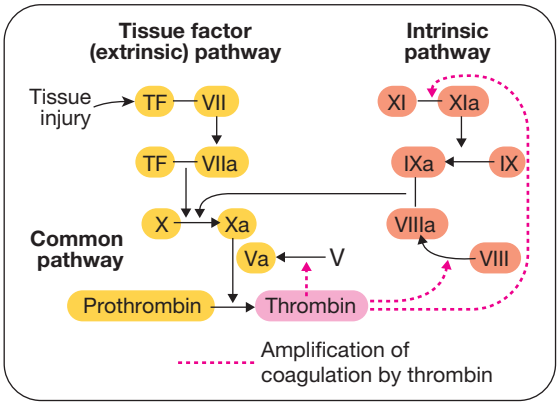
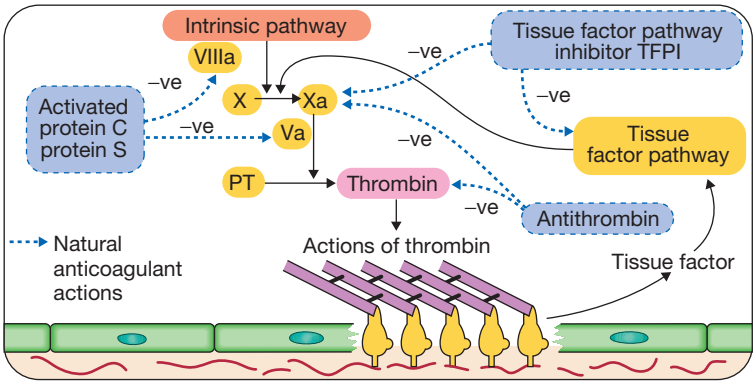
A *Stage 1 Pre-injury conditions encourage flow* The vascular endothelium produces substances (including nitric oxide, prostacyclin and heparans) to prevent adhesion of platelets and white cells to the vessel wall. Platelets and coagulation factors circulate in a non-activated state.

B *Stage 2 Early haemostatic response: platelets adhere; coagulation is activated.* At the site of injury, the endothelium is breached, exposing subendothelial collagen. Small amounts of tissue factor (TF) are released. Platelets bind to collagen via a specific receptor, glycoprotein Ia (GPIa), causing a change in platelet shape and its adhesion to the area of damage by the binding of other receptors (GPIb and GPIIb/IIIa) to von Willebrand factor and fibrinogen, respectively. Coagulation is activated by the tissue factor (extrinsic) pathway, generating small amounts of thrombin.

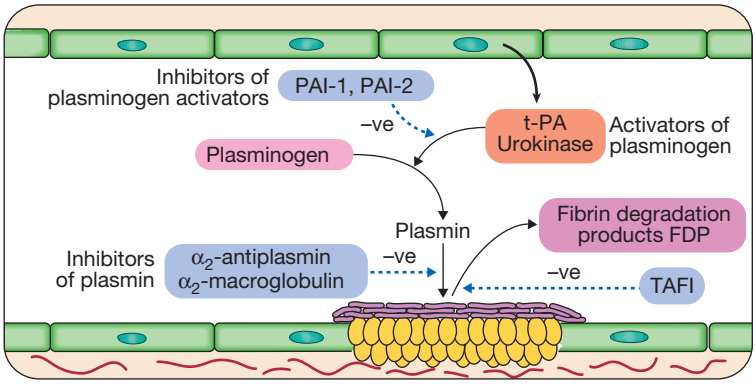
C *Stage 3 Fibrin clot formation: platelets become activated and aggregate; fibrin formation is supported by the platelet membrane; stable fibrin clot forms.* The adherent platelets are activated by many pathways, including binding of adenosine diphosphate (ADP), collagen, thrombin and adrenaline (epinephrine) to surface receptors. The cyclo-oxygenase pathway converts arachidonic acid from the platelet membrane into thromboxane A_2, which causes aggregation of platelets. Activation of the platelets results in release of the platelet granule contents, enhancing coagulation further (see Fig. 24.7). Thrombin plays a key role in the control of coagulation: the small amount generated via the TF pathway massively amplifies its own production; the 'intrinsic' pathway becomes



reticulo-endothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.



Under normal conditions platelets are discoid, with a diameter of 2–4 μm (Fig. 24.7). The surface membrane invaginates to form a tubular network, the canalicular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs which inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopidogrel (adenosine diphosphate (ADP)-mediated activation inhibitor), dipyridamole (phosphodiesterase inhibitor), and the IIb/IIIa inhibitors abciximab, tirofiban and eptifibatide (which prevent fibrinogen binding; p. 594).



Clotting factors

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman numerals. When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix 'a'. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways: it is initiated by the extrinsic (or tissue factor) pathway and amplified by the 'intrinsic pathway' (see Fig. 24.6).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow them to participate in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is inhibited by warfarin, and this is the basis of the anticoagulant effect of coumarins (p. 1019). Congenital (e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.

activated and large amounts of thrombin are generated. Thrombin directly causes clot formation by cleaving fibrinopeptides (FP) from fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see D and E).

D *Stage 4 Limiting clot formation: natural anticoagulants reverse activation of coagulation factors.* Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as XIa, Xa and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates VIIa and Xa. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor protein S (PS), and cleaves Va and VIIIa. PC and PS are vitamin K-dependent and are depleted by coumarin anticoagulants such as warfarin.

E *Stage 5 Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair.* The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (t-PA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products, including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by α_2-antiplasmin and α_2-macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.

INVESTIGATION OF DISEASES OF THE BLOOD

The full blood count

To obtain a full blood count (FBC), anticoagulated blood is processed through automated blood analysers which use a variety of technologies (particle-sizing, radio-frequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices which give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a number of conditions can lead to spurious results (Box 24.1). The reference ranges for a number of common haematological parameters in adults are given in Chapter 29.

Blood film examination

Although technical advances in full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the 'blood film') can often yield valuable information (Box 24.2 and Fig. 24.8). Analysers cannot identify abnormalities of red cell shape and content (e.g. Howell–Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

24.1 Spurious FBC results from autoanalysers

Result	Explanation
Increased haemoglobin	Lipaemia, jaundice, very high white cell count
Reduced haemoglobin	Improper sample mixing, blood taken from vein into which an infusion is flowing
Increased red cell volume (MCV)	Cold agglutinins, non-ketotic hyperosmolarity
Increased white cell count	Nucleated red cells present
Reduced platelet count	Clot in sample, platelet clumping

Bone marrow examination

In adults, bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow can be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 24.9). A bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome and molecular studies to assess malignant disease, or marrow culture for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow fibrosis, and infiltration by abnormal cells such as metastatic carcinoma.

24.2 How to interpret red cell appearances

Microcytosis (reduced average cell size, MCV < 76 fL) A

- Iron deficiency
- Thalassaemia
- Sideroblastic anaemia

Macrocytosis (increased average cell size, MCV > 100 fL) B

- Vitamin B_{12} or folate deficiency
- Liver disease, alcohol
- Hypothyroidism
- Drugs (e.g. zidovudine, trimethoprim, phenytoin, methotrexate)

Target cells (central area of haemoglobinisation) C

- Liver disease
- Thalassaemia
- Post-splenectomy
- Haemoglobin C disease

Spherocytes (dense cells, no area of central pallor) D

- Autoimmune haemolytic anaemia
- Post-splenectomy
- Hereditary spherocytosis

Red cell fragments (intravascular haemolysis) E

- Microangiopathic haemolysis, e.g. HUS, TTP
- DIC

Nucleated red blood cells (normoblasts) F

- Marrow infiltration
- Severe haemolysis
- Myelofibrosis
- Acute haemorrhage

Howell–Jolly bodies (small round nuclear remnants) G

- Hyposplenism
- Post-splenectomy
- Dyshaematopoiesis

Polychromasia (young red cells – reticulocytes present) H

- Haemolysis, acute haemorrhage
- Increased red cell turnover

Basophilic stippling (abnormal ribosomal RNA appears as blue dots) I

- Dyshaematopoiesis
- Lead poisoning

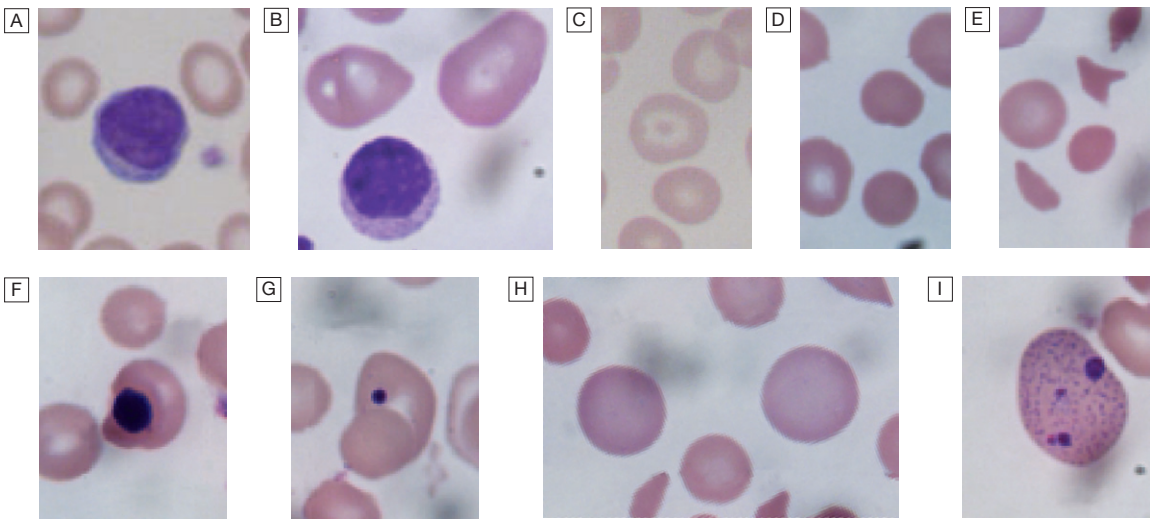

Fig. 24.8 Appearance of red blood cells. A Microcytosis. B Macrocytosis. C Target cells. D Spherocytes. E Red cell fragments. F Nucleated red blood cells. G Howell–Jolly bodies. H Polychromasia. I Basophilic stippling.

(DIC = disseminated intravascular coagulation; HUS = haemolytic uraemic syndrome; MCV = mean cell volume; TTP = thrombotic thrombocytopenic purpura)

Investigation of coagulation

Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 991), there are recommended screening tests (Box 24.3).

Coagulation tests measure the time to clot formation in vitro in a plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The tissue factor ('extrinsic') pathway (see Fig 24.6) is assessed by the prothrombin time (PT), and the 'intrinsic' pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin (PTTK). Coagulation is delayed by deficiencies of coagulation factors and by the presence of inhibitors of coagulation, such as heparin. The approximate reference ranges and causes of abnormalities are shown in Box 24.3. If both the PT and APTT are prolonged, this indicates either deficiency or inhibition of the final common pathway (which includes factors X, V, prothrombin and fibrinogen) or global coagulation factor deficiency involving more than one factor, as occurs in disseminated intravascular coagulation (DIC, pp. 201 and 1055). Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma

D Bone marrow aspirate needle. E Stained macroscopic appearance of marrow aspirate: smear (left) and squash (right). F Microscopic appearance of stained marrow particles and trails of haematopoietic cells.

24.3 Coagulation screening tests

Investigation	Reference range*	Situations in which tests may be abnormal
Platelet count	150–400 × 10^9/L	Thrombocytopenia
Prothrombin time (PT)	9–12 secs	Deficiencies of factors II, V, VII or X Severe fibrinogen deficiency
Activated partial thromboplastin time (APTT)	26–36 secs	Deficiencies of factors II, V, VIII, IX, X, XI, XII Severe fibrinogen deficiency Unfractionated heparin therapy Antibodies against clotting factors Lupus anticoagulant
Fibrinogen concentration	1.5–4.0 g/L	Hypofibrinogenaemia, e.g. liver failure, DIC

N.B. International normalised ratio (INR) is used only to monitor coumarin therapy and is not a coagulation screening test.
*Ranges are approximate and may vary between laboratories.
(DIC = disseminated intravascular coagulation)

allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be chemical (heparins) or an antibody (most often a lupus anticoagulant but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 1053.

Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin and ADP, or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate (ATP)/ADP.

Coagulation screening tests are also performed in patients with suspected DIC, when clotting factors and platelets are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with consumption of fibrinogen and generation of fibrin degradation products (D-dimers). Note, however, that fibrinogen is an acute phase protein which may also be elevated in inflammatory disease (p. 82).

Monitoring anticoagulant therapy

The international normalised ratio (INR) is validated only to assess the therapeutic effect of coumarin anticoagulants, including warfarin. INR is the ratio of the patient's PT to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by comparison with an international reference standard material).

Monitoring of heparin therapy is, on the whole, only required with unfractionated heparins. Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of approximately 1.5–2.5. Low molecular weight heparins have such a predictable dose

response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (glomerular filtration rate less than 30 mL/min). When monitoring is indicated, an anti-Xa activity assay rather than APTT should be used.

Thrombotic disorders

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active venous thrombosis in some patients (see Fig. 24.15, p. 1010).

A variety of tests exist which may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (thrombophilia) (Box 24.4). Examples of possible indications for testing are given in Box 24.5. In most patients, the results do not affect clinical management (p. 1054) but they may influence the duration of anticoagulation (e.g. antiphospholipid antibodies, p. 1055), justify family screening in inherited thrombophilias (p. 1054), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 1031). Anticoagulants can interfere with some of these assays; for example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant, while heparin interferes with antithrombin and lupus anticoagulant assays. Therefore these tests, when required, should be performed when the patient is not taking anticoagulants.

24.4 Investigation of possible thrombophilia

Full blood count

Plasma levels
- Antithrombin
- Protein C
- Protein S (free)
- Antiphospholipid antibodies/lupus anticoagulant and anticardiolipin antibody

Thrombin/reptilase time (for dysfibrinogenaemia)

Genetic testing
- Factor V Leiden
- Prothrombin G20210A
- *JAK-2* mutation

Flow cytometry
- Screen for glycerol phosphatidyl inositol (GPI)-linked cell surface proteins (CD14, 16, 55, 59), deficient in paroxysmal nocturnal haemoglobinuria

24.5 Indications for thrombophilia testing*

- Venous thrombosis < 45 yrs
- Recurrent venous thrombosis
- Family history of unprovoked or recurrent thrombosis
- Combined arterial and venous thrombosis
- Venous thrombosis at an unusual site
  - Cerebral venous thrombosis
  - Hepatic vein (Budd–Chiari syndrome)
  - Portal vein, mesenteric vein

*Antiphospholipid antibodies should be sought where clinical criteria for antiphospholipid syndrome (APS) are fulfilled (p. 1055). Thrombophilia testing may explain the diagnosis without necessarily affecting management.

24.6 Haematological investigations in old age

- **Blood cell counts and film components**: not altered in general by ageing alone, although haemoglobin concentrations fall with increasing age.
- **Ratio of bone marrow cells to marrow fat**: falls.
- **Neutrophils**: maintained throughout life, although leucocytes may be less readily mobilised by bacterial invasion in old age.
- **Lymphocytes**: functionally compromised by age due to a T cell-related defect in cell-mediated immunity.
- **Clotting factors**: no major changes, although mild congenital deficiencies may be first noticed in old age.
- **Erythrocyte sedimentation rate (ESR)**: raised above the reference range, but usually in association with chronic or subacute disease. In truly healthy older people, the ESR range is very similar to that in younger people.

PRESENTING PROBLEMS IN BLOOD DISEASE

Anaemia

Anaemia refers to a state in which the level of haemoglobin in the blood is below the reference range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must be taken into account when considering whether an individual is anaemic. The clinical features of anaemia reflect diminished oxygen supply to the tissues (p. 991). A rapid onset of anaemia (e.g. due to blood loss) causes more profound symptoms than a gradually developing anaemia. Individuals with cardiorespiratory disease are more susceptible to symptoms of anaemia.

The clinical assessment and investigation of anaemia should gauge its severity and define the underlying cause (Box 24.7).

Clinical assessment

- *Iron deficiency anaemia* (p. 1021) is the most common type of anaemia worldwide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia

24.7 Causes of anaemia

Decreased or ineffective marrow production
- Lack of iron, vitamin B_{12} or folate
- Hypoplasia/myelodysplasia
- Invasion by malignant cells
- Renal failure
- Anaemia of chronic disease

Normal marrow production but increased removal of cells
- Blood loss
- Haemolysis
- Hypersplenism

is a common cause of anaemia in pre-menopausal females, so women should always be asked about their periods.

- *A dietary history* should assess the intake of iron and folate, which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; pp. 1025 and 125).
- *Past medical history* may reveal a disease which is known to be associated with anaemia, such as rheumatoid arthritis (anaemia of chronic disease), or previous surgery (e.g. resection of the stomach or small bowel, which may lead to malabsorption of iron and/or vitamin B_{12}).
- *Family history and ethnic background* may raise suspicion of haemolytic anaemias, such as the haemoglobinopathies and hereditary spherocytosis. Pernicious anaemia may also be familial.
- *A drug history* may reveal the ingestion of drugs which cause blood loss (e.g. aspirin and anti-inflammatory drugs), haemolysis (e.g. sulphonamides) or aplasia (e.g. chloramphenicol).

On examination, as well as the general physical findings of anaemia shown on page 991, there may be specific findings related to the aetiology of the anaemia; for example, a patient may be found to have a right iliac fossa mass due to an underlying caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B_{12} deficiency may be associated with neurological signs, including peripheral neuropathy, dementia and signs of subacute combined degeneration of the cord (p. 1025). Sickle-cell anaemia (p. 1032) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia may be multifactorial and the lack of specific symptoms and signs does not rule out silent pathology.

Investigations

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:

- A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease (ACD) (Fig. 24.10).
- A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia (see Fig. 24.10).
- A high MCV (macrocytic anaemia) suggests vitamin B_{12} or folate deficiency or myelodysplasia (Fig. 24.11).

Specific types of anaemia and their management are described later in this chapter (p. 1021).

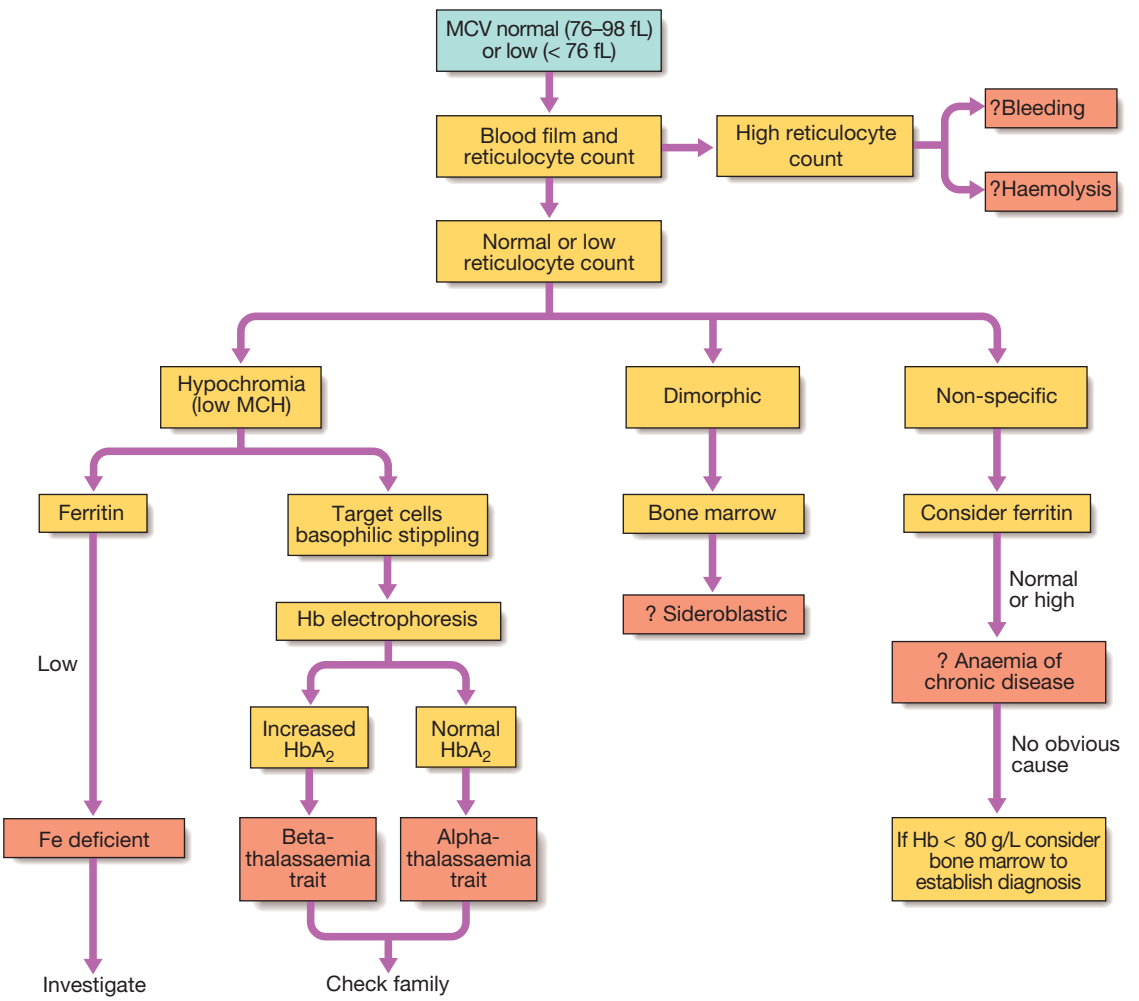

Fig. 24.10 Investigation of anaemia with normal or low MCV.

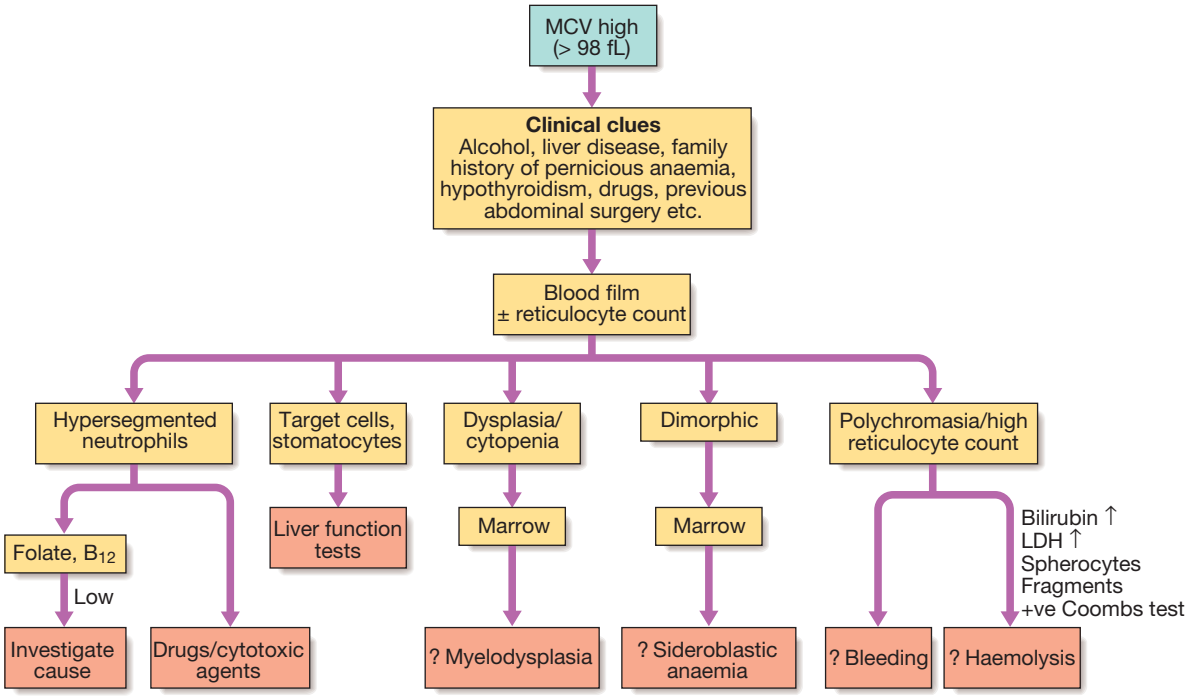

Fig. 24.11 **Investigation of anaemia with high MCV.** (LDH = lactate dehydrogenase)

24.8 Classification and causes of erythrocytosis

	Absolute erythrocytosis	Relative (low-volume) erythrocytosis
Haematocrit	High	High
Red cell mass	High	Normal
Plasma volume	Normal	Low
Causes	*Primary* Myeloproliferative disorder Polycythaemia rubra vera (primary proliferative polycythaemia) *Secondary* High erythropoietin due to tissue hypoxia High altitude Cardiorespiratory disease High-affinity haemoglobins Inappropriately increased erythropoietin Renal disease (hydronephrosis, cysts, carcinoma) Other tumours (hepatoma, bronchogenic carcinoma, uterine fibroids, phaeochromocytoma, cerebellar haemangioblastoma) Exogenous erythropoietin administration Performance-enhancing drug-taking in athletes	Diuretics Smoking Obesity Alcohol excess Gaisbock's syndrome

High haemoglobin

Patients with a persistently raised haematocrit (Hct) (> 0.52 males, > 0.48 females) for more than 2 months should be investigated. 'True' polycythaemia (or absolute erythrocytosis) indicates an excess of red cells, while 'relative' (or 'low-volume') polycythaemia is due to a decreased plasma volume. Causes are shown in Box 24.8.

Clinical assessment and investigations

Males and females with Hct values of over 0.60 and over 0.56, respectively, can be assumed to have an absolute erythrocytosis. A clinical history and examination will identify most patients with polycythaemia secondary to hypoxia. The presence of hypertension, smoking, excess alcohol consumption and/or diuretic use is consistent with low-volume polycythaemia (Gaisbock's syndrome). In polycythaemia rubra vera (PRV), a mutation in a kinase, *JAK-2 V617F*, is found in over 90% of cases (p. 1049). Patients with PRV have an increased risk of arterial thromboses, particularly stroke, and venous thromboembolism. They may also have aquagenic pruritus (worse after a hot bath), hepatosplenomegaly and gout (due to high red cell turnover).

If the *JAK-2* mutation is absent and there is no obvious secondary cause, a measurement of red cell mass is required to confirm an absolute erythrocytosis, followed

by further investigations to exclude hypoxia, and causes of inappropriate erythropoietin secretion. Red cell mass measurement is performed by radiolabelling an aliquot of the patient's red cells, re-injecting them and measuring the dilution of the isotope.

Leucopenia (low white cell count)

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types (usually neutrophils or lymphocytes). Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 1008).

Neutropenia

A reduction in neutrophil count (usually less than 1.5×10^9/L, but dependent on age and race) is called neutropenia. The main causes are listed in Box 24.9.

Drug-induced neutropenia is not uncommon (Box 24.10). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than 0.5×10^9/L considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy is not commenced. Management is discussed on page 302.

Lymphopenia

This is an absolute lymphocyte count of less than 1×10^9/L. The causes are shown in Box 24.9. Although minor reductions may be asymptomatic, deficiencies in cell-mediated immunity may result in infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as

24.9 How to interpret white blood cell results

Neutrophils A

Neutrophilia
- Infection: bacterial, fungal
- Trauma: surgery, burns
- Infarction: myocardial infarct, pulmonary embolus, sickle-cell crisis
- Inflammation: gout, rheumatoid arthritis, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, Hodgkin lymphoma
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Physiological: exercise, pregnancy

Neutropenia
- Infection: viral, bacterial (e.g. *Salmonella*), protozoal (e.g. malaria)
- Drugs: see Box 24.10
- Autoimmune: connective tissue disease
- Alcohol
- Bone marrow infiltration: leukaemia, myelodysplasia
- Congenital: Kostmann's syndrome
- Constitutional: Afro-Caribbean and Middle Eastern descent

Eosinophils B

Eosinophilia
- Allergy: hay fever, asthma, eczema
- Infection: parasitic
- Drug hypersensitivity: e.g. gold, sulphonamides
- Vasculitis, e.g. Churg–Strauss syndrome, granulomatosis with polyangiitis (Wegener's granulomatosis)
- Connective tissue disease: polyarteritis nodosa
- Malignancy: solid tumours, lymphomas
- Primary bone marrow disorders: myeloproliferative disorders, hypereosinophilic syndrome (HES), acute myeloid leukaemia

Basophils C

Basophilia
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn's disease
- Iron deficiency

Monocytes D

Monocytosis
- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, chronic myelomonocytic leukaemia

Lymphocytes E

Lymphocytosis
- Infection: viral, bacterial (e.g. *Bordetella pertussis*)
- Lymphoproliferative disease: chronic lymphocytic leukaemia, lymphoma
- Post-splenectomy

Lymphopenia
- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: corticosteroids, cytotoxics
- Congenital: severe combined immunodeficiency
- HIV infection

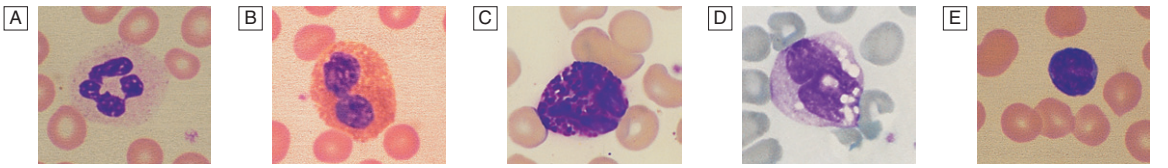

Fig. 24.12 Appearance of white blood cells. A Neutrophil. B Eosinophil. C Basophil. D Monocyte. E Lymphocyte.

24.10 Drugs that can induce neutropenia

Group	Examples
Analgesics/anti-inflammatory agents	Gold, penicillamine, naproxen
Antithyroid drugs	Carbimazole, propylthiouracil
Anti-arrhythmics	Quinidine, procainamide
Antihypertensives	Captopril, enalapril, nifedipine
Antidepressants/psychotropics	Amitriptyline, dosulepin, mianserin
Antimalarials	Pyrimethamine, dapsone, sulfadoxine, chloroquine
Anticonvulsants	Phenytoin, sodium valproate, carbamazepine
Antibiotics	Sulphonamides, penicillins, cephalosporins
Miscellaneous	Cimetidine, ranitidine, chlorpropamide, zidovudine

Epstein–Barr virus (EBV), human papillomavirus (HPV) and human herpesvirus 8 (HHV-8)).

Leucocytosis (high white cell count)

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see Box 24.9). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not increase the total white cell count (WCC) above the upper limit of normal and will only be apparent if the 'differential' of the white count is examined.

Neutrophilia

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends upon age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils but also earlier forms such as metamyelocytes can be found in the blood. The causes of a neutrophilia are shown in Box 24.9.

Eosinophilia

A high eosinophil count of more than 0.5×10^9/L is usually secondary to infection (especially parasites; p. 311), allergy (e.g. eczema, asthma, reactions to drugs; p. 89), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see Box 24.9). Usually, such eosinophilia is short-lived.

In the rarer primary disorders, there is a persistently raised, often clonal, eosinophilia: for example, in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hypereosinophilic syndrome (HES). Recently, specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing re-arrangements of platelet-derived growth factor receptors α and β or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib.

Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); therefore evaluation of eosinophilia includes not only the identification of any underlying cause and its appropriate treatment, but also assessment of any related organ damage.

Lymphocytosis

A lymphocytosis is an increase in circulating lymphocytes above that expected for the patient's age. In adults, this is greater than 3.5×10^9/L. Infants and children have higher counts; age-related reference ranges should be consulted. Causes are shown in Box 24.9; the most common is viral infection.

Lymphadenopathy

Enlarged lymph glands may be an important indicator of haematological disease but they are not uncommon in reaction to infection or inflammation (Box 24.11). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 991. Nodes which enlarge in response to local infection or inflammation ('reactive nodes') usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation in the appropriate drainage area:

- the scalp, ear, mouth, face or teeth for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes.

Generalised lymphadenopathy may be secondary to infection, connective tissue disease or extensive skin disease, but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats that may require a change of night clothes are associated with haematological malignancies, particularly lymphoma.

Initial investigations in lymphadenopathy include an FBC (to detect neutrophilia in infection or evidence of haematological disease), an ESR and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision

24.11 Causes of lymphadenopathy

Infective
- Bacterial: streptococcal, tuberculosis, brucellosis
- Viral: Epstein–Barr virus (EBV), human immunodeficiency virus (HIV)
- Protozoal: toxoplasmosis
- Fungal: histoplasmosis, coccidioidomycosis

Neoplastic
- Primary: lymphomas, leukaemias
- Secondary: lung, breast, thyroid, stomach

Connective tissue disorders
- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)

Sarcoidosis

Amyloidosis

Drugs
- Phenytoin

biopsy of a representative node is indicated to obtain a histological diagnosis.

Splenomegaly

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extramedullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections, or vascular congestion as a result of portal hypertension (Box 24.12). Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating due to stomach compression. Splenic infarction produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation should focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen, which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leucoerythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease (p. 928) may be appropriate. If all investigations are unhelpful, splenectomy may be diagnostic but is rarely carried out in these circumstances.

24.12 Causes of splenomegaly

Congestive	
Portal hypertension	
• Cirrhosis	• Stenosis or malformation of portal or splenic vein
• Hepatic vein occlusion	
• Portal vein thrombosis	
Cardiac	
• Chronic congestive cardiac failure	• Constrictive pericarditis
Infective	
Bacterial	
• Endocarditis	• Brucellosis
• Septicaemia	• Salmonella
• Tuberculosis	
Viral	
• Hepatitis	• Cytomegalovirus
• Epstein–Barr	
Protozoal	
• Malaria*	• Trypanosomiasis
• Leishmaniasis (kala-azar)*	
Fungal	
• Histoplasmosis	
Inflammatory/granulomatous disorders	
• Felty's syndrome in rheumatoid arthritis	• Systemic lupus erythematosus
• Sarcoidosis	
Haematological	
Red cell disorders	
• Megaloblastic anaemia	• Hereditary spherocytosis
• Haemoglobinopathies	
Autoimmune haemolytic anaemias	
Myeloproliferative disorders	
• Chronic myeloid leukaemia*	• Polycythaemia rubra vera
• Myelofibrosis*	• Essential thrombocythaemia
Neoplastic	
• Leukaemias, including chronic myeloid leukaemia*	• Lymphomas
Other malignancies	
• Metastatic cancer – rare	
Lysosomal storage diseases	
• Gaucher's disease	• Niemann–Pick disease
Miscellaneous	
• Cysts, amyloid, thyrotoxicosis	

*Causes of massive splenomegaly.

Bleeding

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, to the coagulation factors, or occasionally to excessive fibrinolysis, which is most commonly observed following therapeutic thrombolysis (p. 596).

Clinical assessment

'Screening' blood tests (see Box 24.3, p. 1000) do not reliably detect all causes of pathological bleeding (e.g. von Willebrand disease, scurvy, certain anticoagulant drugs and the causes of purpura listed in Box 24.13) and should not be used indiscriminately. A careful clinical evaluation is the key to diagnosis of bleeding disorders (p. 1049). It is important to consider the following:

- *Site of bleeding.* Bleeding into muscle and joints, along with retroperitoneal and intracranial haemorrhage, indicates a likely defect in coagulation factors. Purpura, prolonged bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent bleeds at a single site suggest a local structural abnormality.
- *Duration of history.* It may be possible to assess whether the disorder is congenital or acquired.
- *Precipitating causes.* Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.
- *Surgery.* Ask about operations. Dental extractions, tonsillectomy and circumcision are stressful tests of

24.13 Causes of non-thrombocytopenic purpura

- Senile purpura
- Factitious purpura
- Henoch–Schönlein purpura (pp. 501 and 1119)
- Vasculitis (p. 1115)
- Paraproteinaemias
- Purpura fulminans, e.g. in DIC secondary to sepsis

the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis; delayed haemorrhage is more suggestive of a coagulation defect. In post-surgical patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than a bleeding disorder.

- *Family history.* While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history, and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- *Drugs.* Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some 'herbal' remedies may result in a bleeding diathesis.

Clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 24.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction. Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple but become yellow as haemoglobin is degraded. Retroperitoneal bleeding presents with a flank haematoma. Telangiectasia of lips and tongue points to hereditary haemorrhagic telangiectasia (p. 1049). Joints should be examined for evidence of haemarthroses. A full examination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

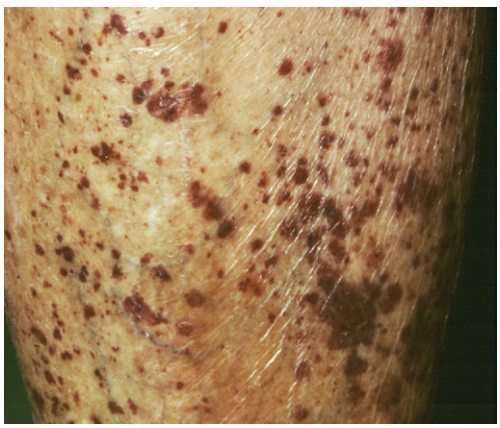

Fig. 24.13 Petechial purpura.

Investigations

Screening investigations and their interpretation are described on page 999. If the patient has a history that is strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed (p. 1053).

Thrombocytopenia (low platelet count)

A reduced platelet count may arise by one of two mechanisms:

- decreased or abnormal production (bone marrow failure and hereditary thrombocytopathies)

24.14 Causes of thrombocytopenia

Decreased production

Marrow hypoplasia

- Childhood bone marrow failure syndromes, e.g. Fanconi's anaemia, dyskeratosis congenita, amegakaryocytic thrombocytopenia
- Idiopathic aplastic anaemia
- Drug-induced: cytotoxics, antimetabolites
- Transfusion-associated graft-versus-host disease

Marrow infiltration

- Leukaemia
- Myeloma
- Carcinoma (rare)
- Myelofibrosis
- Osteopetrosis
- Lysosomal storage disorders, e.g. Gaucher's disease

Haematinic deficiency

- Vitamin B_{12} and/or folate deficiency

Familial (macro-)thrombocytopathies

- Myosin heavy chain abnormalities, e.g. Alport's syndrome, Fechner's syndrome
- Bernard Soulier disease
- Montreal platelet syndrome
- Wiskott–Aldrich syndrome (small platelets)

Increased consumption

Immune mechanisms

- Idiopathic thrombocytopenic purpura*
- Neonatal alloimmune thrombocytopenia
- Post-transfusion purpura
- Drug-associated, especially quinine and vancomycin

Coagulation activation

- Disseminated intravascular coagulation (see Box 24.70, p. 1056)

Mechanical pooling

- Hypersplenism

Thrombotic microangiopathies

- Haemolytic uraemic syndrome
- Liver disease
- Thrombotic thrombocytopenic purpura
- Pre-eclampsia

Others

- Gestational thrombocytopenia
- Type 2B von Willebrand disease

*Associated conditions include collagen vascular diseases (particularly SLE), B cell malignancy, HIV infection and antiphospholipid syndrome.

- increased consumption following release into the circulation (immune-mediated, DIC or sequestration).

Spontaneous bleeding does not usually occur until the platelet count falls below 20×10^9/L, unless their function is also compromised. Purpura and spontaneous bruising are characteristic but there may also be oral, nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia ($< 10 \times 10^9$/L) may result in retinal haemorrhage and potentially fatal intracranial bleeding, but this is rare.

Investigations are directed at the possible causes listed in Box 24.14. A blood film is the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts below 10×10^9/L, or to clinical situations with actual or predicted serious haemorrhage.

Thrombocytosis (high platelet count)

The most common reason for a raised platelet count is that it is reactive to another process such as infection, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 24.15). The presenting clinical features are usually those of the underlying disorder and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets, lack of splenomegaly, and the presence of an associated disorder. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time (reactive thrombocytosis gets better with resolution of the underlying cause).

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia and some forms of myelodysplasia. Patients with PRV, essential thrombocythaemia and occasionally myelofibrosis may present with thrombosis or, rarely, bleeding. Stroke and transient ischaemic attacks, amaurosis fugax, and digital ischaemia or gangrene are also features. In addition, patients with myeloproliferative disorders present with features such as itching after exposure to water (aquagenic pruritus), splenomegaly and systemic upset.

24.15 Causes of a raised platelet count

Reactive thrombocytosis

- Chronic inflammatory disorders
- Malignant disease
- Tissue damage
- Haemolytic anaemias
- Post-splenectomy
- Post-haemorrhage

Clonal thrombocytosis

- Primary thrombocythaemia
- PRV
- Chronic myeloid leukaemia
- Myelofibrosis
- Myelodysplastic syndromes (RARS with thrombocytosis, 5 q⁻ syndrome)

(PRV = polycythaemia rubra vera; RARS = refractory anaemia with sideroblasts)

Pancytopenia

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells as a consequence of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in Box 24.16. A bone marrow aspirate and trephine are usually required to establish the diagnosis.

24.16 Causes of pancytopenia

Bone marrow failure

- Hypoplastic/aplastic anaemia (p. 1048): inherited, idiopathic, viral, drugs

Bone marrow infiltration

- Acute leukaemia
- Myeloma
- Lymphoma
- Carcinoma
- Haemophagocytic syndrome
- Myelodysplastic syndromes

Ineffective haematopoiesis

- Megaloblastic anaemia
- Acquired immunodeficiency syndrome (AIDS)

Peripheral pooling/destruction

- Hypersplenism: portal hypertension, Felty's syndrome, malaria, myelofibrosis
- Systemic lupus erythematosus (SLE)

Infection

Infection is a major complication of haematological disorders. It relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 1004 and 302).

Venous thrombosis

While the most common presentation of venous thromboembolic disease (VTE) is with deep vein thrombosis (DVT) of the leg and/or pulmonary embolism (PE; see also p. 721), similar principles apply to rarer manifestations such as jugular vein thrombosis, upper limb DVT, cerebral sinus thrombosis (p. 1247) and intra-abdominal venous thrombosis (e.g. Budd–Chiari syndrome; p. 976).

DVT has an annual incidence of approximately 1:1000 in Western populations and the case mortality is 1–3%. It is increasingly common with ageing, and many of the deaths are related to coexisting medical conditions, such as active cancer. Risk factors for DVT and PE are often present (Box 24.17). Figure 24.14 illustrates some of the causes and consequences of VTE disease.

Clinical assessment

Lower limb DVT characteristically starts in the distal veins, causing pain, swelling, an increase in temperature

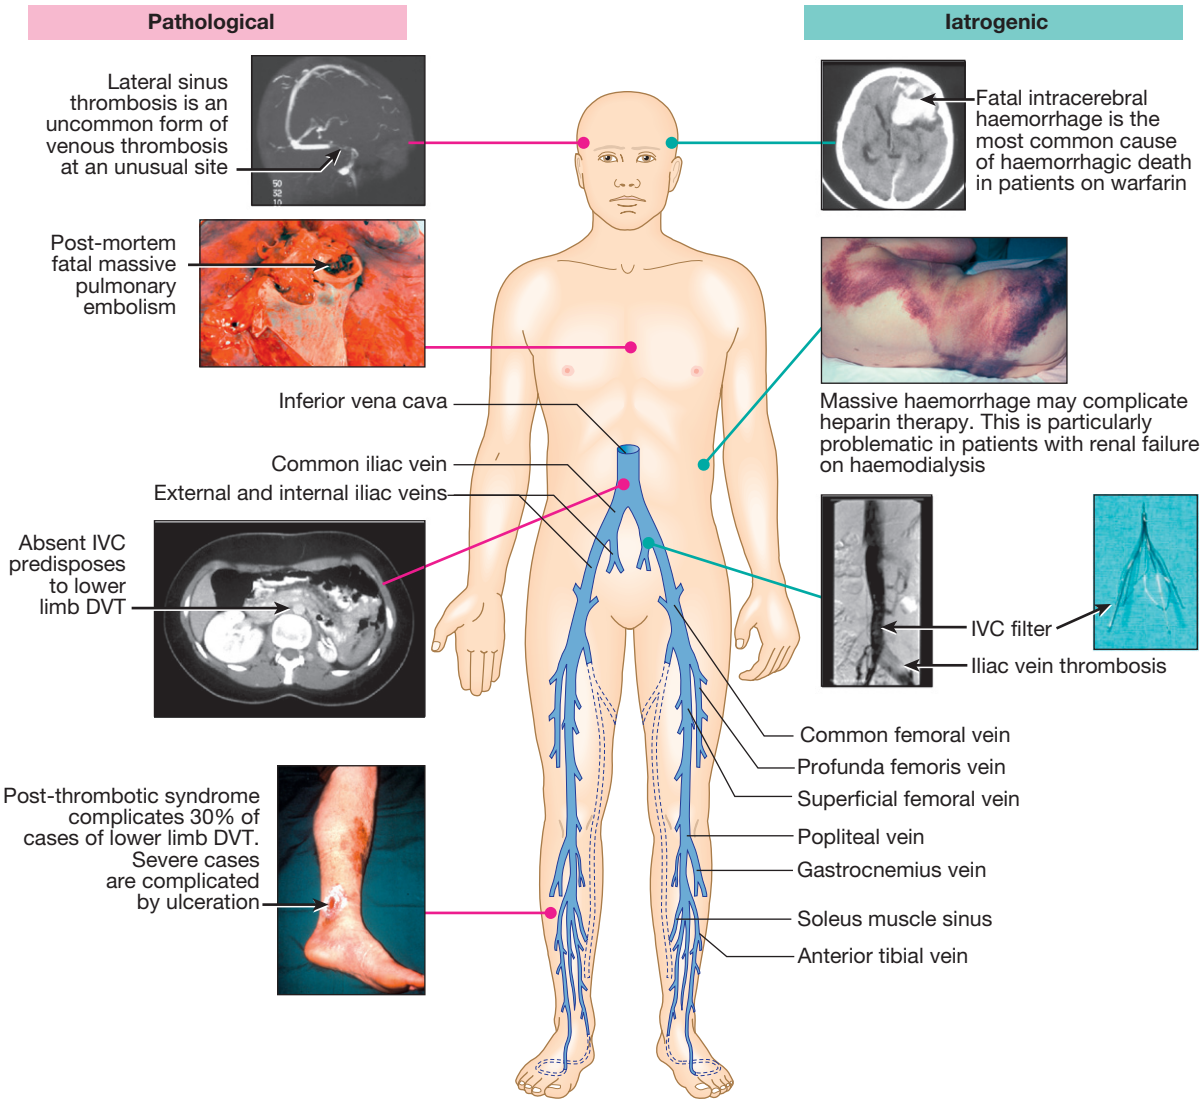

Fig. 24.14 **Causes and consequences of venous thromboembolic disease and its treatment.** (IVC = inferior vena cava)

24.17 Factors predisposing to venous thrombosis

Patient factors

- Increasing age
- Obesity
- Varicose veins
- Previous DVT
- Family history, especially of unprovoked VTE when young
- Pregnancy/puerperium
- Oestrogen-containing oral contraceptives and HRT
- Immobility, e.g. long-distance travel (> 4 hrs)
- IV drug use (femoral vein)

Surgical conditions

- Major surgery, especially if > 30 mins' duration
- Abdominal or pelvic surgery, especially for cancer
- Major lower limb orthopaedic surgery, e.g. joint replacement and hip fracture surgery

Medical conditions

- Myocardial infarction/heart failure
- Inflammatory bowel disease
- Malignancy
- Nephrotic syndrome
- Pneumonia
- Neurological conditions associated with immobility, e.g. stroke, paraplegia, Guillain–Barré syndrome

Haematological disorders

- Polycythaemia rubra vera
- Essential thrombocythaemia
- Deficiency of anticoagulants: antithrombin, protein C, protein S
- Paroxysmal nocturnal haemoglobinuria
- Gain-of-function prothrombotic mutations: factor V Leiden, prothrombin gene *G20210A*
- Myelofibrosis

Antiphospholipid syndrome

- Lupus anticoagulant (more strongly associated with thrombosis than anticardiolipin antibodies)
- Anticardiolipin antibody

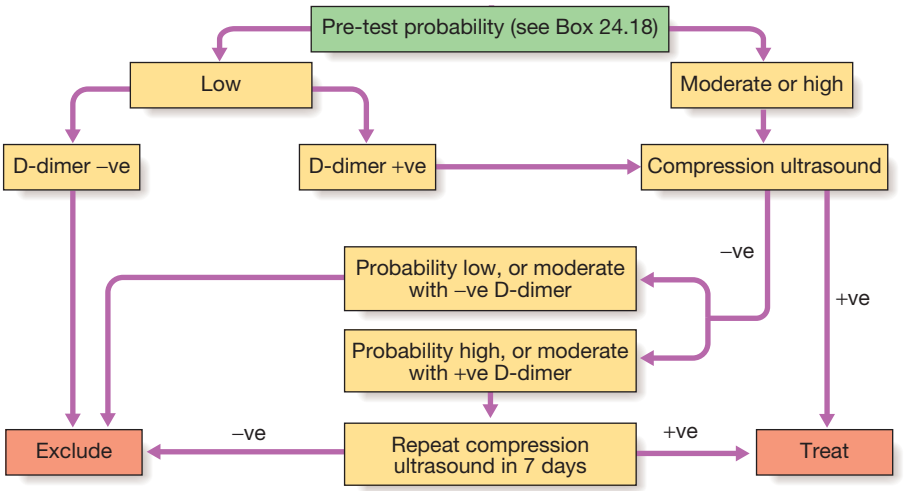

Fig. 24.15 Investigation of suspected deep vein thrombosis. Pre-test probability is calculated in Box 24.18.

and dilatation of the superficial veins. Often, however, symptoms and signs are minimal. It is typically unilateral but may be bilateral, and clot may extend proximally into the inferior vena cava. Bilateral DVT is more commonly seen with underlying malignancy or anomalies of the inferior vena cava. The differential diagnosis of unilateral leg swelling includes a spontaneous or traumatic calf muscle tear or a ruptured Baker's cyst, both characterised by sudden onset and localised tenderness. Infective cellulitis is usually distinguished by marked skin erythema and heat localised within a well-demarcated area of the leg and may be associated with an obvious source of entry of infection (e.g. insect bite, leg ulcer).

Risk factors for DVT should be considered (see Box 24.17), and examination should include assessment for malignancy. Symptoms and signs of PE should be sought (p. 721), particularly in those with proximal thrombosis; asymptomatic PE is thought to be present in approximately 30% of patients with lower limb DVT.

Clinical criteria can be used to rank patients according to their likelihood of DVT or PE: for example, by using scoring systems such as the Wells score (Box 24.18).

24.18 Predicting the pre-test probability of deep vein thrombosis using the Wells score*

Clinical characteristic	Score
Active cancer (patient receiving treatment for cancer within previous 6 mths or currently receiving palliative treatment)	1
Paralysis, paresis or recent plaster immobilisation of lower extremities	1
Recently bedridden for ≥ 3 days, or major surgery within previous 4 wks	1
Localised tenderness along distribution of deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting oedema confined to symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Alternative diagnosis at least as likely as DVT	–2
Clinical probability	**Total score**
DVT low probability	≤ 1
DVT moderate probability	1–2
DVT high probability	≥ 2

*A dichotomised revised Wells score, which classifies patients as 'unlikely' or 'likely', may also be used. From Wells PS. New Engl J Med 2003; 349:1227; copyright © 2003 Massachusetts Medical Society.

Investigations

Figure 24.15 gives an algorithm for investigation of suspected DVT based on initial Wells score. In patients with a low ('unlikely') pre-test probability of DVT, D-dimer levels can be measured; if these are normal, further investigation for DVT is unnecessary. In those with a moderate or high ('likely') probability of DVT or with elevated D-dimer levels, objective diagnosis of DVT should be obtained using appropriate imaging.

Compression ultrasound is the imaging modality of choice in most centres. It has a sensitivity for proximal DVT (clot involving the popliteal vein or above) of 99.5%. Sensitivity and specificity are lower for diagnosing calf vein thrombosis. Contrast venography is an alternative that is now rarely used. In patients with proven DVT, further imaging to diagnose PE is not required unless massive PE is clinically suspected or there is otherwise unexplained breathlessness (p. 722).

Predisposing factors, particularly pelvic malignancy and those listed in Box 24.17, should be considered and investigation pursued. In occasional patients, further investigation for an underlying thrombophilic condition may be considered (see Boxes 24.4 and 24.5, p. 1001).

Management

The management of leg DVT includes elevation and analgesia. Thrombolysis may be considered for limb-threatening DVT, but the mainstay of treatment is anticoagulation with low molecular weight heparin (LMWH), followed by a coumarin anticoagulant, such as warfarin. An alternative is the oral Xa inhibitor, rivaroxaban, which

EBM 24.19 Treatment of venous thromboembolism

'In patients with active cancer, treatment of deep vein thrombosis with low molecular weight heparin (LMWH) for 6 months is superior in preventing recurrence of thrombosis to short-period LMWH followed by warfarin.'

- Lee AY, et al. N Engl J Med 2003; 349(2):146–153.

has a rapid onset of action and can be used immediately from diagnosis without the need for LMWH. Treatment of acute VTE with LMWH should continue for at least 5 days. If a coumarin is being introduced, the heparin should continue until the INR has been in the target range (2–3; pp. 1000 and 1018) for 2 days. Patients who have had a DVT and have a strong contraindication to anticoagulation, and those who, despite therapeutic anticoagulation, continue to have new pulmonary emboli, should have an inferior vena cava filter inserted to prevent life-threatening PE.

The optimal initial duration of anticoagulation is between 6 weeks and 6 months. Patients who have thrombosis in the presence of a temporary risk factor, which is then removed, can usually be treated for shorter periods (e.g. 3 months) than those who sustain unprovoked thrombosis. In patients with active cancer and VTE, there is evidence that LMWH should be continued for 6 months rather than being replaced by a coumarin (Box 24.19). Evidence indicates that periods of anticoagulation of more than 6 months do not alter the rate of recurrence following discontinuation of therapy.

Recurrence of DVT is about 2–3% per annum in patients who have a medical temporary risk factor at presentation and about 8% per annum in those with apparently unprovoked DVT. Recurrence plateaus at around 30–40% at 5 years. Post-thrombotic syndrome is due to damage of venous valves by the thrombus. It results in persistent leg swelling, heaviness and discoloration. The most severe complication of this syndrome is ulceration around the medial malleolus.

BLOOD PRODUCTS AND TRANSFUSION

Blood transfusion from an unrelated donor to a recipient inevitably carries some risk, including adverse immunological interactions between the host and infused blood (p. 94) and transmission of infectious agents. Although there are many compelling clinical indications for blood component transfusion, there are also many clinical circumstances in which transfusion is conventional but the evidence for its effectiveness is limited. In these settings, allogeneic transfusion may be avoided by following protocols that recommend use of low haemoglobin thresholds for red cell transfusion (Box 24.20), perioperative blood salvage and antifibrinolytic drugs.

Blood products

Blood components are prepared from whole blood collected from individual donors and include red cells, platelets, plasma and cryoprecipitate (Box 24.22).

Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes of human plasma obtained from many people and treated to remove transmissible infection. Examples include:

- *Coagulation factors.* Concentrates of factors VIII and IX are used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease. Coagulation factors made by recombinant DNA technology are now preferred due to perceived lack of infection risk but plasma-derived products are still used in many countries.
- *Immunoglobulins.* Intravenous immunoglobulin (IVIgG) is administered as regular replacement therapy to reduce infective complications in patients with immunodeficiency. A short, high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 1049) and Guillain–Barré syndrome (p. 1224). IVIgG can cause acute reactions and must be infused strictly according to the manufacturer's product information. There is a risk of renal dysfunction in susceptible patients and, in these circumstances, immunoglobulin products containing low or no sucrose are preferred. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster (p. 317). Anti-Rhesus D immunoglobulin is used in pregnancy to prevent haemolytic disease of the newborn (see Box 24.24 below).
- *Human albumin.* This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid, but it is no more effective and is more expensive than crystalloid solutions (Box 24.21). Human albumin 20% solution is used in the management of hypoproteinaemic oedema in nephrotic syndrome (p. 476), and ascites in chronic liver disease (p. 938). It is hyperoncotic and expands plasma volume by more than the amount infused.

EBM 24.20 Red cell transfusion in critically ill patients

'A restrictive strategy of red cell transfusion is at least as effective as, and possibly superior to, a liberal transfusion strategy in critically ill patients. A restrictive strategy allows transfusion when Hb is below 70 g/L and maintains Hb at 70–90 g/L, whereas a liberal strategy allows transfusion when Hb is below 100 g/L and maintains Hb at 100–120 g/L.'

- Hébert PC, et al. N Eng J Med 1999; 340(6):409–417.

EBM 24.21 Fluid resuscitation in critically ill patients

'In patients with trauma, burns or following surgery, there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions.'

- Perel P, Roberts I. Colloids versus crystalloids for fluid resuscitation in critically ill patients. Cochrane Database of Systematic Reviews, 2011, issue 3. Art. no. CD000567.

Blood donation

A safe supply of blood components depends on a well-organised system with regular donation by healthy individuals who have no excess risk of infections transmissible in blood (Fig. 24.16). Blood donations are obtained by

24.22 Blood components and their use

Component	Major haemorrhage	Other indications
Red cell concentrate[1] Most of the plasma is removed and replaced with a solution of glucose and adenine in saline to maintain viability of red cells ABO compatibility with recipient is essential	Replace acute blood loss: increase circulating red cell mass to relieve clinical features caused by insufficient oxygen delivery	*Severe anaemia* If no cardiovascular disease, transfuse to maintain Hb at 70 g/L If known or likely to have cardiovascular disease, maintain Hb at 90 g/L
Platelet concentrate One adult dose is made from four donations of whole blood, or from a single platelet apheresis donation ABO compatibility with recipient is preferable	Maintain platelet count > 50×10^9/L, or in multiple or CNS trauma > 100×10^9/L Each adult dose has a minimum of 2.4×10^{11} platelets, which raises platelet count by 40×10^9/L unless there is consumptive coagulopathy, e.g. DIC	*Thrombocytopenia*, e.g. in acute leukaemia Maintain platelet count > 10×10^9/L if not bleeding Maintain platelet count > 20×10^9/L if minor bleeding or at risk (sepsis, concurrent use of antibiotics, abnormal clotting) Increase platelet count > 50×10^9/L for minor invasive procedure (e.g. lumbar puncture, gastroscopy and biopsy, insertion of indwelling lines, liver biopsy, laparotomy) or if acute, major blood loss Increase platelet count > 100×10^9/L for operations in critical sites such as brain or eyes
Fresh frozen plasma[2] 150–300 mL plasma from one donation of whole blood ABO compatibility with recipient is recommended	Dilutional coagulopathy with a PT prolonged > 50% is likely after replacement of 1–1.5 blood volumes with red cell concentrate Initial dose of FFP 15 mL/kg Further doses only if bleeding continues and guided by PT and APTT	*Replacement of coagulation factor deficiency* If no virally inactivated or recombinant product is available *TTP* Plasma exchange (using virus-inactivated plasma if available) is frequently effective
Cryoprecipitate[2] Fibrinogen and coagulation factor concentrated from plasma by controlled thawing 10–20 mL pack contains fibrinogen 150–300 mg, factor VIII 80–120 U, von Willebrand factor 80–120 U In UK, supplied as pools of 5 U	May be indicated if fibrinogen < 0.8 g/L due to dilution and DIC Pooled units (of 10 donations) containing 3 g fibrinogen in 300 mL raise fibrinogen by 1 g/L	*von Willebrand disease and haemophilia* If virus-inactivated or recombinant products are not available

[1]**Whole blood** is an alternative to red cell concentrate. ABO compatibility with recipient is essential.
[2]Pooled plasma can be treated with solvent and detergent or single units treated with methylene blue as an additional viral inactivation step. Virus-inactivated plasma is indicated for large-volume exposure, as in treatment of thrombotic thrombocytopenic purpura, and for treatment of children in the UK born after 1995.
(APTT = activated partial thromboplastin time; CNS = central nervous system; DIC = disseminated intravascular coagulation; FFP = fresh frozen plasma; PT = prothrombin time; TTP = thrombotic thrombocytopenic purpura)

either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis, the donor's blood is drawn via a closed system into a machine which separates the components by centrifugation and collects the desired fraction into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B (HBV), hepatitis C (HCV), HIV and human T cell lymphotropic (HTLV) virus nucleic acid and/or antibodies. Platelet concentrates may be tested for bacterial contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for *Trypanosoma cruzi* (Chagas' disease; p. 360) is necessary in areas of South America and the USA where infection is prevalent; tests for West Nile virus have been required in the USA since this agent became prevalent; plasma donated in the UK is not used at present for producing pooled plasma derivatives in view of concerns about transmission of variant Creutzfeldt–Jakob disease (vCJD; p. 1211).

Adverse effects of transfusion

Death directly attributable to transfusion is rare, at less than 0.3 per 100 000 transfusions. However, relatively minor symptoms of transfusion reactions (fever, itch or urticaria) occur in up to 3% of transfusions, usually in patients who have had repeated transfusions. Any symptoms or signs that arise during a transfusion must be taken seriously, as they may be the first warnings of a serious reaction. Figure 24.18 (p. 1016) outlines the symptoms and signs, management and investigation of acute reactions to blood components.

Red cell incompatibility

Red blood cell membranes contain numerous cell surface molecules which are potentially antigenic (see Fig. 24.4, p. 994). The ABO and Rh(D) antigens are the most important in routine transfusion and antenatal practice.

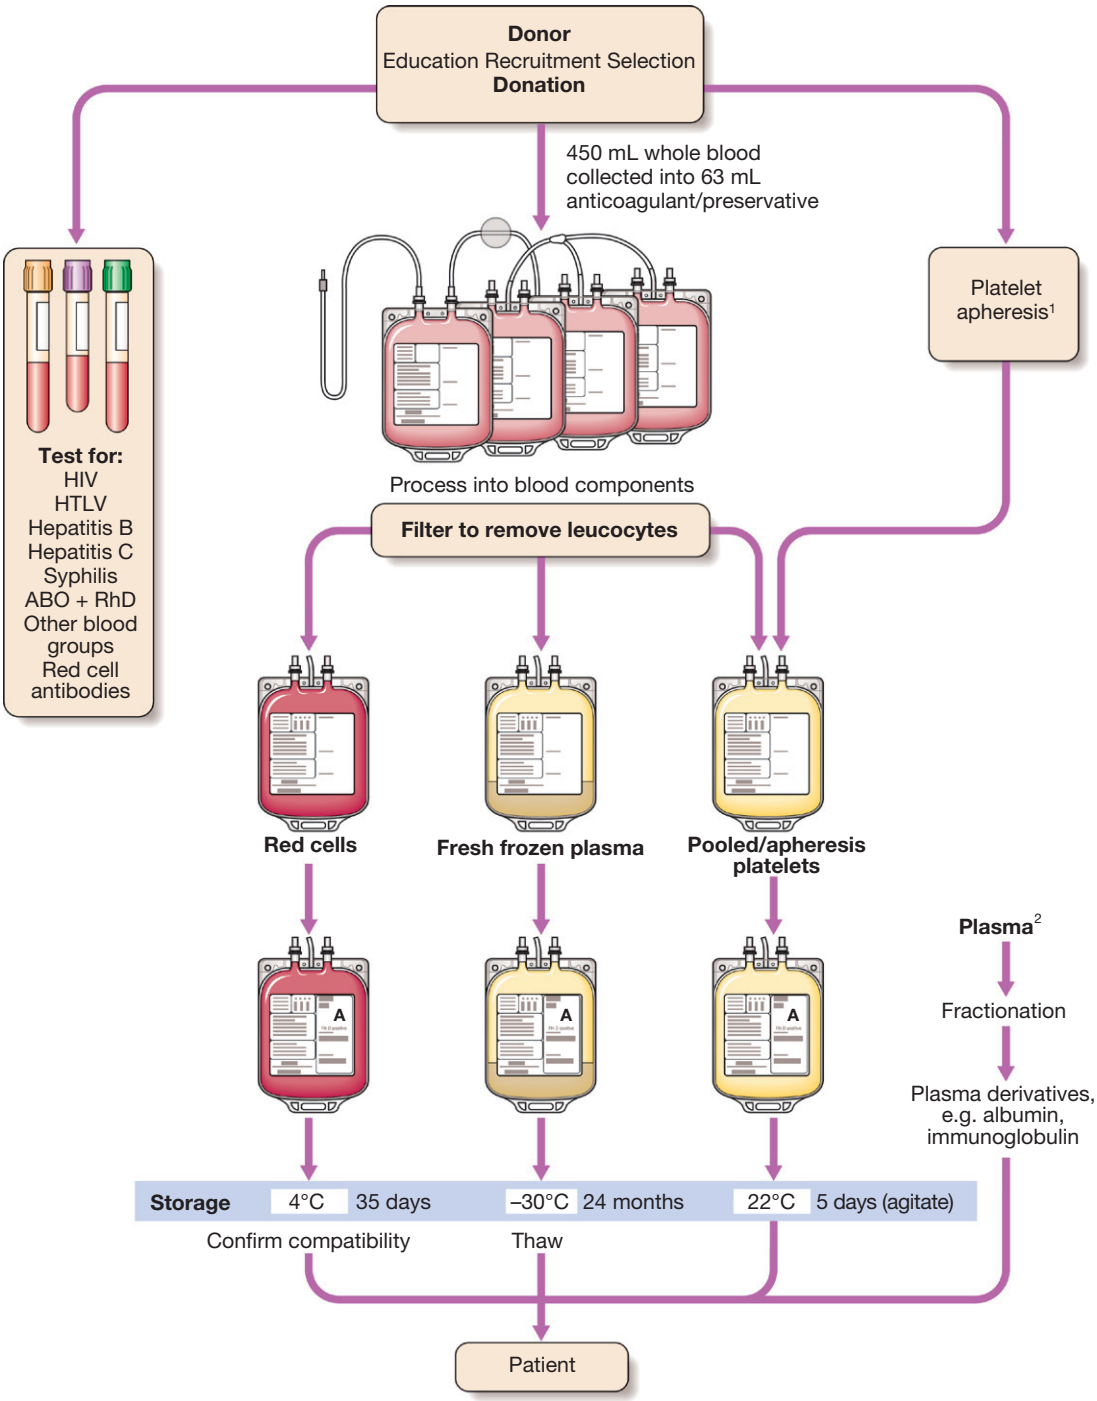

Fig. 24.16 Blood donation, processing and storage. [1]Platelet apheresis involves circulating the donor's blood through a cell separator to remove platelets before returning other blood components to the donor. [2]In the UK, plasma for fractionation is imported as a precautionary measure against variant Creutzfeldt–Jakob disease. (HIV = human immunodeficiency virus; HTLV = human T cell lymphotropic virus)

ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The ABO gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain which has three common alleles: A, B and O. The O allele encodes an inactive enzyme, leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by four amino acids and hence attach different sugars to the end of the chain. Individuals are tolerant to their own ABO antigens, but do not suppress B cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 24.23). They are therefore capable of mounting a humoral immune response to these 'foreign' antigens.

24.23 ABO blood group antigens and antibodies

ABO blood group	Red cell A or B antigens	Antibodies in plasma	UK frequency (%)
O	None	Anti-A and anti-B	46
A	A	Anti-B	42
B	B	Anti-A	9
AB	A and B	None	3

ABO-incompatible red cell transfusion

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the *recipient's* IgM anti-A, anti-B or anti-AB binds to the *transfused* red cells. This activates the full complement pathway (p. 75), creating pores in the red cell membrane and destroying the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin 1 (IL-1) and IL-8, and stimulate degranulation of mast cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension, which may, in turn, cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20–30% of ABO-incompatible transfusions cause some degree of morbidity, and 5–10% cause or contribute to a patient's death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

The Rhesus D blood group and haemolytic disease of the newborn

About 15% of Caucasians are Rhesus-negative; that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 24.4, p. 994). In other populations (e.g. in Chinese and Bengalis), only 1–5% are Rhesus-negative. RhD-negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD-positive red cells enter the circulation of an RhD-negative individual, IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via feto-maternal haemorrhage, or following transfusion. If a woman is so sensitised, during a subsequent pregnancy anti-RhD antibodies can cross the placenta; if the fetus is RhD-positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD-negative female who may subsequently become pregnant should never be transfused with RhD-positive blood.

In RhD-negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of Rhesus antibodies (Box 24.24).

HDN can also be caused by other alloantibodies against red cell antigens, usually after previous pregnancies or transfusions. These antigens include Rhc, RhC, RhE, Rhe, and the Kell, Kidd and Duffy antigen systems. HDN can also occur if there is fetomaternal ABO incompatibility, most commonly seen in a group O mother with a group A fetus. The fetus is generally less severely affected by ABO incompatibility than by RhD, Rhc or Kell antigen mismatch.

24.24 Rhesus D blood groups in pregnancy

- **Haemolytic disease of the newborn (HDN)**: occurs when the mother has anti-red cell IgG antibodies that cross the placenta and haemolyse fetal red cells.
- **Screening for HDN in pregnancy**: at the time of booking (12–16 wks) and again at 28–34 wks gestation, every pregnant woman should have a blood sample sent for determination of ABO and RhD group and testing for red cell alloantibodies that may be directed against paternal blood group antigens present in fetal red cells.
- **Anti-D immunoglobulin prophylaxis in a pregnant woman who is RhD-negative**: antenatal anti-D prophylaxis is offered at 28–34 wks to RhD-negative pregnant women who have no evidence of immune anti-D. This prevents the formation of antibodies that could cause HDN. Following delivery of an RhD-positive baby, the mother is given further anti-D within 72 hrs; a maternal sample is checked for remaining fetal red cells and additional anti-D is given if indicated. Additional anti-D is also given after potential sensitising events antenatally (e.g. early bleeding). Doses vary according to national recommendations.

Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease (TA GVHD). The latter occurs when there is sharing of a human leucocyte antigen (HLA) haplotype between donor and recipient, which allows transfused lymphocytes to engraft, proliferate and recognise the recipient as foreign, resulting in acute GVHD (p. 1017). Prevention is by gamma- or X-ray irradiation of blood components before their administration to prevent lymphocyte proliferation. Those at risk of TA GVHD who must receive irradiated blood components include: patients with congenital T cell immunodeficiencies or Hodgkin lymphoma; patients with aplastic anaemia receiving immunosuppressive therapy with anti-thymocyte globulin; recipients of haematopoietic stem cell transplants or of blood from a family member; neonates who have received an intrauterine transfusion; and patients taking T lymphocyte-suppressing drugs, such as fludarabine and other purine analogues.

Transfusion-transmitted infection

Over the past 30 years, HBV, HIV-1 and HCV have been identified and effective tests introduced to detect and exclude infected donations. Where blood is from 'safe' donors and correctly tested, the current risk of a donated unit being infectious is very small. By 2010 in the UK, the estimated chance that a unit of blood from a 'safe' donor might transmit one of the viruses for which blood is tested was 1 in 6.4 million units for HIV-1, 1 in 100 million for HCV and 1 in 1.4 million for HBV. However, some patients who received transfusions before these tests were available suffered serious consequences from infection; this serves as a reminder to avoid non-essential transfusion,

since it is impossible to exclude the emergence of new or currently unrecognised transfusion-transmissible infection. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

vCJD is a human prion disease linked to bovine spongiform encephalitis (BSE; p. 1211). The risk of a recipient acquiring the agent of vCJD from a transfusion is uncertain, but of 16 recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 1 other had postmortem pathological features of infection.

Bacterial contamination of a blood component – usually platelets – is extremely rare (e.g. no reports in the UK in either 2010 or 2011) but can result in severe bacteraemia/septicaemia in the recipient.

Safe transfusion procedures

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative, and this should be documented. Some patients, e.g. Jehovah's Witnesses, may refuse transfusion and require specialised management to survive profound anaemia following blood loss.

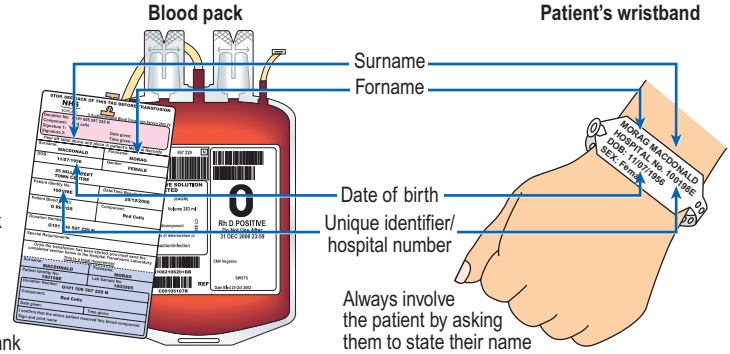
Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a 'group and screen' procedure or a 'cross-match'. In the group and screen procedure, the red cells from the patient's blood sample are tested to determine the ABO and RhD type, and the patient's serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen can be selected. The patient's sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cells with the patient's serum. Full cross-matching takes about 45 minutes if no red cell antibodies are present, but may require hours if a patient has multiple antibodies.

Blood can be supplied by 'electronic issue', without the need for compatibility cross-matching, if the laboratory's computer system shows that the patient's ABO and RhD groups have been identified and confirmed on two separate occasions and their antibody screen is negative.

Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Most incompatible transfusions result from failure to adhere to standard procedures for taking correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2011, there were 247 reports of transfusion of an incorrect blood component (8 per 100 000 units transfused). Every hospital where blood is transfused should have a written transfusion policy used by all staff who order, check or administer blood products (Fig. 24.17). Management of suspected transfusion reactions is shown in Figure 24.18.



Taking blood for pre-transfusion testing

- Positively identify the patient at the bedside
- Label the sample tube and complete the request form clearly and accurately after identifying the patient
- Do not write forms and labels in advance

Administering blood

- Positively identify the patient at the bedside
- Ensure that the identification of each blood pack matches the patient's identification
- Check that the ABO and RhD groups of each pack are compatible with the patient's
- Check each pack for evidence of damage
- If in doubt, do not use and return to the blood bank
- Complete the forms that document the transfusion of each pack

Check the compatibility label on the pack against the patient's wristband

Record-keeping

- Record in the patient's notes the reason for transfusion, the product given, dose, any adverse effects and the clinical response

Observations

- Transfusions should only be given when the patient can be observed
- Blood pressure, pulse and temperature should be monitored before and 15 minutes after starting each pack
- In concious patients, further observations are only needed if the patient has symptoms or signs of a reaction
- In unconscious patients, check pulse and temperature at intervals during transfusion
- Signs of abnormal bleeding during the transfusion could be due to disseminated intravascular coagulation resulting from an acute haemolytic reaction

Fig. 24.17 Bedside procedures for safe blood transfusion. The patient's safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.

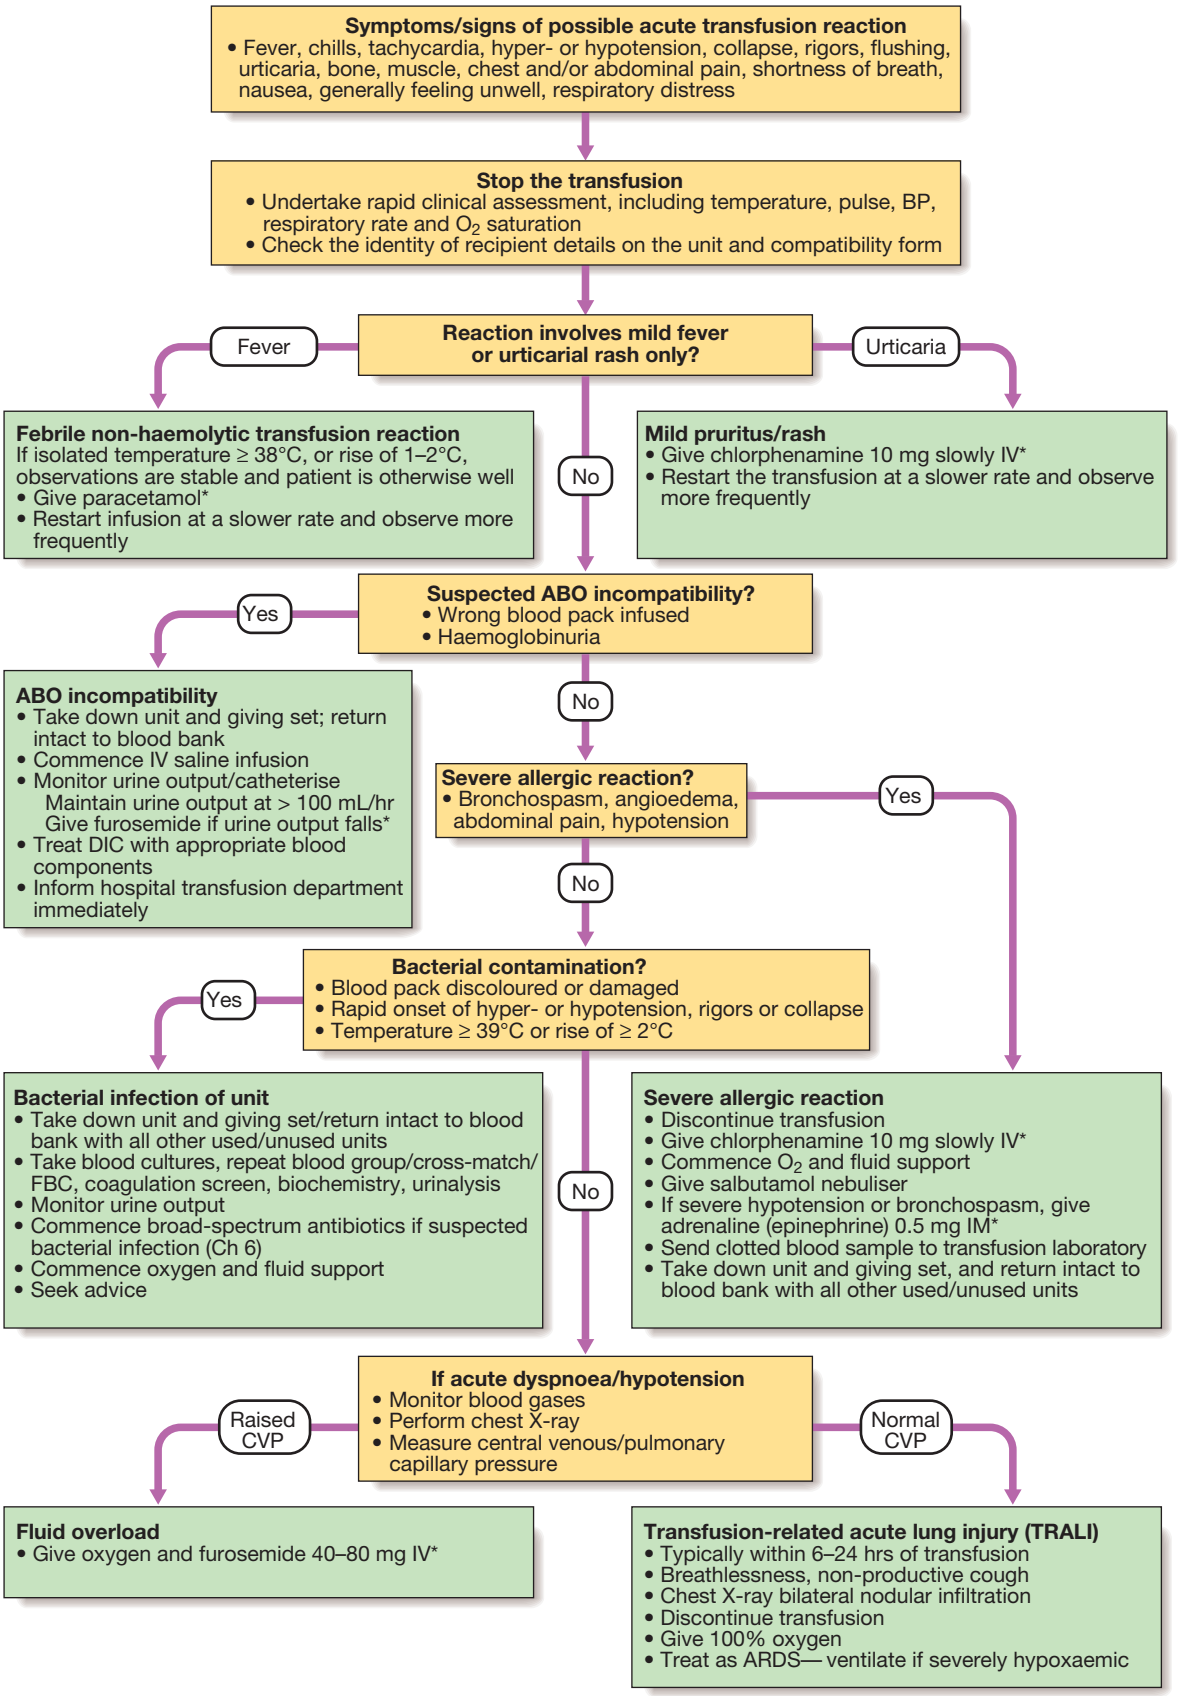


Fig. 24.18 Investigation and management of acute transfusion reactions. *Use size-appropriate dose in children. (ARDS = acute respiratory distress syndrome; DIC = disseminated intravascular coagulation; FBC = full blood count)

HAEMATOPOIETIC STEM CELL TRANSPLANTATION

Transplantation of haematopoietic stem cells (HSCT) has offered the only hope of 'cure' in a variety of haematological and non-haematological disorders (Box 24.25). As standard treatment improves, the indications for HSCT are being refined and extended, although its use remains most common in haematological malignancies. The type of HSCT is defined according to the donor and source of stem cells:

- In *allogeneic* HSCT, the stem cells come from a *donor* – either related (usually an HLA-identical sibling) or a closely HLA-matched volunteer unrelated donor (VUD).
- In an *autologous* transplant, the stem cells are harvested from the *patient* and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from the bone marrow or from the blood.

Allogeneic HSCT

Healthy bone marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably 'conditioned'. The conditioning treatment (chemotherapy with or without radiotherapy) destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient's haematopoietic tissues (myeloablation). The infused donor cells 'home' to the marrow, engraft and produce enough erythrocytes, granulocytes and platelets for the patient's needs after about 3–4 weeks. During this period of aplasia, patients are at risk of infection and bleeding, and require intensive supportive care as described on page 1038. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, in particular in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor's immune system can recognise residual recipient malignant cells and destroy them. This immunological 'graft versus disease' effect is a powerful tool against many haematological tumours and can be boosted post transplantation by the infusion of T cells taken from the donor, so-called donor lymphocyte infusion (DLI).

Considerable morbidity and mortality are associated with HSCT. The best results are obtained with minimal residual disease, and in those under 20 years of age who have an HLA-identical sibling donor. Reduced-intensity HSCT has enabled treatment of older or less fit patients. In this form of transplantation, rather than using very intensive conditioning which causes morbidity from organ damage, relatively low doses of drugs, such as fludarabine and cyclophosphamide, are used to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the 'graft versus disease' effect, which may be boosted by the elective use of donor T cell infusions post transplant.

24.25 Indications for allogeneic HSCT

- Neoplastic disorders affecting stem cell compartments (e.g. leukaemias)
- Failure of haematopoiesis (e.g. aplastic anaemia)
- Major inherited defects in blood cell production (e.g. thalassaemia, immunodeficiency diseases)
- Inborn errors of metabolism with missing enzymes or cell lines

Complications

These are outlined in Boxes 24.26 and 24.27. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications, such as infection and GVHD, and there remains a significant risk of relapse of the haematological malignancy. The long-term survival for patients undergoing allogeneic HSCT in acute leukaemia is around 50%.

Graft-versus-host disease

Graft-versus-host disease (GVHD) is caused by the cytotoxic activity of donor T lymphocytes which become

24.26 Complications of allogeneic HSCT

Early

- Anaemia
- Infections
- Bleeding
- Acute GVHD
- Mucositis – pain, nausea, diarrhoea
- Liver veno-occlusive disease

Late

- Chronic GVHD
- Infertility
- Cataracts
- Secondary malignancy

(GVHD = graft-versus-host disease)

24.27 Infections during recovery from HSCT

Infection	Time after HSCT	Management
Herpes simplex (p. 325)	0–4 wks (aplastic phase)	Aciclovir prophylaxis and therapy
Bacterial, fungal	0–4 wks (aplastic phase)	As for acute leukaemia (p. 1036) – antibiotic and antifungal prophylaxis and therapy
Cytomegalovirus (p. 321)	5–21 wks (cell-mediated immune deficiency)	Antigen screening in blood (PCR) and pre-emptive therapy (e.g. ganciclovir)
Varicella zoster (p. 316)	After 13 wks	Aciclovir prophylaxis and therapy
Pneumocystis jirovecii (p. 400)	8–26 wks	Co-trimoxazole
Encapsulated bacteria	8 wks to years (immunoglobulin deficiency, prolonged with GVHD)	Prophylaxis and revaccination

(GVHD = graft-versus-host disease; PCR = polymerase chain reaction)

sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppressant drugs, including methotrexate, ciclosporin, alemtuzumab or antithymocyte globulin. Severe presentations are very difficult to control and, despite high-dose corticosteroids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, and carries an increased risk of infection, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with corticosteroids and prolonged immunosuppression with, for example, ciclosporin. However, associated with chronic GVHD are the graft-versus-leukaemia effect and a lower relapse rate of the underlying malignancy.

Autologous HSCT

This procedure can also be used in haematological malignancies. The patient's own stem cells from blood or marrow are first harvested and frozen. After conditioning myeloablative therapy, the autologous stem cells are reinfused into the blood stream in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. Autologous HSCT may be used for disorders which do not primarily involve the haematopoietic tissues, or in patients in whom very good remissions have been achieved. The preferred source of stem cells for autologous transplants is peripheral blood. These stem cells engraft more quickly, marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Thus autologous stem cell transplantation carries a lower procedure-related mortality rate than allogeneic HSCT at around 5%, but there is a higher rate of recurrence of malignancy. Whether the stem cells should be treated (purged) in an attempt to remove any residual malignant cells remains controversial.

ANTICOAGULANT AND ANTITHROMBOTIC THERAPY

There are numerous indications for anticoagulant and antithrombotic medications (Box 24.28). The guiding principles are outlined here, but management in specific indications is discussed elsewhere in the book. Broadly speaking, antiplatelet medications are of greater efficacy in the prevention of arterial thrombosis and of less value in the prevention of VTE. Thus, antiplatelet agents, such as aspirin and clopidogrel, are the drugs of choice in acute coronary events and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in VTE. In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and antiplatelet drugs is used.

A range of anticoagulant and antithrombotic drugs is used in clinical practice (Box 24.29). Newer agents allow predictable anticoagulation without the need for frequent monitoring and dose titration. Although warfarin remains the mainstay for oral anticoagulation, newer oral anticoagulants (dabigatran, rivaroxaban and apixaban), which can be given at fixed doses with predictable effects and no need for monitoring, have now been approved for the prevention of perioperative VTE, the treatment of established VTE and the prevention of cardioembolic stroke in patients with atrial fibrillation.

24.28 Indications for anticoagulation

Heparin/LMWH	
• Prevention and treatment of VTE • Percutaneous coronary intervention • Post-thrombolysis for MI • Unstable angina pectoris • Non-Q wave MI • Acute peripheral arterial occlusion • Cardiopulmonary bypass • Haemodialysis and haemofiltration	
Coumarins (warfarin etc.)	
• Prevention and treatment of VTE • Arterial embolism • Atrial fibrillation with specific stroke risk factors (p. 562) • Mobile mural thrombus post-MI • Extensive anterior MI • Dilated cardiomyopathy • Cardioversion • Ischaemic stroke in antiphospholipid syndrome • Mitral stenosis and mitral regurgitation with atrial fibrillation	Therapeutic INR 2.5
• Recurrent venous thrombosis whilst on warfarin • Mechanical prosthetic cardiac valves	INR 3.5
Rivaroxaban	
• Prevention and treatment of VTE • Atrial fibrillation with risk factor for stroke	
Dabigatran etexilate	
• Prevention of VTE • Atrial fibrillation with risk factors for stroke	
Apixaban	
• Prevention of VTE	

(INR = international normalised ratio; LMWH = low molecular weight heparin; MI = myocardial infarction; VTE = venous thromboembolism)

Heparins

Unfractionated heparin (UFH) and low molecular weight heparins (LMWH) both act by binding via a specific pentasaccharide to antithrombin which potentiates its natural anticoagulant activity (see Fig. 24.6, p. 996). Increased cleavage of activated proteases, particularly factor Xa and thrombin (IIa), accounts for the anticoagulant effect. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH but have several advantages:

- LMWHs are nearly 100% bioavailable and therefore produce reliable dose-dependent anticoagulation.

24.29 Modes of action of anticoagulant and antithrombotic drugs

Mode of action	Drug
Antiplatelet drugs	
Cyclo-oxygenase (COX) inhibition	Aspirin
Adenosine diphosphate (ADP) receptor inhibition	Clopidogrel Prasugrel Ticagrelor
Glycoprotein IIb/IIIa inhibition	Abciximab Tirofiban Eptifibatide
Phosphodiesterase inhibition	Dipyridamole
Oral anticoagulants	
Vitamin K antagonism	Warfarin/coumarins
Direct thrombin inhibition	Dabigatran
Direct Xa inhibition	Rivaroxaban Apixaban
Injectable anticoagulants	
Antithrombin-dependent inhibition of thrombin and Xa	Heparin
Antithrombin-dependent inhibition of Xa	Fondaparinux Idraparinux
Direct thrombin inhibition	Lepirudin Argatroban Bivalirudin

- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients with very low body weight and with a glomerular filtration rate below 30 mL/min).
- LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or prophylactic twice-daily subcutaneous administration required for UFH.
- While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.
- However, UFH is more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice.

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 24.28. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous, except when rapid reversibility is required. UFH is useful in patients with a high risk of bleeding: for example, those who have peptic ulceration or may require surgery. It is also favoured in the treatment of life-threatening thromboembolism: for example, major PE with significant hypoxaemia, hypotension and right-sided heart strain. In this situation, UFH is started with a loading intravenous dose of 80 U/kg., followed by a continuous infusion of 18 U/kg/hr initially. The level of anticoagulation should be assessed by the APTT after 6 hours and, if satisfactory, twice daily thereafter. It is usual to aim for a patient APTT which is 1.5–2.5 times the control time of the test.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a rare complication of heparin therapy, caused by induction of anti-heparin/PF4 antibodies which bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with a paradoxical thrombocytopenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin.

Clinical features

Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of more than 30% from baseline. The count may still be in the reference range. They may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms, such as shivering, following heparin injections. Patients who have received heparin in the preceding 100 days and who have preformed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

Investigations

The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the thrombocytopenia
- the timing of the fall in platelet count
- the presence of new thrombosis
- the likelihood of another cause for the thrombocytopenia.

Individuals at low risk need no further test; those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using an anti-PF4 enzyme-linked immunosorbent assay (ELISA).

Management

Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant which does not cross-react with the antibody substituted. Argatroban (a direct thrombin inhibitor) and danaparoid (a heparin analogue) are licensed for use in the UK. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poor prognosis.

Coumarins

Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K-dependent post-translational carboxylation of factors II, VII, IX and X in the liver. This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (p. 1000). Recommended target INR values for specific indications are given in Box 24.28.

Warfarin anticoagulation typically takes 3–5 days to become established, even using initial loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regime in this situation is to give 10 mg warfarin on the first and second days, with 5 mg on the third day; subsequent doses are titrated against the INR. Patients without an urgent need for anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supratherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication, and while treatment of DVT or preparation for cardioversion requires a limited duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- a narrow therapeutic window
- metabolism that is affected by many factors
- numerous drug interactions.

Drug interactions are common through protein binding and metabolism by the cytochrome P450 system. Inter-individual differences in warfarin doses required to achieve a therapeutic INR are mostly accounted for by naturally occurring polymorphisms in the *CYP2C9* and the *VKORC1* genes and dietary intake of vitamin K.

Major bleeding is the most common serious side-effect of warfarin and occurs in 1–2% of patients each year. Fatal haemorrhage, most commonly intracranial, occurs in about 0.25% per annum. There are scoring systems which predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box 24.30). There are also some specific contraindications to anticoagulation (see Box 24.30). Management of warfarin includes strategies for over-anticoagulation and for bleeding:

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or IV (1–2.5 mg), especially if the INR is greater than 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K IV. Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly IV, combined with coagulation factor replacement. This should optimally be a prothrombin complex concentrate (30–50 U/kg) which contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

Prophylaxis of venous thrombosis

All patients admitted to hospital should be assessed for their risk of developing VTE and appropriate prophylactic measures put in place. Both medical and surgical patients are at increased risk. A summary of the risk categories is given in Box 24.31. Early mobilisation of patients is important to prevent DVT. Patients at medium

24.30 How to assess risks of anticoagulation

Contraindications

- Recent surgery, especially to eye or CNS
- Pre-existing haemorrhage state, e.g. liver disease, haemophilia, thrombocytopenia
- Pre-existing structural lesions, e.g. peptic ulcer
- Recent cerebral or gastrointestinal haemorrhage
- Uncontrolled hypertension
- Cognitive impairment
- Frequent falls

Bleeding risk score*

- Age > 65 yrs (1 point)
- Previous gastrointestinal bleed (1 point)
- Previous stroke (1 point)
- Medical illness (1 point)
  - Recent myocardial infarction
  - Renal failure
  - Anaemia
  - Diabetes mellitus

Score: annual rate of major haemorrhage

0 = 3%
1–2 = 12%
3–4 = 30–48%

*Other bleeding risk scores have been applied to different clinical circumstances, e.g. HAS-BLED score in atrial fibrillation.

24.31 Antithrombotic prophylaxis

Indications

Patients in the following categories should be considered for specific antithrombotic prophylaxis:

Moderate risk of DVT

Major surgery

- In patients > 40 yrs or with other risk factor for VTE

Major medical illness, e.g.

- Heart failure
- MI with complications
- Sepsis
- Inflammatory conditions, including inflammatory bowel disease
- Active malignancy
- Nephrotic syndrome
- Stroke and other conditions leading to lower limb paralysis

High risk of DVT

- Major abdominal or pelvic surgery for malignancy or with history of DVT or known thrombophilia (see Box 24.4, p. 1001)
- Major hip or knee surgery
- Neurosurgery

Methods of VTE prophylaxis

Mechanical

- Intermittent pneumatic compression
- Mechanical foot pumps
- Graduated compression stockings

Pharmacological

- LMWHs
- Unfractionated heparin
- Fondaparinux
- Dabigatran
- Rivaroxaban
- Apixaban
- Warfarin

(DVT = deep vein thrombosis; MI = myocardial infarction; VTE = venous thromboembolism)

or high risk require additional antithrombotic measures; these may be pharmacological or mechanical. There is increasing evidence in high-risk groups, such as patients who have had major lower limb orthopaedic surgery and abdominal or pelvic cancer surgery, for protracted thromboprophylaxis for as long as 30 days after the procedure. Particular care should be taken with the use of pharmacological prophylaxis in patients with a high risk of bleeding or with specific risks of haemorrhage related to the site of surgery or the use of spinal or epidural anaesthesia.

ANAEMIAS

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs 24.10 and 24.11, pp. 1002 and 1003).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 24.19). Whilst in the marrow compartment, red cell precursors undergo cell division, driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when finally released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassaemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease.

In megaloblastic anaemia, the biochemical consequence of vitamin B_{12} or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow, such as myelodysplasia. In these states, cells haemoglobinise normally but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer which will freely exchange with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised – for example, in haemolysis – this may also increase the MCV.

Iron deficiency anaemia

This occurs when iron losses or physiological requirements exceed absorption.

Blood loss

The most common explanation in men and postmenopausal women is gastrointestinal blood loss (p. 853). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angiodysplastic lesions. Worldwide, hookworm and schistosomiasis are the most common causes of gut blood loss (pp. 369 and 376). Gastrointestinal blood loss may be exacerbated by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal

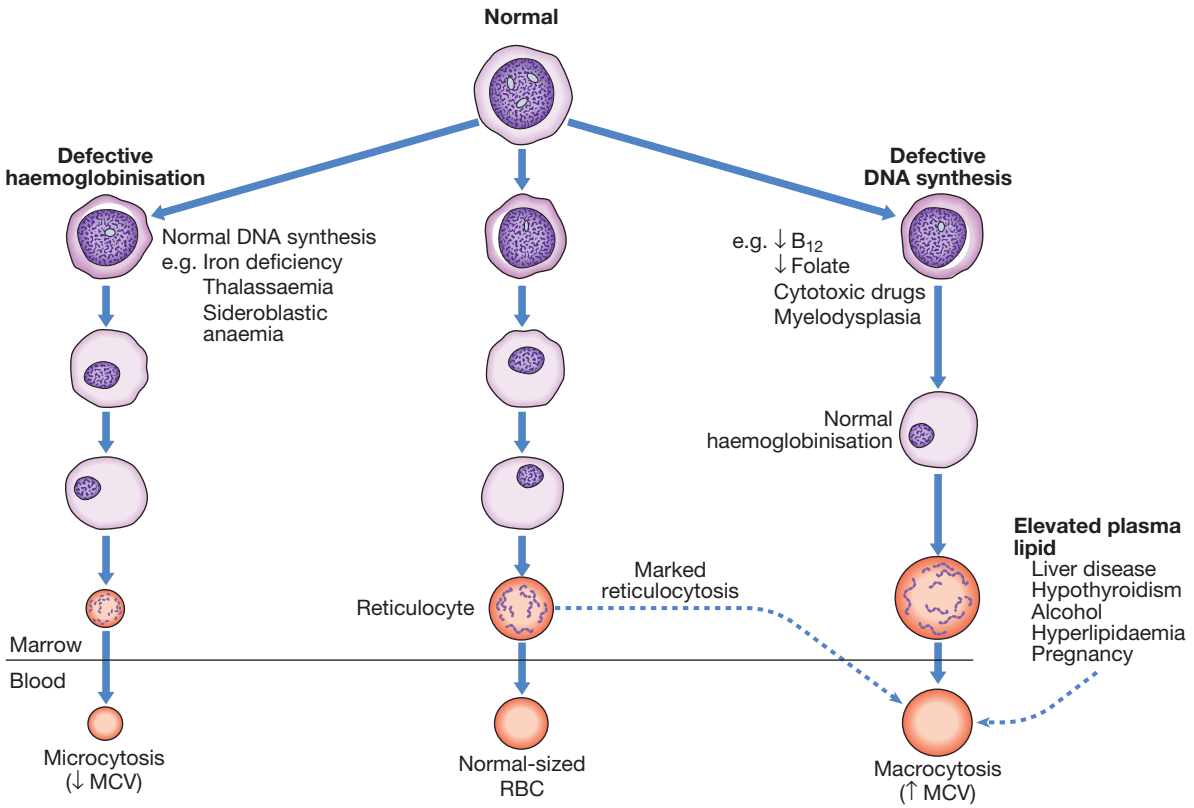

Fig. 24.19 Factors which influence the size of red cells in anaemia. In microcytosis, the MCV is < 76 fL. In macrocytosis, the MCV is > 100 fL. (MCV = mean cell volume; RBC = red blood cell)

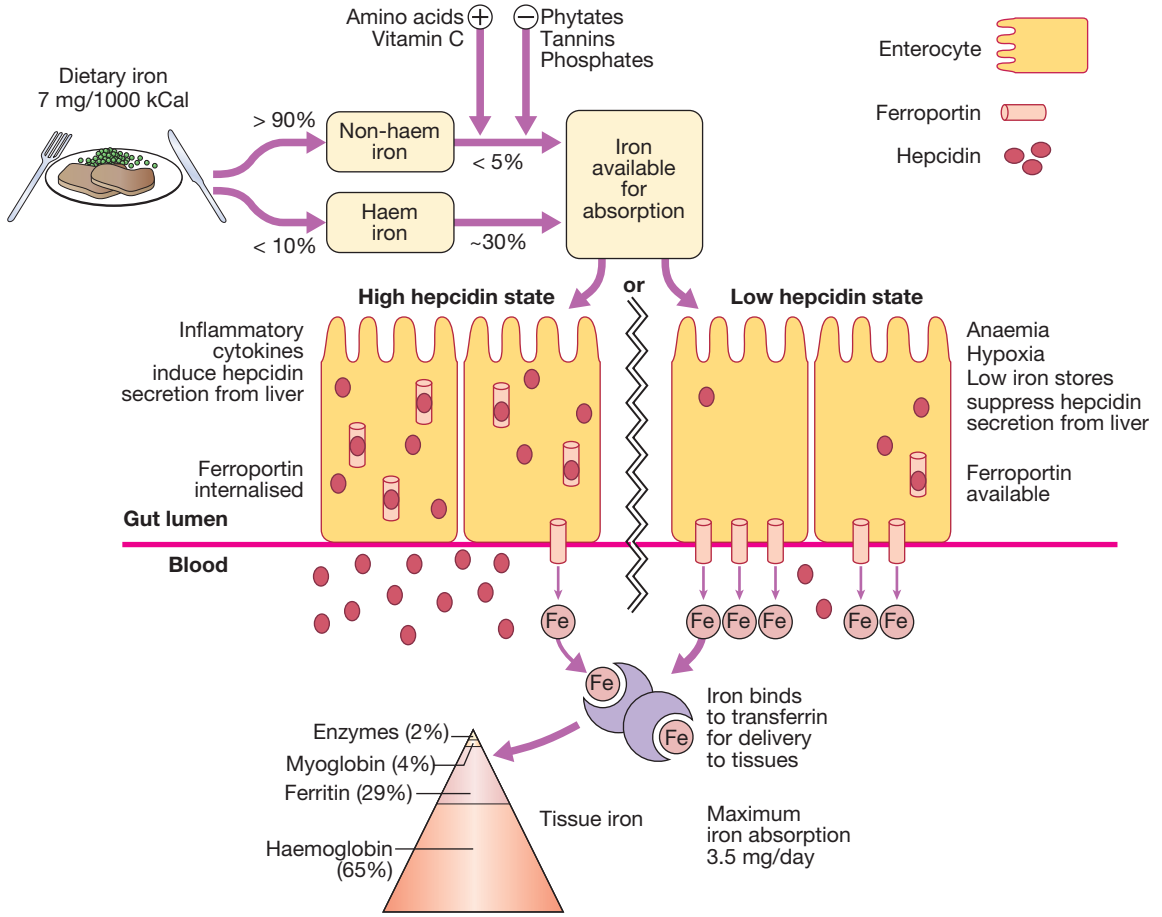

Fig. 24.20 The regulation of iron absorption, uptake and distribution in the body. The transport of iron is regulated in a similar fashion to enterocytes in other iron-transporting cells such as macrophages.

erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries, one-third of pre-menopausal women have low iron stores but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

Malabsorption

A dietary assessment should be made in all patients to ascertain their iron intake (p. 130). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 24.20). Achlorhydria in the elderly or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 880).

Physiological demands

At times of rapid growth, such as infancy and puberty, iron requirements increase and may outstrip absorption. In pregnancy, iron is diverted to the fetus, the placenta and the increased maternal red cell mass, and is lost with bleeding at parturition (Box 24.32).

24.32 Haematological physiology in pregnancy

- **Full blood count**: increased plasma volume (40%) lowers normal Hb (reference range reduced to > 105 g/L at 28 wks). The MCV may increase by 5 fL. A progressive neutrophilia occurs. Gestational thrombocytopenia (rarely < 60×10^9/L) is a benign phenomenon.
- **Depletion of iron stores**: iron deficiency is a common cause of anaemia in pregnancy and, if present, should be treated with oral iron supplement.
- **Vitamin B_{12}**: serum levels are physiologically low in pregnancy but deficiency is uncommon.
- **Folate**: tissue stores may become depleted, and folate supplementation is recommended in all pregnancies (see Box 5.32, p. 125).
- **Coagulation factors**: from the second trimester, procoagulant factors increase approximately threefold, particularly fibrinogen, von Willebrand factor and factor VIII. This causes activated protein C resistance and a shortened activated partial thromboplastin time (APTT), and contributes to a prothrombotic state.
- **Anticoagulants**: levels of protein C increase from the second trimester, while levels of free protein S fall as C4b binding protein increases.

24.33 Investigations to differentiate anaemia of chronic disease from iron deficiency anaemia

	Ferritin	Iron	TIBC	Transferrin saturation	Soluble transferrin receptor
Iron deficiency anaemia	↓	↓	↑	↓	↑
Anaemia of chronic disease	↑/Normal	↓	↓	↓	↓/Normal

(TIBC = total iron binding capacity)

Investigations

Confirmation of iron deficiency

Plasma ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 24.33). It is a very specific test; a subnormal level is due to iron deficiency or, very rarely, hypothyroidism or vitamin C deficiency. Ferritin levels can be raised in liver disease and in the acute phase response; in these conditions, a ferritin level of up to 100 µg/L may still be compatible with low bone marrow iron stores.

Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, the acute phase response and nephrotic syndrome, but raised by pregnancy and the oral contraceptive pill. A transferrin saturation (i.e. iron/TIBC × 100) of less than 16% is consistent with iron deficiency but is less specific than a ferritin measurement.

All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. At times of poor iron stores, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can now be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease, when a raised level indicates iron deficiency. In difficult cases, it may still be necessary to examine a bone marrow aspirate for iron stores.

Investigation of the cause

This will depend upon the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or radiological studies. Serum anti-endomysial or anti-transglutaminase antibodies and possibly a duodenal biopsy are indicated (p. 881) to detect coeliac disease. In the tropics, stool and urine should be examined for parasites (p. 311).

Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not necessary and oral iron replacement is appropriate. Ferrous sulphate 200 mg 3 times daily (195 mg of elemental iron per day) is adequate and should be continued for 3–6 months to replete iron stores. Many patients suffer gastrointestinal side-effects with ferrous sulphate, including dyspepsia and altered bowel habit. When this occurs, reduction in dose to 200 mg twice daily or a switch to ferrous gluconate 300 mg twice daily (70 mg of elemental iron per day) should be tried. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine, where it cannot be absorbed.

The haemoglobin should rise by around 10 g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-compliance, continued blood loss, malabsorption or an incorrect diagnosis. Patients with malabsorption or chronic gut disease may need parenteral iron therapy. Previously, iron dextran or iron sucrose was used, but new preparations of iron isomaltose and iron carboxymaltose have fewer allergic effects and are preferred. Doses required can be calculated based on the patient's starting haemoglobin and body weight. Observation for anaphylaxis following an initial test dose is recommended.

Anaemia of chronic disease

Anaemia of chronic disease (ACD) is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with haemoglobin in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low but iron stores are normal or increased, as indicated by the ferritin or stainable marrow iron.

Pathogenesis

It has recently become clear that the key regulatory protein that accounts for the findings characteristic of ACD is hepcidin, which is produced by the liver (see Fig. 24.20). Hepcidin production is induced by pro-inflammatory cytokines, especially IL-6. Hepcidin binds to ferroportin on the membrane of iron-exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood. The iron remains trapped inside the cells in the form of ferritin, levels of which are therefore normal or high in the face of significant anaemia. Inhibition or blockade of hepcidin is a potential target for treatment of this form of anaemia.

Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 24.33 summarises the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A positive response occurs in true iron deficiency but not in ACD. Measures which reduce the severity of the underlying disorder generally help to improve the ACD.

Megaloblastic anaemia

This results from a deficiency of vitamin B_{12} or folic acid, or from disturbances in folic acid metabolism. Folate is an important substrate of, and vitamin B_{12} a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B_{12} or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The end result is cells with arrested nuclear maturation but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early nucleated red cell precursors, and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis characteristic of other forms of haemolysis (p. 1026). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of 'giant' metamyelocytes with a large 'sausage-shaped' nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, a pancytopenia may be present in the peripheral blood.

Vitamin B_{12} deficiency, but not folate deficiency, is associated with neurological disease in up to 40% of cases, although advanced neurological disease due to B_{12} deficiency is now uncommon in the developed world. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesiae and ataxia of gait. The clinical and diagnostic features of megaloblastic anaemia are summarised in Boxes 24.34 and 24.35, and the neurological features of B_{12} deficiency in Box 24.36.

24.34 Clinical features of megaloblastic anaemia

Symptoms

- Malaise (90%)
- Breathlessness (50%)
- Paraesthesiae (80%)
- Sore mouth (20%)
- Weight loss
- Altered skin pigmentation
- Impotence
- Poor memory
- Depression
- Personality change
- Hallucinations
- Visual disturbance

Signs

- Smooth tongue
- Angular cheilosis
- Vitiligo
- Skin pigmentation
- Heart failure
- Pyrexia

24.35 Investigations in megaloblastic anaemia

Investigation	Result
Haemoglobin	Often reduced, may be very low
MCV	Usually raised, commonly > 120 fL
Erythrocyte count	Low for degree of anaemia
Blood film	Oval macrocytosis, poikilocytosis, red cell fragmentation, neutrophil hypersegmentation
Reticulocyte count	Low for degree of anaemia
Leucocyte count	Low or normal
Platelet count	Low or normal
Bone marrow	Increased cellularity, megaloblastic changes in erythroid series, giant metamyelocytes, dysplastic megakaryocytes, increased iron in stores, pathological non-ring sideroblasts
Serum ferritin	Elevated
Plasma lactate dehydrogenase (LDH)	Elevated, often markedly

24.36 Neurological findings in B_{12} deficiency

Peripheral nerves
- Glove and stocking paraesthesiae
- Loss of ankle reflexes

Spinal cord
- Subacute combined degeneration of the cord
  - Posterior columns – diminished vibration sensation and proprioception
  - Corticospinal tracts – upper motor neuron signs

Cerebrum
- Dementia
- Optic atrophy

Autonomic neuropathy

Vitamin B_{12}

Vitamin B_{12} absorption

The average daily diet contains 5–30 µg of vitamin B_{12}, mainly in meat, fish, eggs and milk – well in excess of the 1 µg daily requirement. In the stomach, gastric enzymes release vitamin B_{12} from food and at gastric pH it binds to a carrier protein termed R protein. The gastric parietal cells produce intrinsic factor, a vitamin B_{12}-binding protein which optimally binds vitamin B_{12} at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B_{12} released from the diet switches from the R protein to intrinsic factor. Bile also contains vitamin B_{12} which is available for reabsorption in the intestine. The vitamin B_{12}–intrinsic factor complex binds to specific receptors in the terminal ileum, and vitamin B_{12} is actively transported by the enterocytes to plasma, where it binds to transcobalamin II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The liver stores enough vitamin B_{12} for 3 years and this, together with the enterohepatic circulation, means that vitamin B_{12} deficiency takes years to

become manifest, even if all dietary intake is stopped or severe B_{12} malabsorption supervenes.

Blood levels of vitamin B_{12} provide a reasonable indication of tissue stores and are usually diagnostic of deficiency. Levels of cobalamins fall in normal pregnancy. Reference ranges vary between laboratories but levels below 150 ng/L are common and, in the last trimester, 5–10% of women have levels below 100 ng/L. Spuriously low B_{12} values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B_{12} assays.

Causes of vitamin B_{12} deficiency

Dietary deficiency

This only occurs in strict vegans but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B_{12} levels but are not tissue vitamin B_{12}-deficient.

Gastric pathology

Release of vitamin B_{12} from the food requires normal gastric acid and enzyme secretion, and this is impaired by hypochlorhydria in elderly patients or following gastric surgery. Total gastrectomy invariably results in vitamin B_{12} deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin B_{12} injections. After partial gastrectomy, vitamin B_{12} deficiency only develops in 10–20% of patients by 5 years; an annual injection of vitamin B_{12} should prevent deficiency in this group.

Pernicious anaemia

This is an organ-specific autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin B_{12} is absorbed. Pernicious anaemia has an incidence of 25/100 000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto's thyroiditis, Graves' disease, vitiligo, hypoparathyroidism or Addison's disease; Ch. 20) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of B_{12} deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely but a positive result is not diagnostic. The Schilling test, involving measurement of absorption of radio-labelled B_{12} after oral administration before and after replacement of intrinsic factor, has fallen out of favour with the availability of autoantibody tests, greater caution in the use of radioactive tracers, and limited availability of intrinsic factor.

Small bowel pathology

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin B_{12} from R protein to intrinsic factor. This usually results in slightly low vitamin B_{12} values but no tissue evidence of vitamin B_{12} deficiency.

Motility disorders or hypogammaglobulinaemia can result in bacterial overgrowth, and the ensuing competition for free vitamin B_{12} can lead to deficiency. This is corrected to some extent by appropriate antibiotics.

A small number of people heavily infected with the fish tapeworm (p. 378) develop vitamin B_{12} deficiency.

Inflammatory disease of the terminal ileum, such as Crohn's disease, may impair the absorption of vitamin B_{12}–intrinsic factor complex, as may surgery on that part of the bowel.

Folate

Folate absorption

Folates are produced by plants and bacteria; hence dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50 µg but excess cooking destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is an enterohepatic circulation. Total body stores of folate are small and deficiency can occur in a matter of weeks.

Folate deficiency

The causes and diagnostic features of folate deficiency are shown in Boxes 24.37 and 24.38. The edentulous elderly or psychiatric patient is particularly susceptible to dietary deficiency and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis worldwide and is more likely in the context of twin pregnancies, multiparity and hyperemesis

24.37 Causes of folate deficiency

Diet
- Poor intake of vegetables

Malabsorption
- e.g. Coeliac disease

Increased demand
- Cell proliferation, e.g. haemolysis
- Pregnancy

Drugs*
- Certain anticonvulsants (e.g. phenytoin)
- Contraceptive pill
- Certain cytotoxic drugs (e.g. methotrexate)

*Usually only a problem in patients deficient in folate from another cause.

24.38 Investigation of folic acid deficiency

Diagnostic findings
- Serum folate levels may be low but are difficult to interpret
- Low red cell folate levels indicate prolonged folate deficiency and are probably the most relevant measure

Corroborative findings
- Macrocytic dysplastic blood picture
- Megaloblastic marrow

gravidarum. Serum folate is very sensitive to dietary intake; a single folate-rich meal can normalise it in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant therapy can reduce it in the absence of megaloblastosis. For this reason, red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

Management of megaloblastic anaemia

If a patient with a severe megaloblastic anaemia is very ill and treatment must be started before vitamin B_{12} and red cell folate results are available, that treatment should always include both folic acid and vitamin B_{12}. The use of folic acid alone in the presence of vitamin B_{12} deficiency may result in worsening of neurological deficits.

Rarely, if severe angina or heart failure is present, transfusion can be used in megaloblastic anaemia. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis, and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 U of red cells with diuretic cover may be given cautiously.

Vitamin B_{12} deficiency

Vitamin B_{12} deficiency is treated with hydroxycobalamin 1000 µg IM for 6 doses 2 or 3 days apart, followed by maintenance therapy of 1000 µg every 3 months for life. The reticulocyte count will peak by the 5th–10th day after starting replacement therapy. The haemoglobin will rise by 10 g/L every week until normalised. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. A sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

Folate deficiency

Oral folic acid 5 mg daily for 3 weeks will treat acute deficiency and 5 mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at risk, and reduces the risk of fetal neural tube defects (p. 125). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. haemolytic anaemias). There is some evidence that supraphysiological supplementation (400 µg/day) can reduce the risk of coronary and cerebrovascular disease by lowering plasma homocysteine levels. This has led the US Food and Drug Administration to introduce fortification of bread, flour and rice with folic acid.

Haemolytic anaemia

Haemolysis indicates that there is shortening of the normal red cell lifespan of 120 days. There are many causes, as shown in Figure 24.21. To compensate, the bone marrow may increase its output of red cells six- to eightfold by increasing the proportion of red cells produced, expanding the volume of active marrow, and releasing reticulocytes prematurely. Anaemia only occurs if the rate of destruction exceeds this increased production rate.

24.39 Investigation results indicating active haemolysis

Hallmarks of haemolysis	
• ↓Haemoglobin	• ↑Reticulocytes
• ↑Unconjugated bilirubin	• ↑Urinary urobilinogen
• ↑Lactate dehydrogenase	
Additional features of intravascular haemolysis	
• ↓Haptoglobin	• Positive urinary haemosiderin
• ↑Methaemalbumin	• Haemoglobinuria

Results of investigations which establish the presence of haemolysis are shown in Box 24.39. Red cell destruction overloads pathways for haemoglobin breakdown in the liver (p. 927), causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobilinogen from the gut results in an increase in urinary urobilinogen (pp. 936 and 994). Red cell destruction releases LDH into the serum. The bone marrow compensation results in a reticulocytosis, and sometimes nucleated red cell precursors appear in the blood. Increased proliferation of the bone marrow can result in a thrombocytosis, neutrophilia and, if marked, immature granulocytes in the blood, producing a leucoerythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis:

- Spherocytes are small, dark red cells which suggest autoimmune haemolysis or hereditary spherocytosis.
- Sickle cells suggest sickle-cell disease.
- Red cell fragments indicate microangiopathic haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 24.21).

Extravascular haemolysis

Physiological red cell destruction occurs in the reticuloendothelial cells in the liver or spleen, so avoiding free haemoglobin in the plasma. In most haemolytic states, haemolysis is predominantly extravascular.

To confirm the haemolysis, patients' red cells can be labelled with ^{51}chromium. When re-injected, they can be used to determine red cell survival; when combined with body surface radioactivity counting, this test may indicate whether the liver or the spleen is the main source of red cell destruction. However, it is seldom performed in clinical practice.

Intravascular haemolysis

Less commonly, red cell lysis occurs within the blood stream due to membrane damage by complement (ABO transfusion reactions, paroxysmal nocturnal haemoglobinuria), infections (malaria, *Clostridium perfringens*),

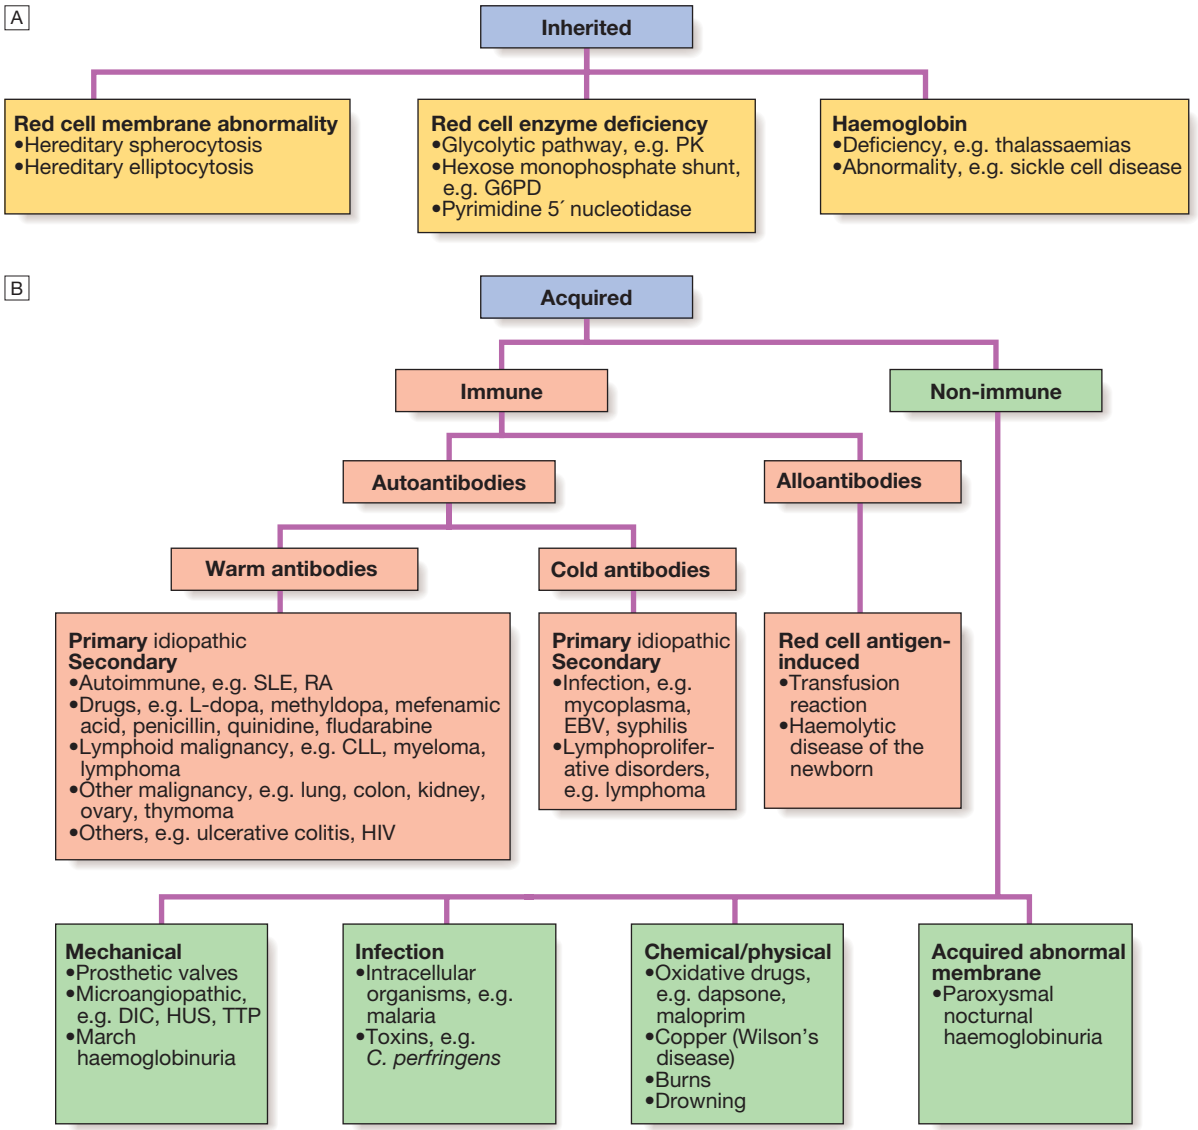

Fig. 24.21 Causes of haemolysis. A Inherited causes. B Acquired causes. (CLL = chronic lymphatic leukaemia; DIC = disseminated intravascular coagulation; EBV = Epstein–Barr virus; G6PD = glucose-6-phosphate dehydrogenase; HUS = haemolytic uraemic syndrome; PK = pyruvate kinase; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; TTP = thrombotic thrombocytopenic purpura)

mechanical trauma (heart valves, DIC) or oxidative damage (e.g. drugs such as dapsone and maloprim). When intravascular red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an α_2-globulin produced by the liver, which binds free haemoglobin, resulting in a fall in its levels during active haemolysis. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin, which binds to albumin, in turn forming methaemalbumin, which can be detected spectrophotometrically in the Schumm's test. Methaemoglobin is degraded and any free haem is bound to a second binding protein called haemopexin. If all the protective mechanisms are saturated, free haemoglobin may appear in the urine (haemoglobinuria). When fulminant, this gives rise to black urine, as in severe *falciparum* malaria infection (p. 353). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give rise to haemosiderinuria, which is always indicative of intravascular haemolysis.

Red cell membrane defects

The structure of the red cell membrane is shown in Figure 24.4 (p. 994). The basic structure is a cytoskeleton 'stapled' on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity; the red cell diameter is 8 µm but the narrowest capillaries in the circulation are in the spleen, measuring just 2 µm in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell

shape (see Box 24.2, p. 999) and reduced red cell survival due to extravascular haemolysis.

Hereditary spherocytosis

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1:5000 in developed countries but this may be an underestimate, since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 24.4, p. 994). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, a reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or co-inheritance of a second defect involving a different protein.

The clinical course may be complicated by crises:

- *A haemolytic crisis* occurs when the severity of haemolysis increases; this is rare, and usually associated with infection.
- *A megaloblastic crisis* follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- *An aplastic crisis* occurs in association with parvovirus B19 infection (p. 315). Parvovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

Investigations

The patient and other family members should be screened for features of compensated haemolysis (see Box 24.39). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes but the direct Coombs test (see Fig. 24.22) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions but is limited by lack of sensitivity and specificity. More specific flow cytometric tests, detecting binding of eosin-5-maleimide to red cells, are recommended in borderline cases.

Management

Folic acid prophylaxis, 5 mg daily, should be given for life. Consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed until after 6 years of age in view of the risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 24.40.

Acute, severe haemolytic crises require transfusion support, but blood must be cross-matched carefully and transfused slowly as haemolytic transfusion reactions may occur (p. 1016).

24.40 Management of the splenectomised patient

- Vaccinate with pneumococcal, *Haemophilus influenzae* type B, meningococcal group C and influenza vaccines at least 2–3 wks before elective splenectomy. Vaccination should be given after emergency surgery but may be less effective
- Pneumococcal re-immunisation should be given at least 5-yearly and influenza annually. Vaccination status must be documented
- Life-long prophylactic penicillin V 500 mg twice daily is recommended. In penicillin-allergic patients, consider a macrolide
- Patients should be educated regarding the risks of infection and methods of prophylaxis
- A card or bracelet should be carried to alert health professionals to the risk of overwhelming sepsis
- In septicaemia, patients should be resuscitated and given IV antibiotics to cover pneumococcus, *Haemophilus* and meningococcus, according to local resistance patterns
- The risk of cerebral malaria is increased in the event of infection
- Animal bites should be promptly treated with local disinfection and antibiotics, to prevent serious soft tissue infection and septicaemia

Hereditary elliptocytosis

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional abnormality of one or more anchor proteins in the red cell membrane, e.g. alpha spectrin or protein 4.1. Inheritance may be autosomal dominant or recessive. Hereditary elliptocytosis is less common than hereditary spherocytosis in Western countries, with an incidence of 1/10000, but is more common in equatorial Africa and parts of South-east Asia. The clinical course is variable and depends upon the degree of membrane dysfunction caused by the inherited molecular defect(s); most cases present as an asymptomatic blood film abnormality, but occasional cases result in neonatal haemolysis or a chronic compensated haemolytic state. Management of the latter is the same as for hereditary spherocytosis.

A characteristic variant of hereditary elliptocytosis occurs in South-east Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The blood film is often very abnormal and immediate differential diagnosis is broad.

Red cell enzymopathies

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume whilst protecting itself from the oxidative stress presented by oxygen carriage. Anaerobic glycolysis via the Embden–Meyerhof pathway generates ATP, and the hexose monophosphate shunt produces nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends upon the importance of the steps affected and the presence of

alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis precipitated by episodic oxidative stress, whilst those in the Embden–Meyerhof pathway result in shortened red cell survival and chronic haemolysis.

Glucose-6-phosphate dehydrogenase deficiency

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzymopathy, affecting 10% of the world's population, with a geographical distribution which parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits which are encoded by a gene on the X chromosome. The deficiency therefore affects males and rare homozygous females (p. 53), but it is carried by females. Carrier heterozygous females are usually only affected in the neonatal period or in the presence of extreme lyonisation, producing selective inactivation of the non-affected X chromosome.

Over 400 subtypes of G6PD are described. The most common types associated with normal activity are the B^+ enzyme present in most Caucasians and 70% of Afro-Caribbeans, and the A^+ variant present in 20% of Afro-Caribbeans. The two common variants associated with reduced activity are the A^- variety in approximately 10% of Afro-Caribbeans, and the Mediterranean or B^- variety in Caucasians. In East and West Africa, up to 20% of males and 4% of females (homozygotes) are affected and have enzyme levels of about 15% of normal. The deficiency in Caucasian and Oriental populations is more severe, with enzyme levels as low as 1%.

Clinical features and investigation findings are shown in Box 24.41.

Management aims to stop any precipitant drugs and treat any underlying infection. Acute transfusion support may be life-saving.

24.41 Glucose-6-phosphate dehydrogenase deficiency

Clinical features

- Acute drug-induced haemolysis to (e.g.):
  - Analgesics: aspirin, phenacetin
  - Antimalarials: primaquine, quinine, chloroquine, pyrimethamine
  - Antibiotics: sulphonamides, nitrofurantoin, ciprofloxacin
  - Miscellaneous: quinidine, probenecid, vitamin K, dapsone
- Chronic compensated haemolysis
- Infection or acute illness
- Neonatal jaundice: may be a feature of the B^- enzyme
- Favism, i.e. acute haemolysis after ingestion of broad beans (*Vicia faba*)

Laboratory features

Non-spherocytic intravascular haemolysis during an attack

The blood film will show:

- Bite cells (red cells with a 'bite' of membrane missing)
- Blister cells (red cells with surface blistering of the membrane)
- Irregularly shaped small cells
- Polychromasia reflecting the reticulocytosis
- Denatured haemoglobin visible as Heinz bodies within the red cell cytoplasm with a supravital stain such as methyl violet

G6PD level

- Can be indirectly assessed by screening methods which usually depend upon the decreased ability to reduce dyes
- Direct assessment of G6PD is made in those with low screening values
- Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result

Pyruvate kinase deficiency

This is the second most common red cell enzyme defect. It results in deficiency of ATP production and a chronic haemolytic anaemia. It is inherited as an autosomal recessive trait. The extent of anaemia is variable; the blood film shows characteristic 'prickle cells' which resemble holly leaves. Enzyme activity is only 5–20% of normal. Transfusion support may be necessary.

Pyrimidine 5′ nucleotidase deficiency

The pyrimidine 5′ nucleotidase enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see Box 24.2, p. 999), associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

Autoimmune haemolytic anaemia

This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or M, or more rarely IgE or A. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular. Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:

- *Warm antibodies* bind best at 37°C and account for 80% of cases. The majority are IgG and often react against Rhesus antigens.
- *Cold antibodies* bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. To be clinically relevant, they must act within the range of normal body temperatures. They account for the other 20% of cases.

Warm autoimmune haemolysis

The incidence of warm autoimmune haemolysis is approximately 1/100 000 population per annum; it occurs at all ages but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions (see Fig. 24.21B).

Investigations

There is evidence of haemolysis and spherocytes on the blood film. The diagnosis is confirmed by the direct

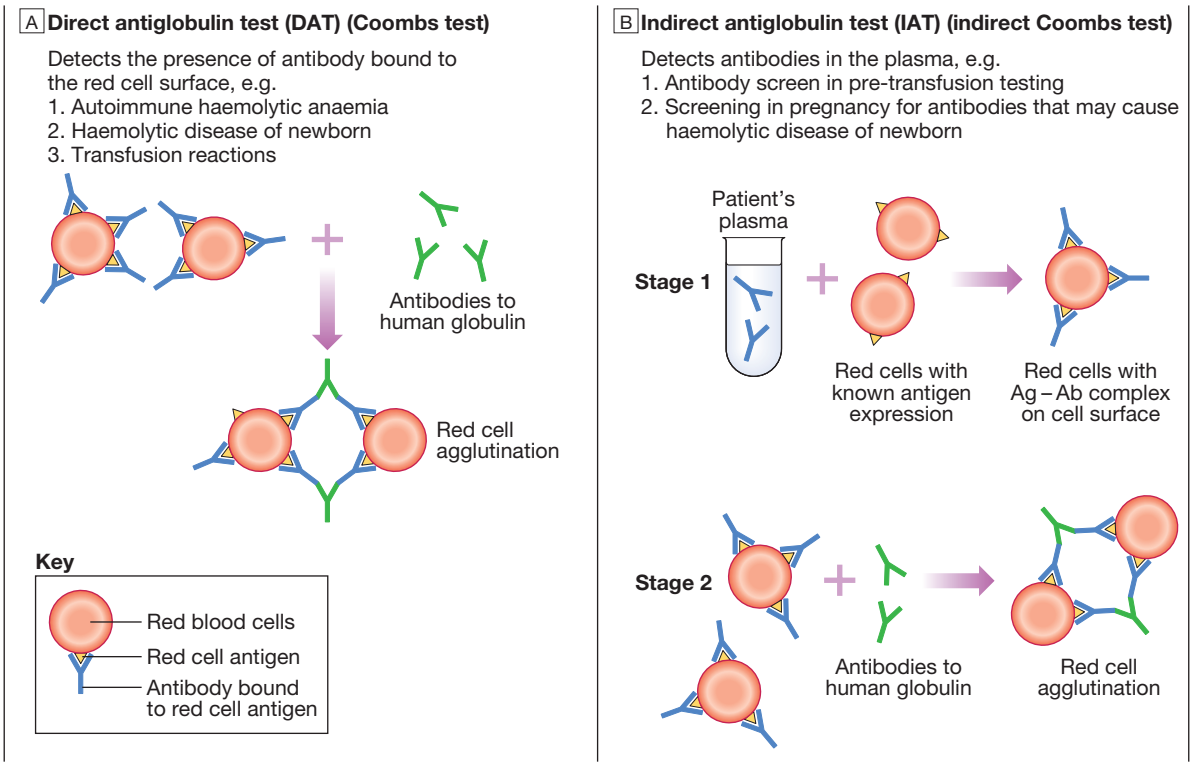

Fig. 24.22 Direct and indirect antiglobulin tests.

Coombs or antiglobulin test (Fig. 24.22). The patient's red cells are mixed with Coombs reagent, which contains antibodies against human IgG/M/complement. If the red cells have been coated by antibody in vivo, the Coombs reagent will induce their agglutination and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is Rhesus and most often anti-e; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies. Around 10% of all warm autoimmune haemolytic anaemias are Coombs test-negative.

Management

If the haemolysis is secondary to an underlying cause, this must be treated and any implicated drugs stopped.

It is usual to treat patients initially with prednisolone 1 mg/kg orally. A response is seen in 70–80% of cases but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticulocyte levels. Once the haemoglobin has normalised and the reticulocytosis resolved, the corticosteroid dose can be reduced slowly over about 10 weeks. Corticosteroids work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production.

Transfusion support may be required for life-threatening problems, such as the development of heart failure or rapid unabated falls in haemoglobin. The least incompatible blood should be used but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to corticosteroids or can only be stabilised by large doses, then splenectomy should be considered. This removes a main site of red cell destruction and antibody production, with a good response in 50–60% of cases. The operation can be performed laparoscopically with reduced morbidity. If splenectomy is not appropriate, alternative immunosuppressive therapy with azathioprine or cyclophosphamide may be considered. This is least suitable for young patients, in whom long-term immunosuppression carries a risk of secondary neoplasms. The anti-CD20 (B cell) monoclonal antibody, rituximab, has shown some success in difficult cases.

Cold agglutinin disease

This is due to antibodies, usually IgM, which bind to the red cells at low temperatures and cause them to agglutinate. It may cause intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.

Chronic cold agglutinin disease

This affects elderly patients and may be associated with an underlying low-grade B cell lymphoma. It causes a low-grade intravascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (so-called acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously high because the automated

analysers detect aggregates as single cells. Monoclonal IgM usually has anti-I or, less often, anti-i specificity. Treatment is directed at any underlying lymphoma but if the disease is idiopathic, then patients must keep extremities warm, especially in winter. Some patients respond to corticosteroid therapy and blood transfusion may be considered, but the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood administered via a blood-warmer. All patients should receive folic acid supplementation.

Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneumoniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children, in association with viral or bacterial infection. An IgG antibody binds to red cells in the peripheral circulation but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath–Landsteiner antibody and has specificity against the P antigen on the red cells.

Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is caused by antibodies against non-self red cells, and occurs after unmatched transfusion (p. 1016), or after maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, p. 1014).

Non-immune haemolytic anaemia

Physical trauma

Physical disruption of red cells may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- *Mechanical heart valves.* High flow through incompetent valves or periprosthetic leaks through the suture ring holding a valve in place result in shear stress damage.
- *March haemoglobinuria.* Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- *Thermal injury.* Severe burns cause thermal damage to red cells, characterised by fragmentation and the presence of microspherocytes in the blood.
- *Microangiopathic haemolytic anaemia.* Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (p. 495), thrombotic thrombocytopenic purpura (p. 1056) and disseminated intravascular coagulation (p. 1055).

Infection

Plasmodium falciparum malaria (p. 353) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever because of the associated haemoglobinuria. *Clostridium perfringens* septicaemia (p. 305), usually in the context of ascending cholangitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecithinase which destroys the red cell membrane.

Chemicals or drugs

Dapsone and sulfasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrites and nitrobenzene derivatives may all cause haemolysis.

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired, non-malignant clonal expansion of haematopoietic stem cells deficient in GPI-anchor protein; it results in intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine, which has a characteristic red–brown colour. The disease is associated with an increased risk of venous thrombosis in unusual sites, such as the liver or abdomen. PNH is also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (pp. 1048 and 1041). Management is supportive with transfusion and treatment of thrombosis. Recently, the anti-complement C5 monoclonal antibody eculizumab was shown to be effective in reducing haemolysis.

Haemoglobinopathies

These diseases are caused by mutations affecting the genes encoding the globin chains of the haemoglobin molecule. Normal haemoglobin is comprised of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, including in the fetus, so severe mutations may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (HbF-$\alpha\alpha/\gamma\gamma$) has two gamma chains, while the predominant adult haemoglobin (HbA-$\alpha\alpha/\beta\beta$) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A_2 (HbA_2-$\alpha\alpha/\delta\delta$, usually less than 2%) is made from birth.

The geographical distribution of the common haemoglobinopathies is shown in Figure 24.23. The haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

Qualitative abnormalities – abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobins), there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but are now described by names usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell anaemia. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the

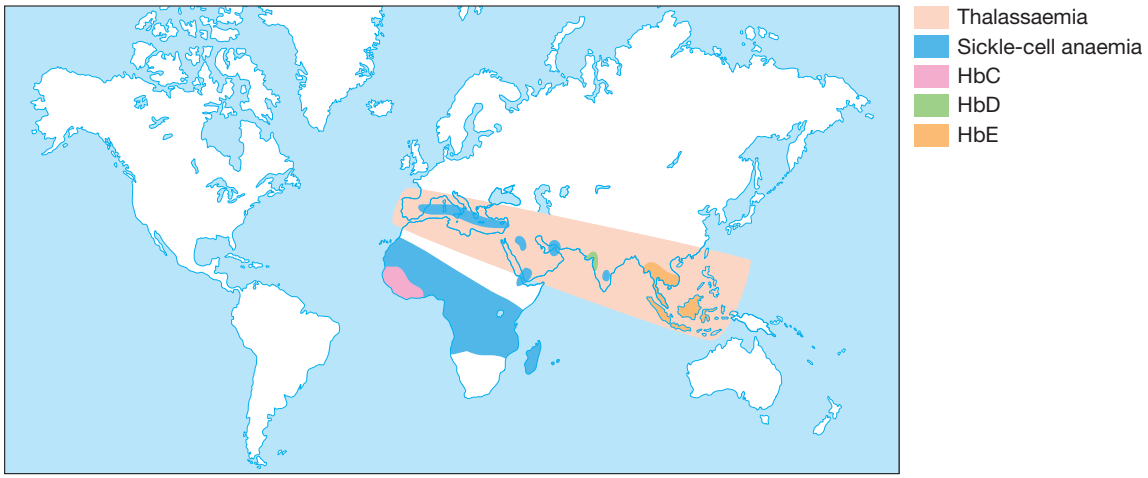

Fig. 24.23 The geographical distribution of the haemoglobinopathies. From Hoffbrand and Pettit 1992 – see p. 1056.

diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

Quantitative abnormalities – thalassaemias

In quantitative abnormalities (the thalassaemias), there are mutations causing a reduced rate of production of one or other of the globin chains, altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, whilst in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival.

Sickle-cell anaemia

Sickle-cell disease results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait (p. 53). Homozygotes only produce abnormal beta chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disease. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in the clinically asymptomatic sickle-cell trait.

Epidemiology

The heterozygote frequency is over 20% in tropical Africa (see Fig. 24.23). In black American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the lethal effects of *falciparum* malaria in early childhood; the high prevalence in equatorial Africa can be explained by the survival advantage it confers in areas where *falciparum* malaria is endemic. However, homozygous patients with sickle-cell anaemia do not have correspondingly greater resistance to *falciparum* malaria.

Pathogenesis

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as 'tactoids'. These distort the red cell membrane and produce characteristic sickle-shaped cells (Fig. 24.24). The polymerisation is reversible when re-oxygenation occurs. The distortion of the red cell membrane, however, may become permanent and the red cell 'irreversibly sickled'. The greater the concentration of sickle-cell haemoglobin in the individual cell, the more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus, the abnormal haemoglobin C variant participates in the polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

Clinical features

Sickling is precipitated by hypoxia, acidosis, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the microcirculation. This results in a number of acute syndromes, termed 'crises', and chronic organ damage (Fig. 24.24):

- Painful *vaso-occlusive crisis*. Plugging of small vessels in the bone produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebrae in adults. Patients usually have a systemic response with tachycardia, sweating and a fever. This is the most common crisis.
- *Sickle chest syndrome*. This may follow a vaso-occlusive crisis and is the most common cause of death in adult sickle disease. Bone marrow infarction results in fat emboli to the lungs, which cause further sickling and infarction, leading to ventilatory failure if not treated.
- *Sequestration crisis*. Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children, the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction and adults may have no functional spleen. In adults, the liver may undergo sequestration with severe pain due to capsular stretching. Priapism is a complication seen in affected men.
- *Aplastic crisis*. Infection with human parvovirus B19 results in a severe but self-limiting red cell aplasia. This produces a very low haemoglobin, which may cause heart failure. Unlike in all other sickle crises, the reticulocyte count is low.

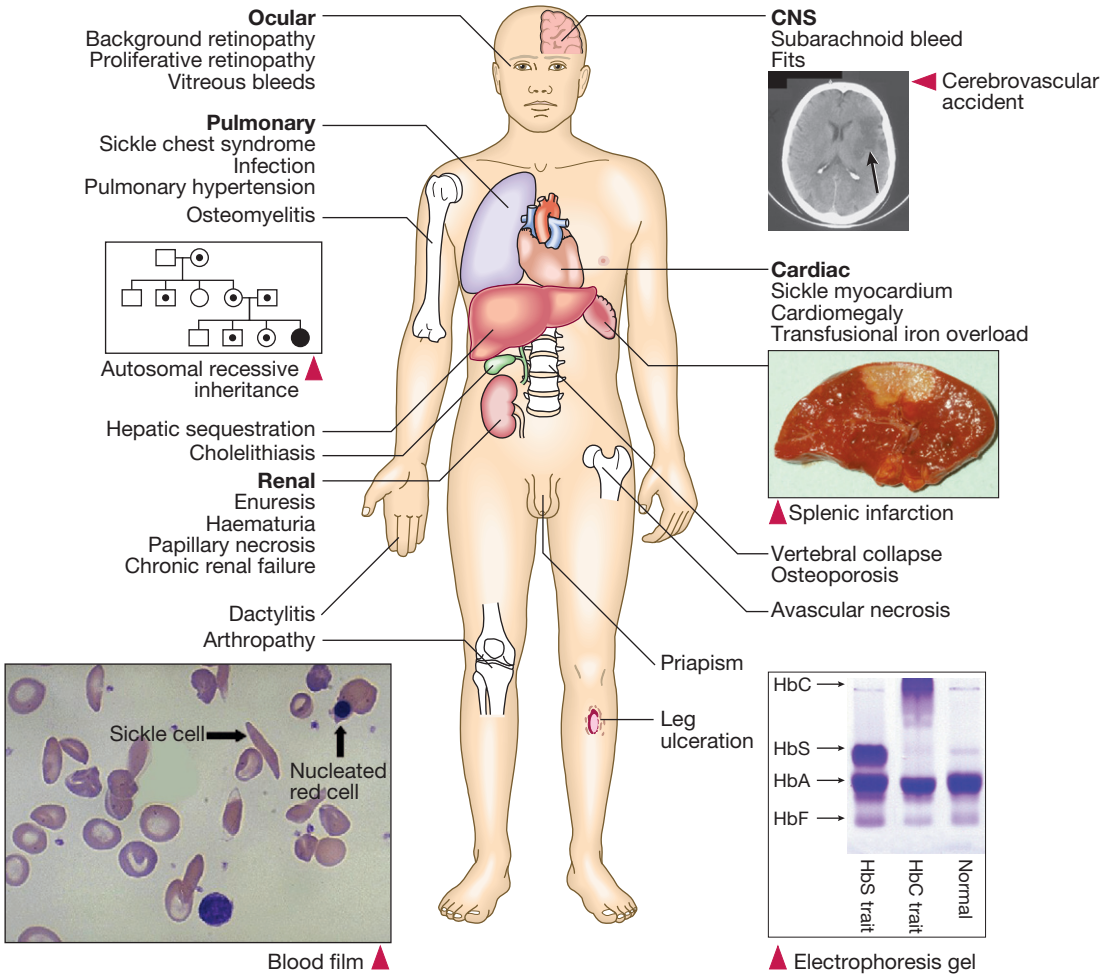

Fig. 24.24 Clinical and laboratory features of sickle-cell disease.

Investigations

Patients with sickle-cell disease have a compensated anaemia, usually around 60–80 g/L. The blood film shows sickle cells, target cells and features of hyposplenism. A reticulocytosis is present. The presence of HbS can be demonstrated by exposing red cells to a reducing agent such as sodium dithionite; HbA gives a clear solution, whereas HbS polymerises to produce a turbid solution. This forms the basis of emergency screening tests before surgery in appropriate ethnic groups but cannot distinguish between sickle-cell trait and disease. The definitive diagnosis requires haemoglobin electrophoresis to demonstrate the absence of HbA, 2–20% HbF and the predominance of HbS. Both parents of the affected individual will have sickle-cell trait.

Management

All patients with sickle-cell disease should receive prophylaxis with daily folic acid, and penicillin V to protect against pneumococcal infection, which may be lethal in the presence of hyposplenism. These patients should be vaccinated against pneumococcus, meningococcus, *Haemophilus influenzae* B, hepatitis B and seasonal influenza.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with fully genotyped blood wherever possible. Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications, such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesected and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disease and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxycarbamide has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises.

Relatively few allogeneic stem cell transplants from HLA-matched siblings have been performed but this procedure appears to be potentially curative (p. 1017).

Prognosis

In Africa, few children with sickle-cell anaemia survive to adult life without medical attention. Even with

standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

Other abnormal haemoglobins

Another beta chain haemoglobinopathy, haemoglobin C (HbC) disease, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one HbS gene and one HbC gene from their parents have haemoglobin SC disease, which behaves like a mild form of sickle-cell disease. SC disease is associated with a reduced frequency of crises but is not uncommonly linked with complications in pregnancy and retinopathy.

The thalassaemias

Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesise a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point mutations causing no (β^0) or reduced (β^-) beta chain production.

Beta-thalassaemia

Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild anaemia and little or no clinical disability, which may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or, at best, produce very little; after the first 4–6 months of life, they develop profound hypochromic anaemia. The diagnostic features are summarised in Box 24.42. Intermediate grades of severity occur.

Management and prevention

See Box 24.43. Cure is now a possibility for selected children, with allogeneic haematopoietic stem cell transplantation (p. 1017).

It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA analysis sufficiently early in pregnancy to allow termination. This examination is only appropriate if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

Alpha-thalassaemia

Reduced or absent alpha chain synthesis is common in Southeast Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.

- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H

24.42 Diagnostic features of beta-thalassaemia

Beta-thalassaemia major (homozygotes)

- Profound hypochromic anaemia
- Evidence of severe red cell dysplasia
- Erythroblastosis
- Absence or gross reduction of the amount of haemoglobin A
- Raised levels of haemoglobin F
- Evidence that both parents have thalassaemia minor

Beta-thalassaemia minor (heterozygotes)

- Mild anaemia
- Microcytic hypochromic erythrocytes (not iron-deficient)
- Some target cells
- Punctate basophilia
- Raised haemoglobin A_2 fraction

24.43 Treatment of beta-thalassaemia major

Problem	Management
Erythropoietic failure	Allogeneic HSCT from HLA-compatible sibling Transfusion to maintain Hb > 100 g/L Folic acid 5 mg daily
Iron overload	Iron therapy contraindicated Iron chelation therapy
Splenomegaly causing mechanical problems, excessive transfusion needs	Splenectomy; see Box 24.40

(Hb = haemoglobin; HLA = human leucocyte antigen; HSCT = haematopoietic stem cell transplantation)

24.44 Anaemia in old age

- **Mean haemoglobin**: falls with age in both sexes but remains well within the reference range. When a low haemoglobin does occur, it is generally due to disease.
- **Anaemia can never be considered 'normal' in old age**.
- **Symptoms**: may be subtle and insidious. Cardiovascular features such as dyspnoea and oedema, and cerebral features such as dizziness and apathy, tend to predominate.
- **Ferritin**: if lower than 45 μg/L in older people, is highly predictive of iron deficiency.
- **Serum iron and transferrin**: fall with age because of the prevalence of other disorders, and are not reliable indicators of deficiency.
- **Most common cause of iron deficiency**: gastrointestinal blood loss.
- **Most common cause of vitamin B_{12} deficiency**: pernicious anaemia, as the prevalence of chronic atrophic gastritis rises in old age.
- **Neuropsychiatric symptoms associated with vitamin B_{12} deficiency**: well-established association but a causal relationship has not been clearly shown. Dementia associated with vitamin B_{12} deficiency in the absence of haematological abnormalities is rare.
- **Anaemia of chronic disease**: frequent in old age because of the rising prevalence of diseases that inhibit iron transport.

disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

HAEMATOLOGICAL MALIGNANCIES

Haematological malignancies arise when the processes controlling proliferation or apoptosis are corrupted in blood cells. If mature differentiated cells are involved, the cells will have a low growth fraction and produce indolent neoplasms, such as the low-grade lymphomas or chronic leukaemias, when patients have an expected survival of many years. In contrast, if more primitive stem cells are involved, the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive, life-threatening illnesses such as the acute leukaemias or high-grade lymphomas. Involvement of pluripotent stem cells produces the most aggressive acute leukaemias. In general, haematological neoplasms are diseases of elderly patients, the exceptions being acute lymphoblastic leukaemia, which predominantly affects children, and Hodgkin lymphoma, which affects people aged 20–40 years. Management of young patients with haematological malignancy is particularly challenging (Box 24.45).

Leukaemias

Leukaemias are malignant disorders of the haematopoietic stem cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days or weeks to many years, depending on the type.

Epidemiology and aetiology

The incidence of leukaemia of all types in the population is approximately 10/100 000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 3:2 in acute leukaemia, 2:1 in chronic lymphocytic leukaemia and 1.3:1 in chronic myeloid leukaemia.

24.45 Consequences of haematological malignancy in adolescence

- **Tailored management protocols**: the most effective treatment schedules for leukaemia and lymphoma differ between children and adults. Adolescent patients may be most appropriately managed in specialist centres.
- **Psychosocial effects**: adolescents undergoing treatment for haematological malignancy may suffer significant consequences for their schooling and social development, and require support from a multidisciplinary team.
- **'Late effects'**: adolescents who have been treated with chemotherapy and/or radiotherapy in childhood may be at risk of a wide range of complications, depending on the region irradiated, radiation dose and the drugs used. Particularly relevant complications in this age group include short stature, growth hormone deficiency, delayed puberty, and cognitive dysfunction affecting schooling (after cranial irradiation). Life-long follow-up is often undertaken to detect and manage these late effects and to deal with consequences such as infertility and secondary malignancy.

24.46 Risk factors for leukaemia

Ionising radiation
• After atomic bombing of Japanese cities (myeloid leukaemia) • Radiotherapy for ankylosing spondylitis • Diagnostic X-rays of the fetus in pregnancy
Cytotoxic drugs
• Especially alkylating agents (myeloid leukaemia, usually after a latent period of several years) • Industrial exposure to benzene
Retroviruses
• One rare form of T-cell leukaemia/lymphoma appears to be associated with a retrovirus similar to the viruses causing leukaemia in cats and cattle
Genetic
• Identical twin of patients with leukaemia • Down's syndrome and certain other genetic disorders
Immunological
• Immune deficiency states (e.g. hypogammaglobulinaemia)

Geographical variation in incidence does occur, the most striking being the rarity of chronic lymphocytic leukaemia in the Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak of incidence in children aged 1–5 years. All forms of acute myeloid leukaemia have their lowest incidence in young adult life and there is a striking rise over the age of 50. Chronic leukaemias occur mainly in middle and old age.

The cause of the leukaemia is unknown in the majority of patients. Several risk factors, however, have been identified (Box 24.46).

Terminology and classification

Leukaemias are traditionally classified into four main groups:

- acute lymphoblastic leukaemia (ALL)
- acute myeloid leukaemia (AML)
- chronic lymphocytic leukaemia (CLL)
- chronic myeloid leukaemia (CML).

In acute leukaemia, there is proliferation of primitive stem cells, leading to an accumulation of blasts, predominantly in the bone marrow, which causes bone marrow failure. In chronic leukaemia, the malignant clone is able to differentiate, resulting in an accumulation of more mature cells. Lymphocytic and lymphoblastic cells are those derived from the lymphoid stem cell (B cells and T cells). Myeloid refers to the other lineages: that is, precursors of red cells, granulocytes, monocytes and platelets (see Fig. 24.2, p. 993).

The diagnosis of leukaemia is usually suspected from an abnormal blood count, often a raised white count, and is confirmed by examination of the bone marrow. This includes the morphology of the abnormal cells, analysis of cell surface markers (immunophenotyping), clone-specific chromosome abnormalities and molecular changes. These results are incorporated in the World Health Organization (WHO) classification of tumours of haematopoietic and lymphoid tissues; the subclassification of acute leukaemias is shown in Box 24.47. The features in the bone marrow not only provide an

24.47 WHO classification of acute leukaemia

Acute myeloid leukaemia (AML) with recurrent genetic abnormalities
- AML with t(8;21), gene product AML-ETO
- AML with eosinophilia inv(16) or t(16;16), gene product CBFβ-MYH11
- Acute promyelocytic leukaemia t(15;17), gene product PML-RARA
- AML with t(9;11)(p22;q23), gene product MLLT3-MLL
- AML with t(6;9)(p23;q34), gene product DEK-NUP214
- AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2), gene product RPN1-EVI1

Acute myeloid leukaemia with myelodysplasia-related changes
- e.g. Following a myelodysplastic syndrome

Therapy-related myeloid neoplasms
- e.g. Alkylating agent or topoisomerase II inhibitor

Myeloid sarcoma

Myeloid proliferations related to Down's syndrome

Acute myeloid leukaemia not otherwise specified
- e.g. AML with or without differentiation, acute myelomonocytic leukaemia, erythroleukaemia, megakaryoblastic leukaemia, myeloid sarcoma

Acute lymphoblastic leukaemia (ALL)
- Precursor B ALL
- Precursor T ALL

accurate diagnosis but also give valuable prognostic information, allowing therapy to be tailored to the patient's disease.

Acute leukaemia

There is a failure of cell maturation in acute leukaemia. Proliferation of cells which do not mature leads to an accumulation of primitive cells which take up more and more marrow space at the expense of the normal haematopoietic elements. Eventually, this proliferation spills into the blood. Acute myeloid leukaemia (AML) is about four times more common than acute lymphoblastic leukaemia (ALL) in adults. In children, the proportions are reversed, the lymphoblastic variety being more common. The clinical features are usually those of bone marrow failure (anaemia, bleeding or infection – pp. 1001, 1006 and 1008).

Investigations

Blood examination usually shows anaemia with a normal or raised MCV. The leucocyte count may vary from as low as 1×10^9/L to as high as 500×10^9/L or more. In the majority of patients, the count is below 100×10^9/L. Severe thrombocytopenia is usual but not invariable. Frequently, blast cells are seen in the blood film but sometimes blast cells may be infrequent or absent. A bone marrow examination will confirm the diagnosis. The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells in varying degrees (but more than 20% of the cells) (Fig. 24.25). The presence of Auer rods in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia. Classification and prognosis are determined by immunophenotyping, chromosome and molecular analysis, as shown in Figure 24.26.

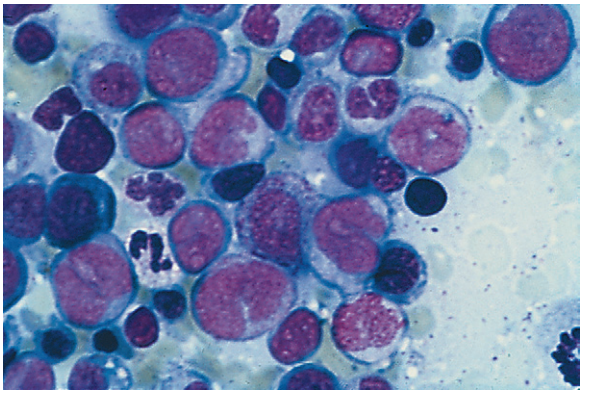

Fig. 24.25 Acute myeloid leukaemia. Bone marrow aspirate showing infiltration with large blast cells which display nuclear folding and prominent nucleoli.

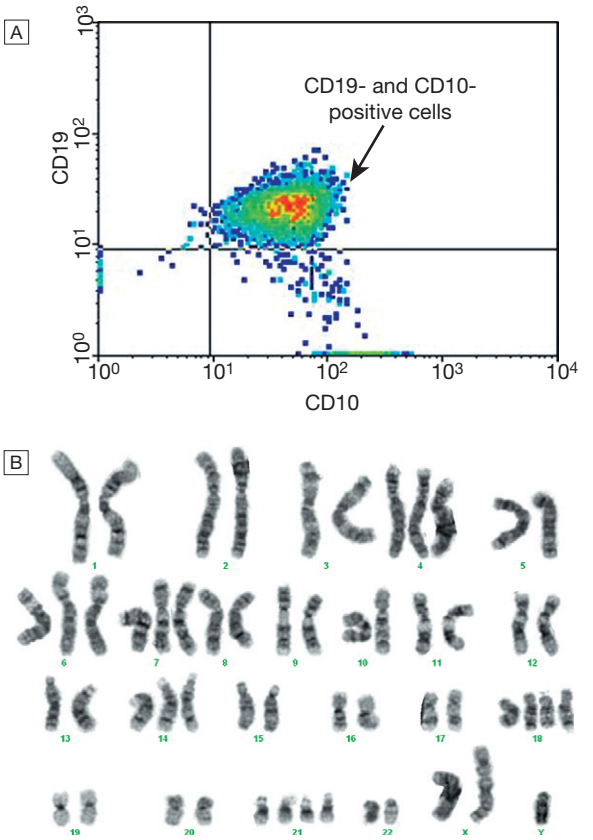

Fig. 24.26 Investigation of acute lymphoblastic leukaemia (ALL). A Flow cytometric analysis of blasts labelled with the fluorescent antibodies anti-CD19 (y axis) and anti-CD10 (x axis). ALL blasts are positive for both CD19 and CD10 (arrow). B Chromosome analysis (karyotype) of blasts showing additional chromosomes X, 4, 6, 7, 14, 18 and 21.

Management

The general strategy for acute leukaemia is shown in Figure 24.27. The first decision must be whether or not to give specific treatment. This is generally aggressive, has numerous side-effects, and may not be appropriate for the very elderly or patients with serious comorbidities (Chs 7 and 11). In these patients, supportive

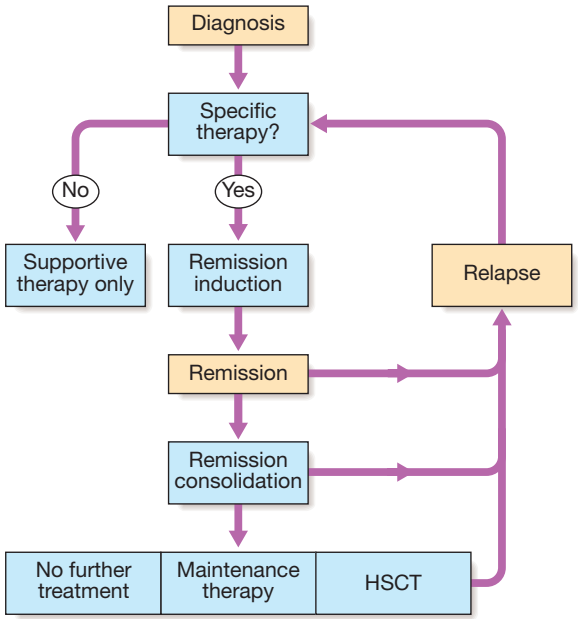

Fig. 24.27 Treatment strategy in acute leukaemia. (HSCT = haematopoietic stem cell transplantation)

treatment can effect considerable improvement in well-being.

Specific therapy

If a decision to embark on specific therapy has been taken, the patient should be prepared as recommended in Box 24.48. It is unwise to attempt aggressive management of acute leukaemia unless adequate services are available for the provision of supportive therapy.

The aim of treatment is to destroy the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of the haematopoietic tissues will occur. There are three phases:

- *Remission induction.* In this phase, the bulk of the tumour is destroyed by combination chemotherapy. The patient goes through a period of severe bone marrow hypoplasia, requiring intensive support and inpatient care from a specially trained multidisciplinary team.
- *Remission consolidation.* If remission has been achieved, residual disease is attacked by therapy during the consolidation phase. This consists of a number of courses of chemotherapy, again resulting in periods of marrow hypoplasia. In poor-prognosis leukaemia, this may include haematopoietic stem cell transplantation.
- *Remission maintenance.* If the patient is still in remission after the consolidation phase for ALL, a period of maintenance therapy is given, with the individual as an outpatient and treatment consisting of a repeating cycle of drug administration. This may extend for up to 3 years if relapse does not occur.

In patients with ALL, it is necessary to give prophylactic treatment to the central nervous system, as this is a sanctuary site where standard therapy does not penetrate. This usually consists of a combination of cranial irradiation, intrathecal chemotherapy and high-dose methotrexate, which crosses the blood–brain barrier.

Thereafter, specific therapy is discontinued and the patient observed.

The detail of the schedules for these treatments can be found in specialist texts. The drugs most commonly employed are listed in Box 24.49. Generally, if a patient fails to go into remission with induction treatment, alternative drug combinations may be tried, but the outlook is poor unless remission can be achieved. Disease which relapses during treatment or soon after the end of treatment carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective.

In some patients, alternative palliative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation. Drugs used for this purpose include hydroxycarbamide and

24.48 Preparation for specific therapy in acute leukaemia

- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Anaemia corrected by red cell concentrate transfusion
- Thrombocytopenic bleeding controlled by platelet transfusions
- If possible, central venous catheter (e.g. Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy, fluids, blood products and other supportive drugs
- Tumour lysis risk assessed and prevention started: fluids with allopurinol or rasburicase
- Therapeutic regimen carefully explained to the patient and informed consent obtained
- Consideration of entry into clinical trial

24.49 Drugs commonly used in the treatment of acute leukaemia

Phase	ALL	AML
Induction	Vincristine (IV) Prednisolone (oral) L-asparaginase (IM) Daunorubicin (IV) Methotrexate (intrathecal) Imatinib (oral)*	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV and oral)
Consolidation	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV) Methotrexate (IV) Imatinib (oral)*	Cytarabine (IV) Amsacrine (IV) Mitoxantrone (IV)
Maintenance	Prednisolone (oral) Vincristine (IV) Mercaptopurine (oral) Methotrexate (oral) Imatinib (oral)*	

*If Philadelphia chromosome-positive.

mercaptopurine. The aim is to reduce the blast count without inducing bone marrow failure.

Supportive therapy

Aggressive and potentially curative therapy, which involves periods of severe bone marrow failure, would not be possible without appropriate supportive care. The following problems commonly arise.

Anaemia. Anaemia is treated with red cell concentrate transfusions.

Bleeding. Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Prophylactic platelet transfusion should be given to maintain the platelet count above 10×10^9/L. Coagulation abnormalities occur and need accurate diagnosis and treatment (p. 1050).

Infection. Fever (> 38°C) lasting over 1 hour in a neutropenic patient indicates possible septicaemia (see also p. 296). Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given according to local bacteriological resistance patterns: for example, with a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam) or a single-agent beta-lactam (e.g. meropenem). The organisms most commonly associated with severe neutropenic sepsis are Gram-positive bacteria, such as *Staphylococcus aureus* and *Staph. epidermidis*, which are present on the skin and gain entry via cannulae and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as *Escherichia coli*, *Pseudomonas* and *Klebsiella* spp. are likely to cause rapid clinical deterioration and must be covered with the initial empirical antibiotic therapy. Gram-positive infection may require vancomycin therapy. If fever has not resolved after 3–5 days, empirical antifungal therapy (e.g. a liposomal amphotericin B preparation, voriconazole or caspofungin) is added.

Patients with ALL are susceptible to infection with *Pneumocystis jirovecii* (p. 400), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis may require either bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal candida infection is common. Fluconazole is effective for the treatment of established local infection and for prophylaxis against systemic candidaemia. Prophylaxis against other systemic fungal infections, including *Aspergillus*, using itraconazole or posaconazole, for example, is usual practice during high-risk intensive chemotherapy. This is often used along with sensitive markers of early fungal infection to guide treatment initiation (a 'pre-emptive approach').

For systemic fungal infection with *Candida* or aspergillosis, intravenous liposomal amphotericin or voriconazole is required.

Reactivation of herpes simplex infection (p. 325) occurs frequently around the lips and nose during ablative therapy for acute leukaemia, and is treated with aciclovir. This may also be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chickenpox or, after reactivation, as shingles (p. 318) should be treated in the early stage with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable but may contribute to staff awareness of careful reverse barrier nursing practice. The isolation can be psychologically stressful for the patient.

Metabolic problems. Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic and diarrhoea is common as a consequence of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy (tumour lysis syndrome) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may cause renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome, prophylactic rasburicase (a recombinant urate oxidase enzyme) can be used. Occasionally, dialysis may be required.

Psychological problems. Psychological support is a key aspect of care. Patients should be kept informed, and their questions answered and fears allayed as far as possible. A multidisciplinary approach to patient care involves input from many services, including psychology. Key members of the team include haematology specialist nurses, who are often the central point of contact for patients and families throughout the illness.

Haematopoietic stem cell transplantation

This is described on page 1017. In patients with high-risk acute leukaemia, allogeneic HSCT can improve 5-year survival from 20% to around 50%.

Prognosis

Without treatment, the median survival of patients with acute leukaemia is about 5 weeks. This may be extended to a number of months with supportive treatment.

24.50 Outcome in adult acute leukaemia

Disease/risk	Risk factors	5-yr overall survival
Acute myeloid leukaemia		
Good risk	Promyelocytic leukaemia t(15;17) t(8;21) inv 16 or t(16;16)	76%
Poor risk	Cytogenetic abnormalities –5, –7, del 5q, abn(3q), complex (> 5)	21%
Intermediate risk	AML with none of the above	48%
Acute lymphoblastic leukaemia		
Poor risk	Philadelphia chromosome High white count > 100×10^9/L Abnormal short arm of chromosome 11 t(1;19)	20%
Standard	ALL with none of the above	37%

Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 24.50 shows the survival in ALL and AML, and the influence of prognostic features.

Advances in treatment have led to steady improvement in survival from leukaemia. Advances include the introduction of drugs such as ATRA (all transretinoic acid) in acute promyelocytic leukaemia, which has greatly reduced induction deaths from bleeding in this good-risk leukaemia. Current trials aim to improve survival, especially in standard and poor-risk disease, with strategies that include allogeneic HSCT and targeted therapies such as anti-CD33 monoclonal antibodies and FLT3 inhibitors.

Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is a myeloproliferative stem cell disorder resulting in proliferation of all haematopoietic lineages but manifesting predominantly in the granulocytic series. Maturation of cells proceeds fairly normally. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years. It is rare, with an annual incidence in the UK of 1.8/100 000, and accounts for 20% of all leukaemias. It is found in all races.

The defining characteristic of CML is the chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the breakpoint cluster region (BCR). The fragment from chromosome 9 that joins the BCR carries the *abl* oncogene, which forms a fusion gene with the remains of the BCR. This *BCR ABL* fusion gene codes for a 210 kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene (p. 59), influencing cellular proliferation, differentiation and survival. In some patients in whom conventional chromosomal analysis does not detect a Ph chromosome, the BCR ABL gene product is detectable by molecular techniques.

Natural history

The disease has three phases:

- *A chronic phase,* in which the disease is responsive to treatment and is easily controlled, which used to last 3–5 years. With the introduction of imatinib therapy, this phase has been prolonged to longer than 8 years in many patients.
- *An accelerated phase* (not always seen), in which disease control becomes more difficult.
- *Blast crisis*, in which the disease transforms into an acute leukaemia, either myeloid (70%) or lymphoblastic (30%), which is relatively refractory to treatment. This is the cause of death in the majority of patients; therefore survival is dictated by the timing of blast crisis, which cannot be predicted. Prior to imatinib therapy (see below), approximately 10% of patients per year would transform. In those treated with imatinib for up to 5 years, only between 0.5 and 2.5% have transformed each year.

Clinical features

Symptoms at presentation may include lethargy, weight loss, abdominal discomfort and sweating, but about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10%, the enlargement is massive, extending to over 15 cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual.

Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to 600 $\times 10^9$/L. In about one-third of patients, there is a very high platelet count, sometimes as high as 2000 $\times 10^9$/L. In the blood film, the full range of granulocyte precursors, from myeloblasts to mature neutrophils, is seen but the predominant cells are neutrophils and myelocytes (see Fig. 24.3, p. 993). Myeloblasts usually constitute less than 10% of all white cells. There is often an absolute increase in eosinophils and basophils, and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cells increases. Blast transformation is characterised by a dramatic increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophilia tends to increase as the disease progresses.

Bone marrow should be obtained to confirm the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, and RNA analysis to demonstrate the presence of the BCR ABL gene product. Blood LDH levels are elevated and the uric acid level may be high due to increased cell breakdown.

Management

Chronic phase

Imatinib, dasatinib and nilotinib specifically inhibit BCR ABL tyrosine kinase activity and reduce the uncontrolled proliferation of white cells. They are recommended as first-line therapy in chronic-phase CML, producing complete cytogenetic response (disappearance of the Ph chromosome) in 76% at 18 months of therapy (Box 24.51). Patients are monitored by repeated bone marrow examination until there is a complete cytogenetic response, and then by 3-monthly real-time quantitative polymerase chain reaction (PCR) for BCR ABL mRNA transcripts in blood. For those failing to respond or progress on imatinib, options include second-generation tyrosine kinase inhibitors, such as dasatinib or nilotinib, allogeneic HSCT (p. 1017), or

EBM 24.51 Tyrosine kinase inhibition in chronic myeloid leukaemia

'As first-line therapy in CML, imatinib is better tolerated and induces a cytogenetic response in ~87% of cases at 18 months, compared with ~35% response to interferon plus cytarabine.'

- O'Brien SG for the IRIS Investigators. N Engl J Med 2003; 348:994–1004.

classical cytotoxic drugs such as hydroxycarbamide (hydroxyurea) or interferon. Hydroxycarbamide was previously used widely for initial control of disease, and is still useful in this context or in palliative situations. It does not diminish the frequency of the Ph chromosome or affect the onset of blast cell transformation. Interferon-alfa was considered first-line treatment before imatinib was developed. It was given alone or with the chemotherapy agent Ara-C, and controlled CML chronic phase in about 70% of patients.

Accelerated phase and blast crisis

Management is more difficult. For patients presenting in accelerated phase, imatinib is indicated if the patient has not already received it. Hydroxycarbamide can be an effective single agent and low-dose cytarabine can also be tried. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 24.49) is better if disease is lymphoblastic than if it is myeloblastic. Given the very poor response in myeloblastic transformation, there is a strong case for supportive therapy only, particularly in older patients.

Patients progressing to advanced-phase disease on imatinib may respond to a second-generation tyrosine kinase inhibitor and may be considered for allogeneic HSCT (p. 1017).

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common variety of leukaemia, accounting for 30% of cases. The male to female ratio is 2:1 and the median age at presentation is 65–70 years. In this disease, B lymphocytes, which would normally respond to antigens by transformation and antibody formation, fail to do so. An ever-increasing mass of immuno-incompetent cells accumulates, to the detriment of immune function and normal bone marrow haematopoiesis.

Clinical features

The onset is usually insidious. Indeed, in around 70% of patients, the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss. However, these more often occur later in the course of the disease.

Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis ($> 5 \times 10^9$/L) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T cell antigen, CD5.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test, as autoimmune haemolytic anaemia may occur (p. 1029). Serum immunoglobulin levels should be estimated to establish the degree of immunosuppression, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for prognosis (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. The main prognostic factor is stage of disease (Box 24.52); however, malignant cell characteristics, such as CD38 expression, abnormalities of chromosome 11 or 17, and absence of mutations of IgV_H genes, also indicate a poorer prognosis.

24.52 Staging of chronic lymphocytic leukaemia

Clinical stage A (60% patients)
• No anaemia or thrombocytopenia and fewer than three areas of lymphoid enlargement
Clinical stage B (30% patients)
• No anaemia or thrombocytopenia, with three or more involved areas of lymphoid enlargement
Clinical stage C (10% patients)
• Anaemia and/or thrombocytopenia, regardless of the number of areas of lymphoid enlargement

Management

No specific treatment is required for most clinical stage A patients, unless progression occurs. Life expectancy is usually normal in older patients. The patient should be offered clear information about CLL, and be reassured about the indolent nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety.

Treatment is only required if there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count or autoimmune haemolytic anaemia or thrombocytopenia. Initial therapy for those requiring treatment (stages B and C) may consist of oral chemotherapy with the alkylating agent chlorambucil. This will reduce the abnormal lymphocyte mass and produce symptomatic improvement in most patients. More recently, the purine analogue fludarabine, in combination with the alkylating agent cyclophosphamide and the anti-CD20 monoclonal antibody rituximab, has increased remission rates and disease-free survival, although there are increased risks of infection and secondary malignancies. Bone marrow failure or autoimmune cytopenias may respond to corticosteroids.

Supportive care is increasingly required in progressive disease, e.g. transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections and, for some patients with hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymphadenopathy which is causing discomfort or local obstruction, and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism, and can relieve massive splenomegaly.

Prognosis

The majority of clinical stage A patients have a normal life expectancy but patients with advanced CLL are more likely to die from their disease or infectious complications. Survival is influenced by prognostic features of the leukaemia and whether patients can tolerate intensive treatment. In those treated with chemotherapy and rituximab, 90% are alive 4 years later (Box 24.53).

EBM 24.53 Chemotherapy plus anti-CD20 monoclonal antibody therapy in CLL

'The addition of rituximab (R) to first-line chemotherapy (with fludarabine and cyclophosphamide, RFC) improves median progression free survival (51.8 compared with 32.8 months) and overall survival in CLL. The time to 25% of patients dying was 62.5 months with RFC and 46.8 months with chemotherapy alone.'

- Hallek M, et al. Lancet 2010; 376:21 164–21 174.

Rarely, CLL transforms to an aggressive high-grade lymphoma, called Richter's transformation.

Prolymphocytic leukaemia

This is a variant of chronic lymphocytic leukaemia found mainly in males over the age of 60 years; 25% of cases are of the T cell variety. There is typically massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often in excess of 400×10^9/L; the characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis very poor. Leukapharesis, splenectomy and chemotherapy may be tried.

Hairy cell leukaemia

This is a rare chronic B-cell lymphoproliferative disorder. The male to female ratio is 6:1 and the median age at diagnosis is 50 years. Presenting symptoms are those of general ill health and recurrent infections. Splenomegaly occurs in 90% but lymph node enlargement is unusual.

Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B lymphocyte immunotype but they also characteristically express CD25 and CD103. Recently, all patients with hairy cell leukaemia have been found to have a mutation in the *BRAF* gene.

Over recent years, a number of treatments, including cladribine and deoxycoformycin, have been shown to produce long-lasting remissions.

Myelodysplastic syndrome

Myelodysplastic syndrome (MDS) consists of a group of clonal haematopoietic disorders which represent steps in the progression to the development of leukaemia. MDS presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), usually in older people (median age at diagnosis is 69 years). The overall incidence is 4/100 000 in the population, rising to more than 30/100 000 in the over-seventies. The blood film is characterised by cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular, with dysplastic changes in all three cell lines. Blast cells may be increased but do not reach the 20% level that indicates acute leukaemia. Chromosome analysis frequently reveals abnormalities, particularly of chromosome 5 or 7. The WHO classification of MDS is shown in Box 24.54.

Inevitably, MDS progresses to AML, although the time to progression varies (from months to years) with the subtype of MDS, being slowest in refractory anaemia and most rapid in refractory anaemia with excess of blasts. An international prognostic scoring system (IPSS) predicts clinical outcome based upon karyotype and cytopenias in blood, as well as percentage of bone marrow blasts. In low-risk patients, median survival is 5.7 years and time for 25% of patients to develop AML is 9.4 years; equivalent figures in high-risk patients are 0.4 and 0.2 years, respectively.

24.54 WHO classification of myelodysplastic syndromes

Disease	Bone marrow findings
Refractory anaemia (RA)	Blasts < 5% Erythroid dysplasia only
Refractory anaemia with sideroblasts (RARS)	Blasts < 5% Ringed sideroblasts > 15%
Refractory cytopenias with multilineage dysplasia (RCMD)	Blasts < 5% 2–3 lineage dysplasia
Refractory anaemia with excess blasts (RAEB)	Blasts 5–20% 2–3 lineage dysplasia
Myelodysplastic syndrome with 5q–	Myelodysplastic syndrome associated with a del (5q) cytogenetic abnormality Blasts < 5% Often normal or increased blood platelet count
Myelodysplastic syndrome unclassified	None of the above or inadequate material

Management

For the vast majority of patients who are elderly, the disease is incurable, and supportive care with red cell and platelet transfusions is the mainstay of treatment. A trial of erythropoietin and granulocyte–colony-stimulating factor (G-CSF) is recommended in some patients with early disease to improve haemoglobin and white cell counts. For younger patients with higher-risk disease, allogeneic HSCT may afford a cure. Transplantation should be preceded by intensive chemotherapy in those with more advanced disease. More recently, the hypomethylating agent azacytidine has improved survival by a median of 9 months for high-risk patients, and in the UK is recommended for those not eligible for transplantation.

Lymphomas

These neoplasms arise from lymphoid tissues, and are diagnosed from the pathological findings on biopsy as Hodgkin or non-Hodgkin lymphoma. The majority are of B cell origin. Non-Hodgkin lymphomas are classified as low- or high-grade tumours on the basis of their proliferation rate.

- *High-grade tumours* divide rapidly, are typically present for a matter of weeks before diagnosis, and may be life-threatening.
- *Low-grade tumours* divide slowly, may be present for many months before diagnosis, and typically behave in an indolent fashion.

Hodgkin lymphoma

The histological hallmark of Hodgkin lymphoma (HL) is the presence of Reed–Sternberg cells, large malignant lymphoid cells of B cell origin (Fig. 24.28). They are often only present in small numbers but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and eosinophils.

The epidemiology of HL is shown in Box 24.55 and its histological WHO classification in Box 24.56.

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. Classical HL is divided into four histological subtypes from the appearance of the Reed–Sternberg cells and surrounding reactive cells. The nodular sclerosing type is more common in young patients and in women. Mixed cellularity is more common in the elderly. Lymphocyte-rich HL usually presents in men. Lymphocyte-depleted HL is rare and probably represents large-cell or anaplastic non-Hodgkin lymphoma.

Clinical features

There is painless, rubbery lymphadenopathy, usually in the neck or supraclavicular fossae; the lymph nodes may fluctuate in size. Young patients with nodular sclerosing disease may have large mediastinal masses which are surprisingly asymptomatic but may cause dry cough and some breathlessness. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present but does not always indicate disease in those organs. Spread is contiguous from one node to the next and extranodal disease, such as bone, brain or skin involvement, is rare.

Investigations

Treatment of HL depends upon the stage at presentation; therefore investigations aim not only to diagnose lymphoma but also to determine the extent of disease (Box 24.57).

- *FBC* may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor. An eosinophilia or a neutrophilia may be present.
- *ESR* may be raised.
- *Renal function tests* are required to ensure function is normal prior to treatment.
- *Liver function* may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatis.

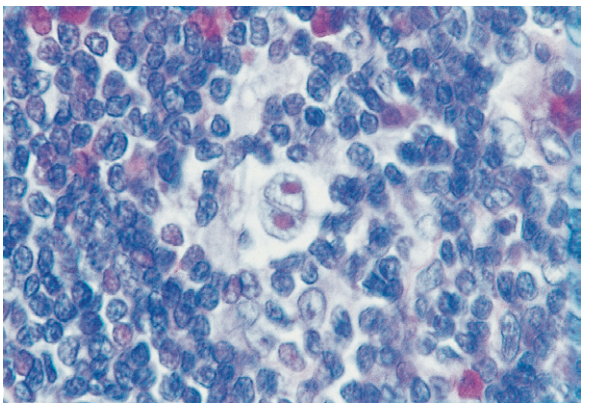

Fig. 24.28 Hodgkin lymphoma. In the centre of this lymph node biopsy is a large typical Reed–Sternberg cell with two nuclei containing a prominent eosinophilic nucleolus.

24.55 Epidemiology and aetiology of Hodgkin lymphoma

Incidence

- ~4 new cases/100 000 population/yr

Sex ratio

- Slight male excess (1.5 : 1)

Age

- Median age 31 yrs; first peak at 20–35 yrs and second at 50–70 yrs

Aetiology

- Unknown
- More common in patients from well-educated backgrounds and small families
- Three times more likely with a past history of infectious mononucleosis but no definitive causal link to Epstein–Barr virus infection is proven

24.56 WHO pathological classification of Hodgkin lymphoma

Type	Histology classification	Proportion of HL
Nodular lymphocyte-predominant HL		5%
Classical HL	Nodular sclerosing	70%
	Mixed cellularity	20%
	Lymphocyte-rich	5%
	Lymphocyte-depleted	Rare

24.57 Clinical stages of Hodgkin lymphoma (Ann Arbor classification)

Stage	Definition
I	Involvement of a single lymph node region (I) or extralymphatic* site (I_E)
II	Involvement of two or more lymph node regions (II) or an extralymphatic site and lymph node regions on the same side of (above or below) the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm with (III_E) or without (III) localised extralymphatic involvement or involvement of the spleen (III_S), or both (III_{SE})
IV	Diffuse involvement of one or more extralymphatic tissues, e.g. liver or bone marrow
Each stage is subclassified:	
A	No systemic symptoms
B	Weight loss > 10%, drenching sweats, fever

*The lymphatic structures are defined as the lymph nodes, spleen, thymus, Waldeyer's ring, appendix and Peyer's patches.

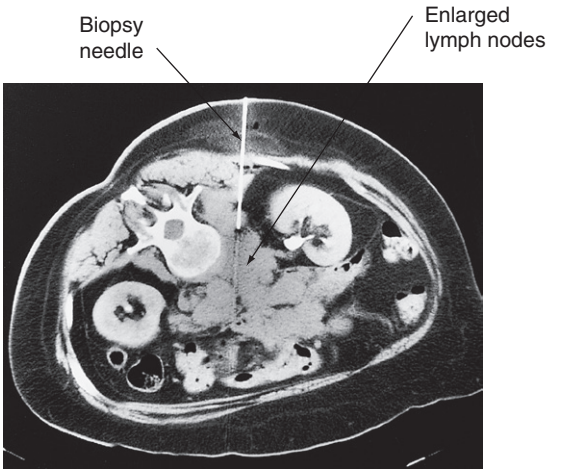

Fig. 24.29 CT-guided percutaneous needle biopsy of retroperitoneal nodes involved by lymphoma.

- *LDH measurements* showing raised levels are an adverse prognostic factor.
- *Chest X-ray* may show a mediastinal mass.
- *CT scan* of chest, abdomen and pelvis permits staging. Bulky disease (> 10 cm in a single node mass) is an adverse prognostic feature.
- *Lymph node biopsy* may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 24.29).

Management

Historically, radiotherapy to lymph nodes alone has been used to treat localised stage IA or stage IIA disease effectively, with no adverse prognostic features. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues. Fertility is usually preserved after radiotherapy. Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a screening programme. Patients continuing to smoke after lung irradiation are at particular risk of lung cancer.

Clinical trials have shown that patients with early-stage disease have better outcomes if chemotherapy is included in their treatment. The majority of HL patients are now treated with chemotherapy and adjunctive radiotherapy. The ABVD regimen (doxorubicin, vinblastine, bleomycin and dacarbazine) is widely used in the UK. Standard therapy of early-stage patients usually includes additional treatment with radiotherapy to the involved lymph nodes after four courses of ABVD. Treatment response is assessed clinically and by repeat CT and newer scanning modalities such as positron emission tomography (PET). ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. The incidence of infertility and secondary myelodysplasia/AML is low with this regime.

Patients with advanced-stage disease are most commonly managed with chemotherapy alone. Standard treatment in the UK is 6–8 cycles of ABVD, followed by an assessment of response. As with early disease, achieving PET-negative remission predicts a better long-term remission rate. Overall, the long-term disease control/cure rates are lower with advanced disease.

24.58 The Hasenclever prognostic index for advanced Hodgkin lymphoma

Score 1 for each of the following risk factors present at diagnosis:

- Age > 45 yrs
- Male gender
- Serum albumin < 40 g/L
- Haemoglobin < 105 g/L
- Stage IV disease
- White blood count > 15 × 10^9/L
- Lymphopenia < 0.6 × 10^9/L

Score	5-yr rate of freedom from progression (%)	5-yr rate of overall survival (%)
0–1	79	90
> 2	60	74
> 3	55	70
> 4	47	59

Patients with disease which is resistant to therapy may be considered for autologous HSCT (p. 1018).

Prognosis

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy followed by involved field radiotherapy, and the great majority are cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group.

Between 50 and 70% of those with advanced-stage HL can be cured. The Hasenclever index (Box 24.58) can be helpful in assigning approximate chances of cure when discussing treatment plans with patients. Patients who fail to respond to initial chemotherapy or relapse within a year have a poor prognosis but some may achieve long-term survival after autologous HSCT. Patients relapsing after 1 year may obtain long-term survival with further chemotherapy alone.

Non-Hodgkin lymphoma

Non-Hodgkin lymphoma (NHL) represents a monoclonal proliferation of lymphoid cells of B cell (70%) or T cell (30%) origin. The incidence of these tumours increases with age, to 62.8/million population per annum at age 75 years, and the overall rate is increasing at about 3% per year.

The epidemiology of NHL is shown in Box 24.59. Previous classifications were based principally on histological appearances. The current WHO classification stratifies according to cell lineage (T or B cells) and incorporates clinical features, histology, chromosomal abnormalities and cell surface markers of the malignant cells. Clinically, the most important factor is grade, which is a reflection of proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months before presentation, runs an indolent course, but is not curable by conventional therapy. Of all cases of NHL in the developed world, over two-thirds are either diffuse large B-cell NHL (high-grade) or follicular NHL (low-grade) (Fig. 24.30). Other forms of NHL, including Burkitt lymphoma, mantle cell lymphoma, MALT lymphomas and T-cell lymphomas, are less common.

24.59 Epidemiology and aetiology of non-Hodgkin lymphoma

Incidence

- 12 new cases/100 000 people/year

Sex ratio

- Slight male excess

Age

- Median age 65–70 yrs

Aetiology

- No single causative abnormality described
- Lymphoma is a late manifestation of HIV infection (p. 405)
- Specific lymphoma types are associated with viruses: e.g. Epstein–Barr virus (EBV) with post-transplant NHL, human herpesvirus 8 (HHV8) with a primary effusion lymphoma, and human T-cell lymphotropic virus (HTLV) with adult T-cell leukaemia lymphoma
- Gastric lymphoma can be associated with *Helicobacter pylori* infection
- Some lymphomas are associated with specific chromosomal translocations; the t(14;18) in follicular lymphoma results in the dysregulated expression of the BCL-2 gene product, which inhibits apoptotic cell death. The t(8;14) found in Burkitt lymphoma and the t(11;14) in mantle cell lymphoma alter function of c-myc and cyclin D1, respectively, resulting in malignant proliferation
- Lymphoma occurs in congenital immunodeficiency states and in immunosuppressed patients after organ transplantation

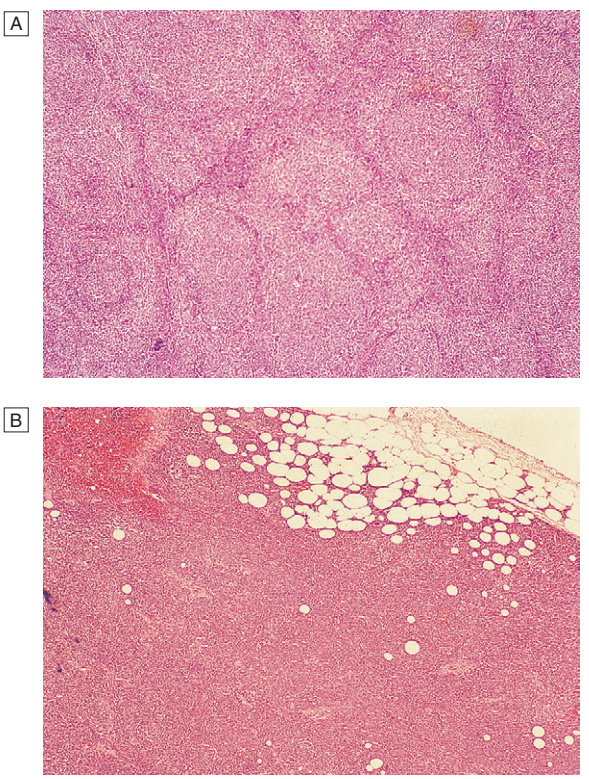

Fig. 24.30 Histology of non-Hodgkin lymphoma. A (Low-grade) follicular or nodular pattern. B (High-grade) diffuse pattern.

Clinical features

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement, which may be associated with systemic upset: weight loss, sweats, fever and itching. Hepatosplenomegaly may be present. Sites of extranodal involvement include the bone marrow, gut, thyroid, lung, skin, testis, brain and, more rarely, bone. Bone marrow involvement is more common in low-grade (50–60%) than high-grade (10%) disease. Compression syndromes may occur, including gut obstruction, ascites, superior vena cava obstruction and spinal cord compression.

The same staging system (see Box 24.57) is used for both HL and NHL, but NHL is more likely to be stage III or IV at presentation.

Investigations

These are as for HL, but in addition the following should be performed:

- *Bone marrow aspiration and trephine*.
- *Immunophenotyping of surface antigens to distinguish T from B cell tumours*. This may be done on blood, marrow or nodal material.
- *Cytogenetic analysis to detect chromosomal translocations* and molecular testing for T cell receptor or immunoglobulin gene rearrangements, if available.
- *Immunoglobulin determination*. Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- *Measurement of uric acid levels*. Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started.
- *HIV testing*. This may be appropriate if risk factors are present (p. 392).

Management

Low-grade NHL

Asymptomatic patients may not require therapy. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement, bone marrow failure or compression syndromes. In follicular lymphoma, the options are:

- *Radiotherapy*. This can be used for localised stage I disease, which is rare.
- *Chemotherapy*. Most patients will respond to oral therapy with chlorambucil, which is well tolerated but not curative. More intensive intravenous chemotherapy in younger patients produces better quality of life but no survival benefit. Humanised monoclonal antibodies ('biological' therapy; see p. 1102) can be used to target surface antigens on tumour cells, and induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone, and acts synergistically when given with chemotherapy. Rituximab (R) in combination with cyclophosphamide, vincristine and prednisolone (R-CVP) is commonly used as first-line therapy.
- *Transplantation*. Particular interest centres on the role of high-dose chemotherapy and HSCT in

EBM 24.60 Chemotherapy plus anti-CD20 therapy in high-grade non-Hodgkin lymphoma

'The addition of rituximab to CHOP chemotherapy in diffuse large B-cell NHL improved the 10-year overall survival from 27.6% to 43.5%.'

- Coiffier B, et al. Blood 2010; 116:2040–2045.

patients with relapsed disease. Such high-dose therapy improves disease-free survival but longer follow-up is awaited before conclusions can be drawn about cure.

High-grade NHL

Patients with diffuse large B-cell NHL need treatment at initial presentation:

- *Chemotherapy.* The majority (> 90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin, vincristine and prednisolone). When combined with CHOP chemotherapy, the biological therapy rituximab (R) increases the complete response rates and improves overall survival. R-CHOP is currently recommended as first-line therapy for those with stage II or greater diffuse large B-cell lymphoma (Box 24.60).
- *Radiotherapy.* A few stage I patients without bulky disease may be suitable for radiotherapy. Radiotherapy is also indicated for a residual localised site of bulk disease after chemotherapy, and for spinal cord and other compression syndromes.
- *HSCT.* Autologous HSCT (p. 1018) benefits patients with relapsed chemosensitive disease.

Prognosis

Low-grade NHL runs an indolent remitting and relapsing course, with an overall median survival of 10 years. Transformation to a high-grade NHL occurs in 3% per annum and is associated with poor survival.

In diffuse large B-cell high-grade NHL treated with R-CHOP, some 75% of patients overall respond initially to therapy and 50% will have disease-free survival at 5 years. The prognosis for patients with NHL is further refined according to the international prognostic index (IPI). For high-grade NHL, 5-year survival ranges from 75% in those with low-risk scores (age < 60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Relapse is associated with a poor response to further chemotherapy (< 10% 5-year survival), but in patients under 65 years, HSCT improves survival.

Paraproteinaemias

A gammopathy refers to over-production of one or more classes of immunoglobulin. It may be polyclonal in association with acute or chronic inflammation, such as infection, sarcoidosis, autoimmune disorders or some malignancies. Alternatively, a monoclonal increase in a single immunoglobulin class may occur in association with normal or reduced levels of the other immunoglobulins. Such monoclonal proteins (also called M-proteins, paraproteins or monoclonal gammopathies) occur as a feature of myeloma, lymphoma and amyloidosis, in connective tissue disease such as rheumatoid arthritis or polymyalgia rheumatica, in infection such as HIV, and in solid tumours. In addition, they may be present with no underlying disease. Gammopathies are detected by plasma immunoelectrophoresis.

Monoclonal gammopathy of uncertain significance

In monoclonal gammopathy of uncertain significance (MGUS, also known as benign monoclonal gammopathy), a paraprotein is present in the blood but with no other features of myeloma, Waldenström macroglobulinaemia (see below), lymphoma or related disease. It is a common finding associated with increasing age; a paraprotein can be found in 1% of the population aged over 50 years, increasing to 5% over 80 years.

Clinical features and investigations

Patients are usually asymptomatic, and the paraprotein is found on blood testing for other reasons. The routine blood count and biochemistry are normal, the paraprotein is usually present in small amounts with no associated immune paresis, and there are no lytic bone lesions. The bone marrow may have increased plasma cells but these usually constitute less than 10% of nucleated cells.

Prognosis

After follow-up of 20 years, only one-quarter of cases will progress to myeloma or a related disorder (i.e. around 1% per annum). Patients with low-level IgG paraproteins without reductions in IgM and IgA levels and with normal serum free light chain level are highly unlikely to progress at any time.

Waldenström macroglobulinaemia

This is a low-grade lymphoplasmacytoid lymphoma associated with an IgM paraprotein, causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in the elderly and affects males more commonly.

Patients classically present with features of hyperviscosity, such as nosebleeds, bruising, confusion and visual disturbance. However, presentation may be with anaemia, systemic symptoms, splenomegaly or lymphadenopathy. Patients are found on investigation to have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells and prominent mast cells.

Management

If patients show symptoms of hyperviscosity and anaemia, plasmapheresis is required to remove IgM and make blood transfusion possible. Chemotherapy with alkylating agents, such as chlorambucil, has been the mainstay of treatment, controlling disease in over 50%. Fludarabine may be more effective but has more side-effects. Rituximab can also be effective. The median survival is 5 years.

Multiple myeloma

This is a malignant proliferation of plasma cells. Normal plasma cells are derived from B cells and produce immunoglobulins which contain heavy and light chains. Normal immunoglobulins are polyclonal, which means that a variety of heavy chains are produced and each may be of kappa or lambda light chain type (p. 77). In myeloma, plasma cells produce immunoglobulin of a single heavy and light chain, a monoclonal protein commonly referred to as a paraprotein. In some cases, only light chain is produced and this appears in the urine as Bence Jones proteinuria. The frequency of different isotypes of monoclonal protein in myeloma is shown in Box 24.61.

Although a small number of malignant plasma cells are present in the circulation, the majority are present in the bone marrow. The malignant plasma cells produce cytokines, which stimulate osteoclasts and result in net bone reabsorption. The resulting lytic lesions cause bone pain, fractures and hypercalcaemia. Marrow involvement can result in anaemia or pancytopenia.

24.61 Classification of multiple myeloma

Type of monoclonal (M)-protein	Relative frequency (%)
IgG	55
IgA	21
Light chain only	22
Others (D, E, non-secretory)	2

Clinical features and investigations

The incidence of myeloma is 4/100 000 new cases per annum, with a male to female ratio of 2:1. The median age at diagnosis is 60–70 years and the disease is more common in Afro-Caribbeans. The clinical features are demonstrated in Figure 24.31.

Diagnosis of myeloma requires two of the following criteria:

- increased malignant plasma cells in the bone marrow
- serum and/or urinary M-protein
- skeletal lytic lesions.

Bone marrow aspiration, plasma and urinary electrophoresis, and a skeletal survey are thus required. Other investigations are listed in Box 24.62. Normal immunoglobulin levels, i.e. the absence of immunoparesis, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR (p. 85) but this is a non-specific test; only approximately 5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma.

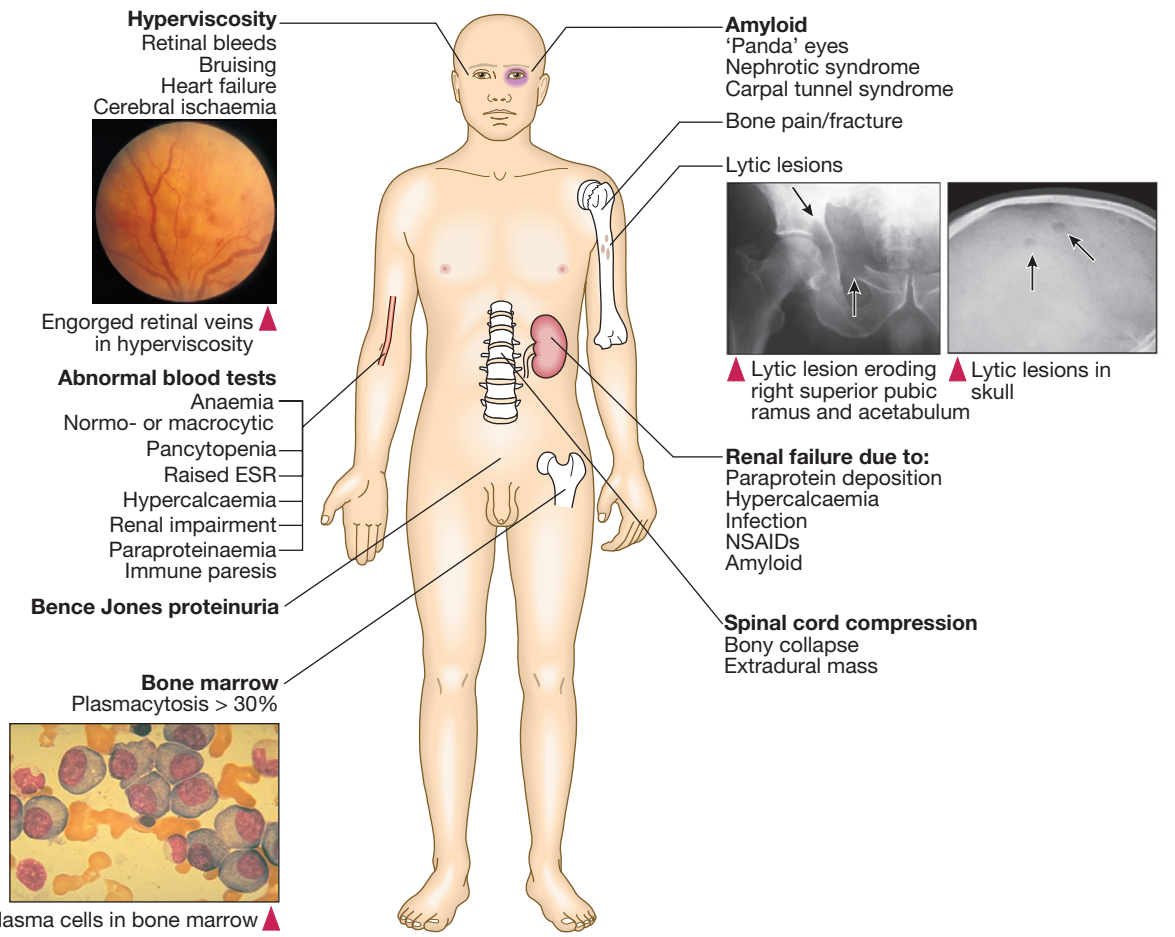

Fig. 24.31 Clinical and laboratory features of multiple myeloma.

24.62 Rationale for investigations in multiple myeloma

Question	Investigations
Presence of lytic lesions, bone fractures?	X-rays (skeletal survey)[1] Alkaline phosphatase[1]
Spinal cord compression?	MRI spine[2]
Presence of urine or plasma M-protein?	Blood and urine protein electrophoresis
Type of M-protein?	Blood and urine immunoelectrophoresis
Amount of M-protein?	Quantification of M-protein
Degree of immune paresis?	Plasma immunoglobulins
Presence of plasma cells in bone marrow?	Bone marrow aspiration and trephine
Degree of bone marrow failure?	Full blood count
Renal function?	Urea and electrolytes, creatinine, urate
Presence of hypercalcaemia?	Blood calcium and albumin
Poor prognostic factors at diagnosis?	β_2 microglobulin > 5.5 mg/L, albumin < 35 g/L

[1]In the absence of fractures, the plasma alkaline phosphatase and isotope bone scan will be normal despite the lytic lesions.
[2]All investigations shown above are routine in myeloma, except MRI of the spine, which is reserved for those with clinical indications.

EBM 24.63 Autologous haematopoietic stem cell transplantation in multiple myeloma

'The addition of autologous HSCT to conventional intravenous chemotherapy improves survival from 42 to 54 months.'

- Child JA, et al. N Engl J Med 2003; 348:1875–1883.

For further information: www.ukmf.org.uk

24.64 Haematological malignancy in old age

- **Median age**: approximately 70 yrs for most haematological malignancies.
- **Poor-risk biological features**: adverse cytogenetics or the presence of a multidrug resistance phenotype are more frequent.
- **Prognosis**: increasing age is an independent adverse variable in acute leukaemia and aggressive lymphoma.
- **Chemotherapy**: may be less well tolerated. Older people are more likely to have antecedent cardiac, pulmonary or metabolic problems, tolerate systemic infection less well and metabolise cytotoxic drugs differently.
- **Cure rates**: similar to those in younger patients, in those who do tolerate treatment.
- **Decision to treat**: should be based on the individual's biological status, the level of social support available, and the patient's wishes and those of the immediate family, but not on chronological age alone.

Management

If patients are asymptomatic with no evidence of end organ damage (e.g. to kidneys, bone marrow or bone), treatment may not be required.

Immediate support

- High fluid intake to treat renal impairment and hypercalcaemia (p. 767).
- Analgesia for bone pain.
- Bisphosphonates for hypercalcaemia and to delay other skeletal related events (p. 1123).
- Allopurinol to prevent urate nephropathy.
- Plasmapheresis, if necessary, for hyperviscosity.

Chemotherapy with or without HSCT

Myeloma therapy has improved with the addition of novel agents, initially thalidomide and more recently the proteasome inhibitor bortezomib, to first-line treatments. In older patients, thalidomide combined with the alkylating agent melphalan and prednisolone has increased the median overall survival to more than 4 years. Thalidomide has both anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. It can cause somnolence, constipation, peripheral neuropathy and thrombosis. It is vital that females of child-bearing age use adequate contraception, as thalidomide is teratogenic. Treatment is administered until paraprotein levels have stopped falling. This is termed 'plateau phase' and can last for weeks or years.

In younger, fitter patients, standard treatment includes first-line chemotherapy to maximum response and then an autologous HSCT, which improves quality of life and prolongs survival (Box 24.63) but does not cure myeloma. The role of allogeneic transplantation (p. 1017) and of reduced-intensity allografting after autologous transplantation in younger patients is under evaluation.

When myeloma progresses, treatment is given to induce a further plateau phase. In the UK at present, bortezomib is recommended, followed by lenalidomide if there is subsequent progression.

Radiotherapy

This is effective for localised bone pain not responding to simple analgesia and for pathological fractures. It is also useful for the emergency treatment of spinal cord compression complicating extradural plasmacytomas.

Bisphosphonates

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone (p. 1123) and may cause apoptosis of malignant plasma cells. There is evidence that intravenous zoledronate in combination with anti-myeloma therapy confers a survival advantage over oral bisphosphonates. Osteonecrosis of the jaw may be associated with long-term use; therefore regular dental review is advisable.

Prognosis

The international staging system (ISS) identifies poor prognostic features, including a high β_2-microglobulin and low albumin at diagnosis (ISS stage 3, median survival 29 months). Those with a normal albumin and a low β_2-microglobulin (ISS stage 1) have a median survival of 62 months. Use of autologous HSCT and

advances in drug therapy have increased survival, with over one-third of patients now surviving for 5 years, compared with only one-quarter 10 years ago. The outlook may improve further with new drugs and combinations of treatments.

APLASTIC ANAEMIA

Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum. The disease is much more common in certain other parts of the world: for example, east Asia. The basic problem is failure of the pluripotent stem cells, producing hypoplasia of the bone marrow with a pancytopenia in the blood. The diagnosis rests on exclusion of other causes of secondary aplastic anaemia (see below) and rare congenital causes, such as Fanconi's anaemia.

Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly, infections. An FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. Bone marrow aspiration and trephine reveal hypocellularity.

Management

All patients will require blood product support and aggressive management of infection. The prognosis of severe aplastic anaemia managed with supportive therapy only is poor and more than 50% of patients die, usually in the first year. The curative treatment for patients under 30 years of age with severe idiopathic aplastic anaemia is allogeneic HSCT if there is an available donor (p. 1017). Those with a compatible sibling donor should proceed to transplantation as soon as possible; they have a 75–90% chance of long-term cure. In older patients, immunosuppressive therapy with ciclosporin and antithymocyte globulin gives 5-year survival rates of 75%. Such patients may relapse or other clonal disorders of haematopoiesis may evolve, such as paroxysmal nocturnal haemoglobinuria (p. 1031), myelodysplastic syndrome (p. 1041) and acute myeloid leukaemia (p. 1036). They must be followed up long-term.

Secondary aplastic anaemia

Causes of this condition are listed in Box 24.65. It is not practical to list all the drugs which have been suspected of causing aplasia. It is important to check the reported side-effects of all drugs taken over the preceding months. In some instances, the cytopenia is more selective and affects only one cell line, most often the neutrophils. Frequently, this is an incidental finding, with no ill health. It probably has an immune basis but this is difficult to prove.

The clinical features and methods of diagnosis are the same as for primary idiopathic aplastic anaemia. An underlying cause should be treated or removed but otherwise management is as for the idiopathic form.

24.65 Causes of secondary aplastic anaemia

- Drugs
  - Cytotoxic drugs
  - Antibiotics – chloramphenicol, sulphonamides
  - Antirheumatic agents – penicillamine, gold, phenylbutazone, indometacin
  - Antithyroid drugs
  - Anticonvulsants
  - Immunosuppressants – azathioprine
- Chemicals
  - Benzene toluene solvent misuse – glue-sniffing
  - Insecticides – chlorinated hydrocarbons (DDT), organophosphates and carbamates (pp. 220 and 222)
- Radiation
- Viral hepatitis
- Pregnancy
- Paroxysmal nocturnal haemoglobinuria

MYELOPROLIFERATIVE NEOPLASMS

These make up a group of chronic conditions characterised by clonal proliferation of marrow precursor cells, and include polycythaemia rubra vera (PRV), essential thrombocythaemia, myelofibrosis, and chronic myeloid leukaemia (p. 1039). Although the majority of patients are classifiable as having one of these disorders, some have overlapping features and there is often progression from one to another, e.g. PRV to myelofibrosis. The recent discovery of the molecular basis of these disorders will lead to changes in classification and treatment; a mutation in the gene on chromosome 9 encoding the signal transduction molecule *JAK-2* has been found in more than 90% of PRV cases and 50% of those with essential thrombocythaemia and myelofibrosis.

Myelofibrosis

In myelofibrosis, the marrow is initially hypercellular, with an excess of abnormal megakaryocytes which release growth factors, e.g. platelet-derived growth factor, to the marrow microenvironment, resulting in a reactive proliferation of fibroblasts. As the disease progresses, the marrow becomes fibrosed.

Most patients present over the age of 50 years, with lassitude, weight loss and night sweats. The spleen can be massively enlarged due to extramedullary haematopoiesis (blood cell formation outside the bone marrow), and painful splenic infarcts may occur.

The characteristic blood picture is leucoerythroblastic anaemia, with circulating immature red blood cells (increased reticulocytes and nucleated red blood cells) and granulocyte precursors (myelocytes). The red cells are shaped like teardrops (teardrop poikilocytes), and giant platelets may be seen in the blood. The white count varies from low to moderately high, and the platelet count may be high, normal or low. Urate levels may be high due to increased cell breakdown, and folate deficiency is common. The marrow is often difficult to

aspirate and a trephine biopsy shows an excess of megakaryocytes, increased reticulin and fibrous tissue replacement. The presence of a *JAK-2* mutation supports the diagnosis.

Management and prognosis

Median survival is 4 years from diagnosis, but ranges from 1 year to over 20 years. Treatment is directed at control of symptoms, e.g. red cell transfusions for anaemia. Folic acid should be given to prevent deficiency. Cytotoxic therapy with hydroxycarbamide may help control spleen size, the white cell count or systemic symptoms. Splenectomy may be required for a grossly enlarged spleen or symptomatic pancytopenia secondary to splenic pooling of cells and hypersplenism. HSCT may be considered for younger patients. Ruxolitinib, an inhibitor of *JAK-2*, has recently been licensed for use.

Essential thrombocythaemia

Increased proliferation of megakaryocytes results in a raised level of circulating platelets that are often dysfunctional. Prior to making a diagnosis of essential thrombocythaemia (ET), reactive causes of thrombocytosis must be excluded (p. 1008). The presence of a *JAK-2* mutation supports the diagnosis but is not universal. Patients present at a median age of 60 years with vascular occlusion or bleeding, or with an asymptomatic isolated raised platelet count. A small percentage transform to acute leukaemia and others to myelofibrosis.

It is likely that most patients with ET benefit from low-dose aspirin to reduce the risk of occlusive vascular events. Low-risk patients (age < 40 years, platelet count $< 1000 \times 10^9$/L and no bleeding or thrombosis) may not require treatment to reduce the platelet count. For those with a platelet count above 1000×10^9/L, with symptoms, or with other risk factors for thrombosis such as diabetes or hypertension, treatment to control platelet counts should be given. Agents include oral hydroxycarbamide or anagrelide, an inhibitor of megakaryocyte maturation. Intravenous radioactive phosphorus (^{32}P) may be useful in old age.

Polycythaemia rubra vera

Polycythaemia rubra vera (PRV) occurs mainly in patients over the age of 40 years and presents either as an incidental finding of a high haemoglobin, or with symptoms of hyperviscosity, such as lassitude, loss of concentration, headaches, dizziness, blackouts, pruritus and epistaxis. Some patients present with manifestations of peripheral arterial disease or a cerebrovascular accident. Venous thromboembolism may also occur. Peptic ulceration is common, sometimes complicated by bleeding. Patients are often plethoric and many have a palpable spleen at diagnosis.

Investigation of polycythaemia is discussed on page 1002. The diagnosis of PRV now rests upon the demonstration of a high haematocrit and the presence of the *JAK-2* mutation. In the occasional *JAK-2*-negative cases, a raised red cell mass and absence of causes of a secondary erythrocytosis must be established. The spleen is enlarged, neutrophil and platelet counts are frequently raised, an abnormal karyotype may be found in the marrow, and in vitro culture of the marrow can be used to demonstrate autonomous growth in the absence of added growth factors.

Management and prognosis

Aspirin reduces the risk of thrombosis. Venesection gives prompt relief of hyperviscosity symptoms. Between 400 and 500 mL of blood (less if the patient is elderly) are removed and the venesection is repeated every 5–7 days until the haematocrit is reduced to below 45%. Less frequent but regular venesection will maintain this level until the haemoglobin remains reduced because of iron deficiency.

Suppression of marrow proliferation with hydroxycarbamide or interferon-alfa may reduce the risk of vascular occlusion, control spleen size and reduce transformation to myelofibrosis. Radioactive phosphorus (5 mCi of ^{32}P IV) is reserved for older patients, as it increases the risk of transformation to acute leukaemia by 6- to 10-fold.

Median survival after diagnosis in treated patients exceeds 10 years. Some patients survive more than 20 years; however, cerebrovascular or coronary events occur in up to 60% of patients. The disease may convert to another myeloproliferative disorder, with about 25% developing acute leukaemia or myelofibrosis.

BLEEDING DISORDERS

Disorders of primary haemostasis

The initial formation of the platelet plug (see Fig. 24.6A, p. 996; also known as 'primary haemostasis') may fail in thrombocytopenia (p. 1007), von Willebrand disease (p. 1053), and also in platelet function disorders and diseases affecting the vessel wall.

Vessel wall abnormalities

Vessel wall abnormalities may be:

- congenital, such as hereditary haemorrhagic telangiectasia
- acquired, as in a vasculitis (p. 1115) or scurvy.

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited condition caused by mutations in the genes encoding endoglin and activin receptor-like kinase, which are endothelial cell receptors for transforming growth factor-beta (TGF-β), a potent angiogenic cytokine. Telangiectasia and small aneurysms are found on the fingertips, face and tongue, and in the nasal passages, lung and gastrointestinal tract. A significant proportion of these patients develop larger pulmonary arteriovenous malformations (PAVMs) that cause arterial hypoxaemia due to a right-to-left shunt. These predispose to paradoxical embolism, resulting in stroke or cerebral abscess. All patients with HHT should be screened for PAVMs; if these are found, ablation by percutaneous embolisation should be considered.

Patients present either with recurrent bleeds, particularly epistaxis, or with iron deficiency due to occult gastrointestinal bleeding. Treatment can be difficult because of the multiple bleeding points but regular iron therapy often allows the marrow to compensate for blood loss. Local cautery or laser therapy may prevent single lesions from bleeding. A variety of medical therapies have been tried but none has been found to be universally effective.

Ehlers–Danlos disease

Vascular Ehlers–Danlos syndrome (type 4) is a rare autosomal dominant disorder (1/100 000) caused by a defect in type 3 collagen which results in fragile blood vessels and organ membranes, leading to bleeding and organ rupture. Classical joint hypermobility (p. 1134) is often limited in this form of the disease but skin changes and facial appearance are typical. The diagnosis should be considered when there is a history of bleeding but normal laboratory tests.

Scurvy

Vitamin C deficiency affects the normal synthesis of collagen and results in a bleeding disorder characterised by perifollicular and petechial haemorrhage, bruising and subperiosteal bleeding. The key to diagnosis is the dietary history (p. 129).

Platelet function disorders

Bleeding may result from thrombocytopenia (see Box 24.14, p. 1007) or from congenital or acquired abnormalities of platelet function. The most common acquired disorders are iatrogenic, resulting from the use of aspirin, clopidogrel, dipyridamole and the IIb/IIIa inhibitors to prevent arterial thrombosis (see Box 24.29, p. 1019). Inherited platelet function abnormalities are relatively rare. Congenital abnormalities may be due to deficiency of the membrane glycoproteins, e.g. Glanzmann's thrombasthenia (IIb/IIIa) or Bernard–Soulier disease (Ib), or due to the presence of defective platelet granules, e.g. a deficiency of dense (delta) granules (see Fig. 24.7, p. 998) giving rise to storage pool disorders. The congenital macrothrombocytopathies that are due to mutations in the myosin heavy chain gene *MYH-9* are characterised by large platelets, inclusion bodies in the neutrophils (Döhle bodies) and a variety of other features, including sensorineural deafness and renal abnormalities.

Apart from Glanzmann's thrombasthenia, these conditions are mild disorders, with bleeding typically occurring after trauma or surgery but rarely spontaneously. Glanzmann's is an autosomal recessive condition associated with a variable but often severe bleeding disorder. These conditions are usually managed by local mechanical measures, but antifibrinolytics, such as tranexamic acid, may be useful and, in severe bleeding, platelet transfusion may be required. Recombinant VIIa is licensed for the treatment of resistant bleeding in Glanzmann's thrombasthenia.

Thrombocytopenia

Thrombocytopenia occurs in many disease processes, as listed in Box 24.14 (p. 1007), many of which are discussed elsewhere in this chapter.

Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is mediated by autoantibodies, most often directed against the platelet membrane glycoprotein IIb/IIIa, which sensitise the platelet, resulting in premature removal from the circulation by cells of the reticulo-endothelial system. It is not a single disorder; some cases occur in isolation while others are associated with underlying immune dysregulation in conditions such as connective tissue diseases, HIV infection, B cell malignancies, pregnancy and certain drug therapies. However, the clinical presentation and pathogenesis are similar, whatever the cause of ITP.

Clinical features and investigations

The presentation depends on the degree of thrombocytopenia. Spontaneous bleeding typically occurs only when the platelet count is below 20×10^9/L. At higher counts, the patient may complain of easy bruising or sometimes epistaxis or menorrhagia. Many cases with counts of more than 50×10^9/L are discovered by chance.

In adults, ITP more commonly affects females and may have an insidious onset. Unlike ITP in children, it is unusual for there to be a history of a preceding viral infection. Symptoms or signs of a connective tissue disease may be apparent at presentation or emerge several years later. Patients aged over 65 years should have a bone marrow examination to look for an accompanying B cell malignancy and appropriate autoantibody testing performed if a diagnosis of connective tissue disease is likely. HIV testing should be considered. The peripheral blood film is normal, apart from a greatly reduced platelet number, whilst the bone marrow reveals an obvious increase in megakaryocytes.

Management

Many patients with stable compensated ITP and a platelet count of more than 30×10^9/L do not require treatment to raise the platelet count, except at times of increased bleeding risk, such as surgery and biopsy. First-line therapy for patients with spontaneous bleeding is with prednisolone 1 mg/kg daily to suppress antibody production and inhibit phagocytosis of sensitised platelets by reticuloendothelial cells. Administration of intravenous immunoglobulin (IVIg) can raise the platelet count by blocking antibody receptors on reticuloendothelial cells, and is combined with corticosteroid therapy if there is severe haemostatic failure or a slow response to steroids alone. Persistent or potentially life-threatening bleeding should be treated with platelet transfusion in addition to the other therapies.

The condition may become chronic, with remissions and relapses. Relapses should be treated by re-introducing corticosteroids. If a patient has two relapses, or primary refractory disease, splenectomy is considered, with the precautions shown in Box 24.40 (p. 1028). Splenectomy produces complete remission in about 70% of patients and improvement in a further 20–25%, so that, following splenectomy, only 5–10% of patients require further medical therapy. If severe thrombocytopenia with or without significant bleeding persists despite splenectomy, second-line therapy with the thrombopoietin analogue romiplostim or the thrombopoietin receptor agonist eltrombopag should be considered. Low-dose corticosteroid therapy, immunosuppressants such as rituximab, ciclosporin and tacrolimus should be considered in cases where the approaches above are ineffective.

Coagulation disorders

Normal coagulation is explained in Figure 24.6 (p. 996). Coagulation factor deficiency may be congenital or acquired, and may affect one or several of the coagulation factors (Box 24.66). Inherited disorders are almost uniformly related to decreased synthesis, as a result of

24.66 Causes of coagulopathy

Congenital

X-linked
- Haemophilia A and B

Autosomal

mutation in the gene encoding a key protein in coagulation. Von Willebrand disease is the most common inherited bleeding disorder. Haemophilia A and B are the most common single coagulation factor deficiencies, but inherited deficiencies of all the other coagulation factors are seen. Acquired disorders may be due to under-production (e.g. in liver failure), increased consumption (e.g. in disseminated intravascular coagulation) or inhibition of function (such as heparin therapy or immune inhibitors of coagulation, e.g. acquired haemophilia A).

Haemophilia A

Factor VIII deficiency resulting in haemophilia A affects 1/10 000 individuals. It is the most common congenital coagulation factor deficiency. Factor VIII is primarily synthesised by the liver and endothelial cells, and has a half-life of about 12 hours. It is protected from proteolysis in the circulation by binding to von Willebrand factor (vWF).

Genetics

The factor VIII gene is located on the X chromosome. Severe haemophilia is associated with large deletions, while single-base changes more often result in moderate or mild disease (Box 24.67). As the gene is on the X chromosome, haemophilia A is a sex-linked disorder (p. 53). Thus all daughters of haemophiliacs are obligate carriers and they, in turn, have a 1 in 4 chance of each pregnancy resulting in the birth of an affected male

24.67 Severity of haemophilia (ISTH criteria)

Severity	Factor VIII or IX level	Clinical presentation
Severe	< 0.01 U/mL	Spontaneous haemarthroses and muscle haematomas
Moderate	0.01–0.05 U/mL	Mild trauma or surgery causes bleeding
Mild	> 0.05 to 0.4 U/mL	Major injury or surgery results in excess bleeding

(ISTH = International Society on Thrombosis and Haemostasis)

baby, a normal male baby, a carrier female or a normal female. Antenatal diagnosis by chorionic villous sampling is possible in families with a known mutation.

Haemophilia 'breeds true' within a family; all members have the same factor VIII gene mutation and a similarly severe or mild phenotype. Female carriers of haemophilia may have reduced factor VIII levels because of random inactivation of their normal X chromosome in the developing fetus (lyonisation). This can result in a mild bleeding disorder; thus all known or suspected carriers of haemophilia should have their factor VIII level measured.

Clinical features

The extent and patterns of bleeding are closely related to residual factor VIII levels. Patients with severe haemophilia (< 1% of normal factor VIII levels) present with spontaneous bleeding into skin, muscle and joints. Retroperitoneal and intracranial bleeding is also a feature. Babies with severe haemophilia have an increased risk of intracranial haemorrhage and, although there is insufficient evidence to recommend routine caesarean section for these births, it is appropriate to avoid head trauma and to perform imaging of the newborn within the first 24 hours of life. Individuals with moderate and mild haemophilia (factor VIII levels 1–40%) present with the same pattern of bleeding, but usually after trauma or surgery, when bleeding is greater than would be expected from the severity of the insult.

The major morbidity of recurrent bleeding in severe haemophilia is musculoskeletal. Bleeding is typically into large joints, especially knees, elbows, ankles and hips. Muscle haematomas are also characteristic, most commonly in the calf and psoas muscles. If early treatment is not given to arrest bleeding, a hot, swollen and very painful joint or muscle haematoma develops. Recurrent bleeding into joints leads to synovial hypertrophy, destruction of the cartilage and secondary osteoarthrosis (Fig. 24.32). Complications of muscle haematomas depend on their location. A large psoas bleed may extend to compress the femoral nerve; calf haematomas may increase pressure within the inflexible fascial sheath, causing a compartment syndrome with ischaemia, necrosis, fibrosis, and subsequent contraction and shortening of the Achilles tendon.

Management

In severe haemophilia A, bleeding episodes should be treated by raising the factor VIII level, usually by

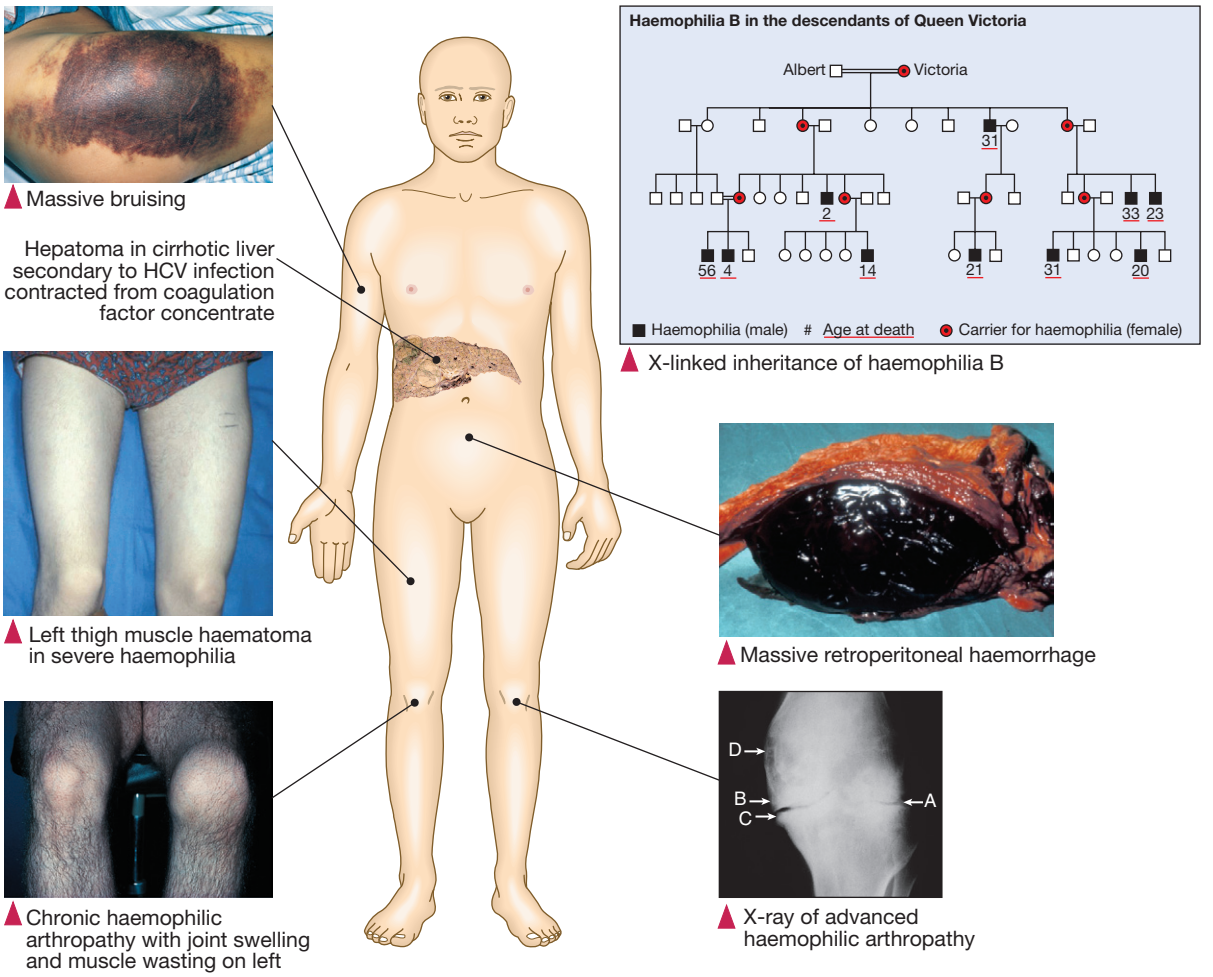

Fig. 24.32 Clinical manifestations of haemophilia. On the knee X-ray, repeated bleeds have led to broadening of the femoral epicondyles, and there is no cartilage present, as evidenced by the close proximity of the femur and tibia (A); sclerosis (B), osteophyte (C) and bony cysts (D) are present. (HCV = hepatitis C virus). *Inset (Massive bruising)* From Hoffbrand 2000 – see p. 1056.

intravenous infusion of factor VIII concentrate. Factor VIII concentrates are freeze-dried and stable at 4°C and can therefore be stored in domestic refrigerators, allowing patients to treat themselves at home at the earliest indication of bleeding. Factor VIII concentrate prepared from blood donor plasma is now screened for HBV, HCV and HIV, and undergoes two separate virus inactivation processes during manufacture; these preparations have a good safety record. However, factor VIII concentrates prepared by recombinant technology are now widely available and, although more expensive, are perceived as being safer than those derived from human plasma. In addition to raising factor VIII concentrations, resting of the bleeding site by either bed rest or a splint reduces continuing haemorrhage. Once bleeding has settled, the patient should be mobilised and physiotherapy used to restore strength to the surrounding muscles. All non-immune potential recipients of pooled blood products should be offered hepatitis A and B immunisation.

The vasopressin receptor agonist DDAVP (p. 794) raises the vWF and factor VIII levels by 3–4-fold, which is useful in arresting bleeding in patients with mild or moderate haemophilia A. The dose required for this purpose is higher than that used in diabetes insipidus, usually 0.3 μg/kg given intravenously or subcutaneously. Alternatively, the same effect can be achieved by intranasal administration of 300 μg. Following repeated administration of DDAVP, patients need to be monitored for evidence of water retention, which can result in significant hyponatraemia. DDAVP is contraindicated in patients with a history of severe arterial disease because of a propensity to provoke a thrombotic event.

In addition to treatment 'on demand' for bleeding, factor VIII can be administered 2 or 3 times per week as 'prophylaxis' to prevent bleeding in severe haemophilia. This is most appropriate in children, but its widespread use is limited by the high cost of factor VIII preparations. New concentrates of factor VIII (and factor IX) will soon add to the treatment options for these conditions.

Complications of coagulation factor therapy

Before 1986, coagulation factor concentrates from human plasma were not virally inactivated with heat or chemicals, and many patients became infected with HIV and hepatitis viruses HBV and HCV. In exposed patients with severe haemophilia, infection with HCV is almost

universal, 80–90% have evidence of HBV exposure, and 60% became HIV-positive. Management is described in Chapters 23 and 14. Since 1989, viral inactivation of these blood products has eradicated the risk of viral infection.

Concern that the infectious agent that causes vCJD (p. 1211) might be transmissible by blood and blood products has been confirmed in recipients of red cell transfusion, and in one recipient of factor VIII. Pooled plasma products, including factor VIII concentrate, are now manufactured from plasma collected in countries with a low incidence of bovine spongiform encephalopathy.

Another serious complication of factor VIII infusion is the development of anti-factor VIII antibodies, which arise in about 20% of severe haemophiliacs. Such antibodies rapidly neutralise therapeutic infusions, making treatment relatively ineffective. Infusions of activated clotting factors, e.g. VIIa or factor VIII inhibitor bypass activity (FEIBA), may stop bleeding.

Haemophilia B (Christmas disease)

Aberrations of the factor IX gene, which is also present on the X chromosome, result in a reduction of the plasma factor IX level, giving rise to haemophilia B. This disorder is clinically indistinguishable from haemophilia A but is less common. The frequency of bleeding episodes is related to the severity of the deficiency of the plasma factor IX level. Treatment is with a factor IX concentrate, used in much the same way as factor VIII for haemophilia A. Although factor IX concentrates shared the problems of virus transmission seen with factor VIII, they do not commonly induce inhibitor antibodies (< 1% patients); when this does occur, however, it may be heralded by the development of a severe allergic-type reaction.

Von Willebrand disease

Von Willebrand disease is a common but usually mild bleeding disorder caused by a quantitative (types 1 and 3) or qualitative (type 2) deficiency of von Willebrand factor (vWF), a protein synthesised by endothelial cells and megakaryocytes, which is involved in both platelet function and coagulation. It normally forms a multimeric structure which is essential for its interaction with subendothelial collagen and platelets (see Fig. 24.7, p. 998). vWF acts as a carrier protein for factor VIII, to which it is non-covalently bound; deficiency of vWF lowers the plasma factor VIII level. vWF also forms bridges between platelets and subendothelial components (e.g. collagen; see Fig. 24.6, p. 996), allowing platelets to adhere to damaged vessel walls; deficiency of vWF therefore leads to impaired platelet plug formation. Blood group antigens (A and B) are expressed on vWF, reducing its susceptibility to proteolysis; as a result, people with blood group O have lower circulating vWF levels than individuals with non-O groups. This needs to be borne in mind when making a diagnosis of von Willebrand disease.

Most patients with von Willebrand disease have a type 1 disorder, characterised by a quantitative decrease in a normal functional protein. Patients with type 2 disorders inherit vWF molecules that are functionally abnormal. The type of abnormality depends on the site of the mutation in the *vWD* gene. Patients with mutations in platelet binding have type 2A disease, those with mutations in the platelet glycoprotein Ib binding site have type 2B, those with mutations in the factor VIII binding site have type 2N disease, and those with other abnormalities in platelet binding have type 2M. The patterns of laboratory abnormality accompanying these types are described in Box 24.68. The gene for vWF is located on chromosome 12 and the disease is usually inherited as an autosomal dominant, except in cases of type 2N and type 3, when it is recessive.

24.68 Classification of von Willebrand disease

Type	Defect	Inheritance	Investigations
1	Partial quantitative	AD	Parallel decrease in vWF: Ag and VIII:c
2A	Qualitative	AD	Absent HWM of vWF Ratio of vWF activity to antigen < 0.7
2B	Qualitative	AD	Reduced HWM of vWF Enhanced platelet agglutination (RIPA)
2M	Qualitative	AD	Normal multimers of vWF Abnormal platelets Interactions
2N	Qualitative	AR	Defective binding of vWF to VIII Low VIII
3	Severe quantitative	AR or CH	Very low vWF activity and VIII:c Absent multimers

(AD = autosomal dominant; AR = autosomal recessive; CH = compound heterozygote; HWM = high-weight multimers of vWF; RIPA = ristocetin-induced platelet agglutination; VIII:c = coagulation factor VIII activity in functional assay; vWF = von Willebrand factor; vWF:Ag = vWF antigen measured by ELISA)

Clinical features

Patients present with haemorrhagic manifestations similar to those in individuals with reduced platelet function. Superficial bruising, epistaxis, menorrhagia and gastrointestinal haemorrhage are common. Bleeding episodes are usually much less common than in severe haemophilia and excessive haemorrhage may only be observed after trauma or surgery. Within a single family, the disease has variable penetrance, so that some members may have quite severe and frequent bleeds, whereas others are relatively asymptomatic.

Investigations

The disorder is characterised by reduced activity of vWF and factor VIII. The disease can be classified using a combination of assays which include functional and antigenic measures of vWF, multimeric analysis of the protein, and specific tests of function to determine binding to platelet glycoprotein Ib (RIPA) and factor VIII (see Box 24.68). In addition, analysis for mutations in the *vWF* gene is informative in most cases.

Management

Many episodes of mild haemorrhage can be successfully treated by local means or with DDAVP, which raises the vWF level, resulting in a secondary increase in factor VIII.

Tranexamic acid may be useful in mucosal bleeding. For more serious or persistent bleeds, haemostasis can be achieved with selected factor VIII concentrates which contain considerable quantities of vWF in addition to factor VIII. Young children and patients with severe arterial disease should not receive DDAVP, and patients with type 2B disease develop thrombocytopenia which may be troublesome following DDAVP. Bleeding in type 3 patients responds to nothing apart from concentrate.

Rare inherited bleeding disorders

Severe deficiencies of factor VII, X and XIII occur as autosomal recessive disorders. They are rare but are associated with severe bleeding. Typical features include haemorrhage from the umbilical stump and intracranial haemorrhage. Factor XIII deficiency is typically associated with female infertility.

Factor XI deficiency may occur in heterozygous or homozygous individuals. Bleeding is very variable and is not accurately predicted by coagulation factor levels. In general, severe bleeding is confined to patients with levels below 15% of normal.

Acquired bleeding disorders

Disseminated intravascular coagulation (DIC) is an important cause of bleeding which begins with exaggerated and inappropriate intravascular coagulation. It is discussed under thrombotic disease on page 1055.

Liver disease

In severe parenchymal liver disease (Ch. 23), bleeding may arise from many different causes. Pathological sources of potential major bleeding, such as oesophageal varices or peptic ulcer, are more likely. There is reduced hepatic synthesis: for example, of factors V, VII, VIII, IX, X, XI, prothrombin and fibrinogen. Clearance of plasminogen activator is reduced. Thrombocytopenia may occur secondary to hypersplenism in portal hypertension. In cholestatic jaundice, there is reduced vitamin K absorption, leading to deficiency of factors II, VII, IX and X. Treatment with plasma products or platelet transfusion should be reserved for acute bleeds or to cover interventional procedures such as liver biopsy. Vitamin K deficiency can be readily corrected with parenteral administration of vitamin K.

Renal failure

The severity of the haemorrhagic state in renal failure is proportional to the plasma urea concentration (p. 478). Bleeding manifestations are those of platelet dysfunction, with gastrointestinal haemorrhage being particularly common. The causes are multifactorial, including anaemia, mild thrombocytopenia and the accumulation of low molecular weight waste products, normally excreted by the kidney, which inhibit platelet function. Treatment is by dialysis to reduce the urea concentration. Rarely, in severe or persistent bleeding, platelet concentrate infusions and red cell transfusions are indicated. Increasing the concentration of vWF, either by cryoprecipitate or by DDAVP, may promote haemostasis.

THROMBOTIC DISORDERS

Venous thromboembolic disease (VTE) and its treatment have many clinical manifestations. The approach to patients with the most common presentation, deep venous thrombosis of the leg, is described on page 1008.

Pulmonary embolism is discussed on page 721. Anticoagulant therapy is discussed on page 1010. Predisposing factors for VTE are listed in Box 24.17 (p. 1009). In a small proportion of cases, there is an underlying haematological disorder predisposing to venous thrombosis, detected using the tests described in Boxes 24.4 and 24.5 (p. 1001). These disorders include myeloproliferative disorders and paroxysmal nocturnal haemoglobinuria, which are discussed above (pp. 1048 and 1031). They also include inherited and acquired conditions, described below.

Inherited abnormalities of coagulation

Several inherited conditions predispose to VTE, and have several points in common that are worth noting:

- None of them is strongly associated with arterial thrombosis.
- All are associated with a slightly increased incidence of adverse outcome of pregnancy, including recurrent early fetal loss, but there are no data to indicate that any specific intervention changes that outcome.
- Apart from in antithrombin deficiency and homozygous factor V Leiden, most carriers of these genes will never have an episode of VTE; if they do, it will be associated with the presence of an additional temporary risk factor.
- There is little evidence that detection of these abnormalities predicts recurrence of VTE.
- None of these conditions per se requires treatment with anticoagulants. Patients with thrombosis should receive anticoagulation, as discussed on page 1009. Patients who are deemed to be at high risk of thrombosis, e.g. those with antithrombin deficiency in pregnancy, should receive treatment or prophylactic doses of heparin to cover the period of risk only.

Antithrombin deficiency

Antithrombin (AT) is a serine protease inhibitor (SERPIN) which inactivates the activated coagulation factors IIa, IXa, Xa and XIa. Heparins, fondaparinux and idraparinux achieve their therapeutic effect by potentiating the activity of AT. Familial deficiency of AT is inherited as an autosomal dominant; homozygosity for mutant alleles is not compatible with life. Around 70% of affected individuals will have an episode of VTE before the age of 60 years and the relative risk for thrombosis compared with the background population is 10–20. Pregnancy is a high-risk period for VTE and this requires fairly aggressive management with doses of LMWH which are greater than the usual prophylactic doses (≥ 100 U/kg/day). AT concentrate (either plasma-derived or recombinant) is available; this is required for cardiopulmonary bypass and may be used as an adjunct to heparin in surgical prophylaxis.

Protein C and S deficiencies

Protein C and S are vitamin K-dependent natural anticoagulants involved in switching off coagulation factor activation (factors Va and VIIIa) and thrombin generation (see Fig. 24.6E, p. 997). Inherited deficiency

of either protein C or S results in a prothrombotic state with a fivefold relative risk of VTE compared with the background population.

Factor V Leiden

Factor V Leiden results from a gain-of-function, single-base pair mutation which prevents the cleavage and hence inactivation of activated factor V. This results in a relative risk of venous thrombosis of 5 in heterozygotes and 50 or more in rare homozygotes. The mutation is found in about 5% of Northern Europeans, 2% of Hispanics, 1.2% of African-Americans, 0.5% of Asian-Americans and 1.25% of Native Americans, and is rare in Chinese and Malay people.

Prothrombin G20210A

This gain-of-function mutation in the non-coding 3′ end of the prothrombin gene is associated with an increased plasma level of prothrombin. It is present in about 2% of Northern Europeans but is rare in native populations of Korea, China, India and Africa. In the heterozygous state, it is associated with a 2–3-fold increase in risk of VTE compared with the background population.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is a clinicopathological entity in which a constellation of clinical conditions, alone or in combination, is found in association with a persistently positive test for an antiphospholipid antibody. The antiphospholipid antibodies are heterogeneous and typically are directed against proteins which bind to phospholipids (Box 24.69). Although causal roles for these antibodies have been proposed, the mechanisms underlying the clinical features of APS are not clear. In clinical practice, two types of test are used, which detect:

- antibodies which bind to negatively charged phospholipid on an ELISA plate (called an anticardiolipin antibody test)
- those which interfere with phospholipid-dependent coagulation tests like the APTT or the dilute Russell viper venom time (DRVVT; called a lupus anticoagulant test).

The term antiphospholipid antibody encompasses both a lupus anticoagulant and an anticardiolipin antibody; individuals may be positive for one or both of these activities.

24.69 Antiphospholipid syndrome

Clinical manifestations

- Adverse pregnancy outcome
  - Recurrent first trimester abortion (≥ 3)
  - Unexplained death of morphologically normal fetus after 10 wks' gestation
  - Severe early pre-eclampsia
- Venous thromboembolism
- Arterial thromboembolism
- Livedo reticularis, catastrophic APS, transverse myelitis, skin necrosis, chorea

Conditions associated with secondary APS

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Systemic sclerosis
- Behçet's syndrome
- Temporal arteritis
- Sjögren's syndrome

Targets for antiphospholipid antibodies

- β_2-glycoprotein 1
- Protein C
- Annexin V
- Prothrombin (may result in haemorrhagic presentation)

Clinical features and management

APS may present in isolation (primary APS) or in association with one of the conditions shown in Box 24.69, most typically systemic lupus erythematosus (secondary APS). Most patients present with a single manifestation and APS is now most frequently diagnosed in women with adverse outcomes of pregnancy. It is extremely important to make the diagnosis in patients with APS, whatever the manifestation, because it affects the prognosis and management of arterial thrombosis, VTE and pregnancy.

Arterial thrombosis, typically stroke, associated with APS should be treated with warfarin, as opposed to aspirin. APS-associated VTE is one of the situations in which the predicted recurrence rate is high enough to indicate long-term anticoagulation after a first event. In women with APS, it is likely that intervention with heparin and possibly aspirin increases the chance of a successful pregnancy outcome.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) may complicate a range of illnesses (Box 24.70). It is characterised by systemic activation of the pathways involved in coagulation and its regulation. This may result in the generation of intravascular fibrin clots causing multi-organ failure, with simultaneous coagulation factor and platelet consumption causing bleeding. The systemic coagulation activation is induced either through cytokine pathways, which are activated as part of a systemic inflammatory response, or by the release of procoagulant substances such as tissue factor. In addition, suboptimal function of the natural anticoagulant pathways and dysregulated fibrinolysis contribute to DIC. There is consumption of platelets, coagulation factors (notably factors V and VIII) and fibrinogen. The lysis of fibrin clot results in production of fibrin degradation products (FDPs), including D-dimers.

Investigations

DIC should be suspected when any of the conditions listed in Box 24.70 are met. Measurement of coagulation times (APTT and PT; p. 1000), along with fibrinogen, platelet count and FDPs, helps in the assessment of prognosis and aids clinical decision-making with regard to both bleeding and thrombotic complications.

Management

Therapy is primarily aimed at the underlying cause. These patients will often require intensive care to deal with concomitant issues, such as acidosis, dehydration, renal failure and hypoxia. Blood component therapy, such as fresh frozen plasma, cryoprecipitate and platelets, should be given if the patient is bleeding or to cover interventions with high bleeding risk, but should not be

24.70 Disseminated intravascular coagulation

Underlying conditions

- Infection/sepsis
- Trauma
- Obstetric, e.g. amniotic fluid embolism, placental abruption, pre-eclampsia
- Severe liver failure
- Malignancy, e.g. solid tumours and leukaemias
- Tissue destruction, e.g. pancreatitis, burns
- Vascular abnormalities, e.g. vascular aneurysms, liver haemangiomas
- Toxic/immunological, e.g. ABO incompatibility, snake bites, recreational drugs

ISTH scoring system for diagnosis of DIC

Presence of an associated disorder	Essential
Platelets	> 100 = 0 < 100 = 1 < 50 = 2
Elevated fibrin degradation products	No increase = 0 Moderate = 2 Strong = 3
Prolonged prothrombin time	< 3 sec = 0 > 3 sec but < 6 sec = 1 > 6 sec = 2
Fibrinogen	> 1 g/L = 0 < 1 g/L = 1

Total score
≥ 5 = Compatible with overt DIC
< 5 = Repeat monitoring over 1–2 days

(ISTH = International Society for Thrombosis and Haemostasis)

prescribed routinely based on coagulation tests and platelet counts alone. Prophylactic doses of heparin should be given, unless there is a clear contraindication. Established thrombosis should be treated cautiously with therapeutic doses of unfractionated heparin, unless clearly contraindicated. Patients with DIC should not, in general, be treated with antifibrinolytic therapy, e.g. tranexamic acid.

Thrombotic thrombocytopenic purpura

Like DIC and also heparin-induced thrombocytopenia (p. 1018), thrombotic thrombocytopenic purpura (TTP) is a disorder in which thrombosis is accompanied by paradoxical thrombocytopenia. TTP is characterised by a pentad of findings, although few patients have all five components:

- thrombocytopenia
- microangiopathic haemolytic anaemia
- neurological sequelae
- fever
- renal impairment.

24.71 Haemostasis and thrombosis in old age

- **Thrombocytopenia**: not uncommon because of the rising prevalence of disorders in which it may be a secondary feature, and also because of the greater use of drugs that can cause it.
- **'Senile' purpura**: presumed to be due to an age-associated loss of subcutaneous fat and the collagenous support of small blood vessels, making them more prone to damage from minor trauma.
- **Thrombosis**: more frequent in old age. This may be due to stasis, to which older people are prone; some studies show increased platelet aggregation with age, and others age-associated hyperactivity of the haemostatic system which could create a prothrombotic state.

It is an acute autoimmune disorder mediated by antibodies against ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type-1 motif).

This enzyme normally cleaves vWF multimers to produce normal functional units, and its deficiency results in large vWF multimers which cross-link platelets. The features are of microvascular occlusion by platelet thrombi affecting key organs, principally brain and kidneys. It is a rare disorder (1 in 750 000 per annum), which may occur alone or in association with drugs (ticlopidine, ciclosporin), HIV, shiga toxins and malignancy. It should be treated by emergency plasma exchange. Corticosteroids, aspirin and rituximab also have a role in management. Untreated mortality rates are 90% in the first 10 days, and even with appropriate therapy, the mortality rate is 20–30% at 6 months.

CLINICAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM

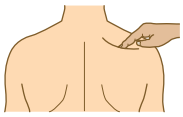
General Assessment of Locomotor System (GALS)

1 Gait

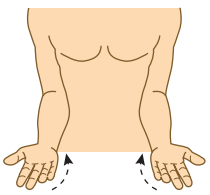
Ask patient to walk for a few steps, then come back. Look for pain or limp

2 Arms

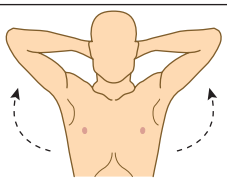
Inspect hands for swelling or deformity

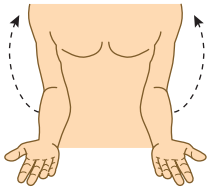


Ask patient to make a fist and open and close fingers (tests hand function)



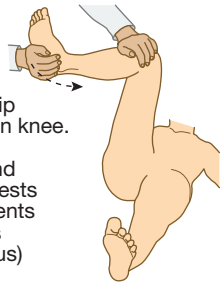
Squeeze metacarpals (tests for inflammation)





Press over supraspinatus (tests for hyperalgesia)

Patient turns palms up and down with elbows at side (tests supination and pronation of wrists and elbow)

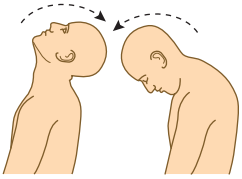


Ask patient to put hands behind head (tests shoulder movements)

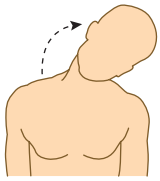
Patient flexes elbows to touch shoulder (tests elbow flexion)

3 Legs

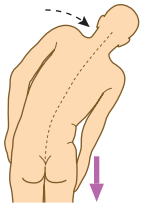
Flex each hip with hand on knee. Rotate hips internally and externally (tests hip movements and detects knee crepitus)



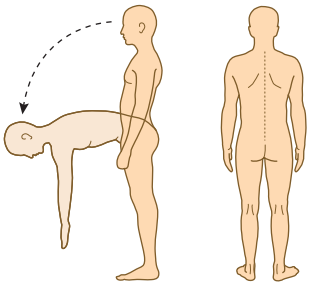
Palpate each knee for warmth and swelling (tests for synovitis and effusion)



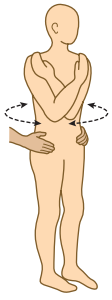
Inspect ankles and feet. Squeeze forefoot (tests for metatarsophalangeal synovitis)



4 Spine



Patient looks at ceiling and then puts chin on chest (tests flexion and extension cervical spine)



Ask patient to try to put ear on shoulder (tests lateral flexion cervical spine)

Patient slides hand down leg to knee (tests lateral spine flexion)

Inspect spine from behind and side, looking for scoliosis, kyphosis or localised deformity. Ask patient to touch toes

Stand behind patient and hold their pelvis. Ask them to turn from side to side without moving their feet (tests thoracolumbar rotation)

Diagnosis: osteoarthritis right knee

Disorders of the musculoskeletal system affect all ages and ethnic groups. In the UK, about 25% of new consultations in general practice are for musculoskeletal symptoms. Musculoskeletal diseases may arise from processes affecting bones, joints, muscles, or connective tissues such as skin and tendon. The principal manifestations are pain and impairment of locomotor function.

25.1 Relative prevalence of musculoskeletal disorders

	Prevalence	Gender ratio	Age association
'Non-inflammatory' conditions			
Neck and back pain	20%	F = M	–
Osteoarthritis			
Knee	10%	F > M	++
Hip	4%	F = M	+
Osteoporosis	15%	F > M	++
Regional 'soft tissue' pain	10%	F > M	++
Fibromyalgia	3%	F > M	++
'Inflammatory' conditions			
Rheumatoid arthritis	1%	F > M	+
Gout	1.5%	M > F	–
Seronegative spondyloarthritis	0.8%	F = M	–
Polymyalgia rheumatica	0.04%	F > M	++
Connective tissue diseases (mainly lupus)	0.02%	F > M	–

Diseases of the musculoskeletal system tend to be more common in women and most increase in frequency with increasing age. The two most common disorders are osteoarthritis and osteoporosis (Box 25.1). Osteoarthritis is the most common type of arthritis and affects up to 80% of people over the age of 75. Osteoporosis is the most common bone disease and affects 50% of women and 20% of men by their eighth decade. Diseases of the musculoskeletal system are the most common cause of physical disability in older people and account for one-third of physical disability at all ages.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The musculoskeletal system is responsible for movement of the body, provides a structural framework to protect internal organs, and acts as a reservoir for storage of calcium and phosphate in the regulation of mineral homeostasis. The main components of the musculoskeletal system are depicted in Figure 25.1.

Bone

Bones fall into two main types based on their embryonic development. Flat bones, such as the skull, develop by intramembranous ossification, in which embryonic fibroblasts differentiate directly into bone within

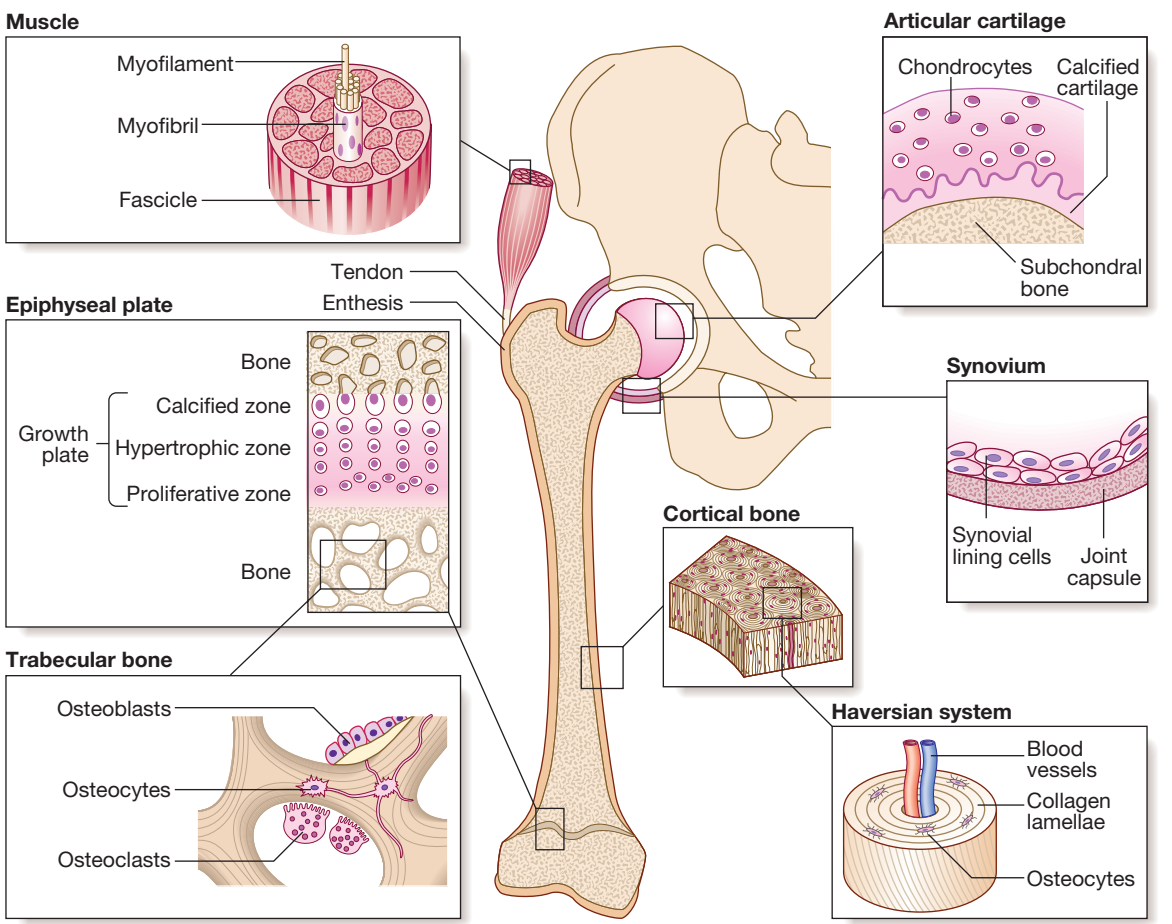

Fig. 25.1 Structure of the major musculoskeletal tissues.

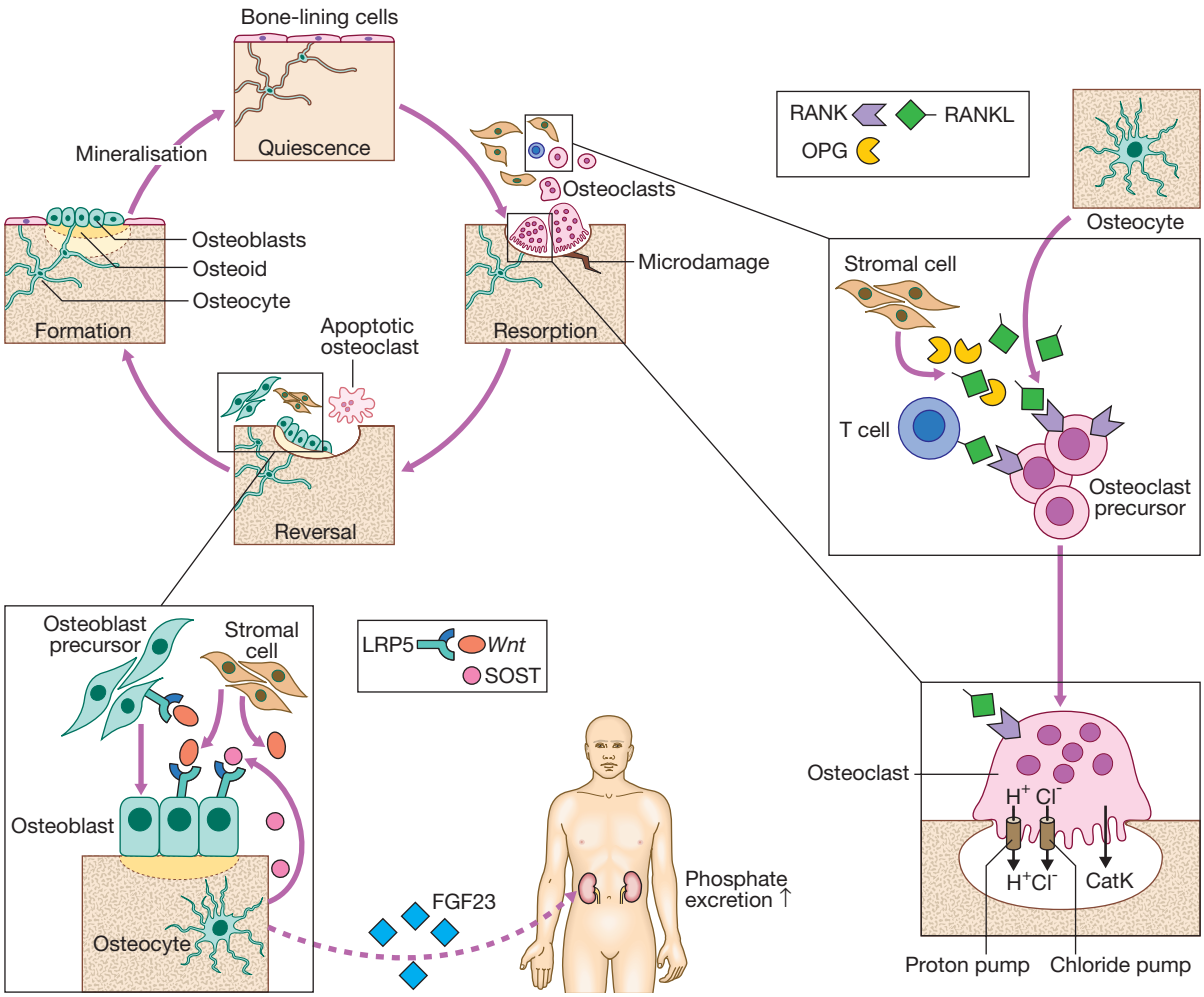

Fig. 25.2 Regulation of bone remodelling. Bone is renewed and repaired during the bone remodelling cycle, in which old and damaged bone is removed by osteoclasts and replaced by osteoblasts. Osteocytes play a central role in bone remodelling by secreting RANKL, which promotes osteoclast differentiation and activity by binding to RANK. Osteocytes regulate bone formation by producing SOST, which binds to the LRP5 receptor and prevents its activation by members of the Wnt family. Osteocytes also regulate phosphate homeostasis by producing fibroblast growth factor 23 (FGF23), which is a circulating hormone that acts on the kidney to promote phosphate excretion. (CatK = cathepsin K; LRP5 = lipoprotein receptor protein 5; OPG = osteoprotegerin; RANK = receptor activator of nuclear factor kappa B; RANKL = RANK ligand; SOST = sclerostin)

condensations of mesenchymal tissue during early fetal life. Long bones, such as the femur and radius, develop by endochondral ossification from a cartilage template. During development, the cartilage is invaded by vascular tissue containing osteoprogenitor cells and is gradually replaced by bone from centres of ossification situated in the middle and at the ends of the bone. A thin remnant of cartilage called the growth plate or epiphysis remains at each end of long bones, and chondrocyte proliferation here is responsible for skeletal growth during childhood and adolescence. During puberty, the rise in levels of sex hormones halts cell division in the growth plate. The cartilage remnant then disappears as the epiphysis fuses and longitudinal bone growth ceases.

The normal skeleton has two forms of bone tissue (see Fig. 25.1). Cortical bone is formed from Haversian systems, comprising concentric lamellae of bone tissue surrounding a central canal that contains blood vessels. Cortical bone is dense and forms a hard envelope around the long bones. Trabecular or cancellous bone fills the centre of the bone and consists of an interconnecting meshwork of trabeculae, separated by spaces filled with bone marrow.

There are three main cell types in bone:

- *Osteoclasts:* multinucleated cells of haematopoietic origin, responsible for bone resorption.
- *Osteoblasts:* mononuclear cells of mesenchymal origin, responsible for bone formation.
- *Osteocytes:* these differentiate from osteoblasts during bone formation and become embedded in bone matrix. Osteocytes are responsible for sensing and responding to mechanical loading of the skeleton and play a critical role in regulating bone formation and bone resorption, by producing receptor activator of nuclear factor kappa B ligand (RANKL) and sclerostin (SOST). They also play a central role in regulating phosphate metabolism by producing the hormone fibroblast growth factor 23 (FGF23), which acts on the kidney to promote phosphate excretion (Fig. 25.2).

Bone matrix and mineral

The most abundant protein of bone is type I collagen, which is formed from two α1 peptide chains and one α2 chain wound together in a triple helix. Type I collagen is proteolytically processed inside the cell before being laid down in the extracellular space, releasing propeptide fragments that can be used as biochemical markers of bone formation (p. 1066). Subsequently, the collagen fibrils become 'cross-linked' to one another by pyridinium molecules, a process that enhances bone strength. When bone is broken down by osteoclasts, the cross-links are released, providing biochemical markers of bone resorption. Bone is normally laid down in an orderly fashion, but when bone turnover is high, as in Paget's disease or severe hyperparathyroidism, it is laid down in a chaotic pattern, giving rise to 'woven bone', which is mechanically weak. Bone matrix also contains growth factors, other structural proteins and proteoglycans, thought to be involved in helping bone cells attach to bone matrix and in regulating bone cell activity. The other major component of bone is mineral, comprised of calcium and phosphate crystals deposited between the collagen fibrils in the form of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$. Mineralisation is essential for bone's rigidity and strength, but over-mineralisation can increase brittleness, which contributes to bone fragility in diseases like osteogenesis imperfecta (p. 1131).

Bone remodelling

Bone remodelling is required for renewal and repair of the skeleton throughout life (see Fig. 25.2). It starts with the attraction of osteoclast precursors in peripheral blood to the target site, probably by local release of chemotactic factors from areas of microdamage. The osteoclast precursors differentiate into mature osteoclasts in response to RANKL, which is produced by osteocytes, activated T cells and bone marrow stromal cells. RANKL activates the RANK receptor, which is expressed on osteoclasts and precursors. This is blocked by osteoprotegerin (OPG), a decoy receptor for RANKL that inhibits osteoclast formation. Mature osteoclasts attach to the bone surface by a tight sealing zone, and secrete hydrochloric acid and proteolytic enzymes such as cathepsin K into the space underneath. The acid dissolves the mineral and cathepsin K degrades collagen. When resorption is complete, osteoclasts undergo programmed cell death, and bone formation begins with the attraction of osteoblast precursors to the resorption site. These differentiate into mature osteoblasts, which deposit new bone matrix in the resorption lacuna, until the hole is filled. Some osteoblasts become trapped in bone matrix and differentiate into osteocytes. These act as biomechanical sensors and produce several molecules that influence bone remodelling and phosphate metabolism. Bone formation is stimulated by Wnt proteins, which bind to and activate lipoprotein-related receptor protein 5 (LRP5), expressed on osteoblasts. This process is inhibited by SOST, which is produced by osteocytes (see Fig. 25.2). Initially, the newly formed bone matrix (osteoid) is uncalcified but subsequently becomes mineralised to form mature bone. Alkaline phosphatase (ALP), produced by osteoblasts, plays an important role in bone mineralisation by degrading pyrophosphate, an inhibitor of mineralisation. Bone remodelling is regulated by circulating hormones such as parathyroid hormone (PTH) and oestrogen, and locally produced factors such as cytokines (Box 25.2). Many systemic hormones exert effects on bone turnover by affecting local expression of RANK, RANKL, OPG, SOST and molecules in the Wnt/LRP5 pathway (Fig. 25.2, Box 25.2).

25.2 Regulators of bone remodelling

Factor	Bone resorption	Bone formation

Receptor activator of nuclear factor kappa B ligand (RANKL)	↑	↔
Osteoprotegerin (OPG)	↓	↔
Sclerostin (SOST)	↔	↓
Interleukin-1 (IL-1)	↑	↓
Tumour necrosis factor-α (TNF-α)	↑	↓
Thyroid hormone	↑	↑
Glucocorticoids	↑	↓↓
Oestrogen/testosterone	↓	↑
Mechanical loading	↓	↑

Joints

Bones are linked by joints. There are three main subtypes: fibrous, fibrocartilaginous and synovial (Box 25.3).

Fibrous and fibrocartilaginous joints

These comprise a simple bridge of fibrous or fibrocartilaginous tissue joining two bones together where there is little requirement for movement. The intervertebral disc is a special type of fibrocartilaginous joint in which an amorphous area, called the nucleus pulposus, lies in the centre of the fibrocartilaginous bridge. The nucleus has a high water content and acts as a cushion to improve the disc's shock-absorbing properties.

Synovial joints

Complex structures containing several cell types, these are found where a wide range of movement is needed (Fig. 25.3).

Articular cartilage

This avascular tissue covers the bone ends in synovial joints. Cartilage cells (chondrocytes) are responsible for synthesis and turnover of cartilage, which consists of a mesh of type II collagen fibrils that extend through a hydrated 'gel' of proteoglycan molecules. The most

25.3 Types of joint

Type	Range of movement	Examples
Fibrous	Minimal	Skull sutures
Fibrocartilaginous	Limited	Symphysis pubis Costochondral junctions Intervertebral discs Sacroiliac joints
Synovial	Large	Most limb joints Temporomandibular Costovertebral

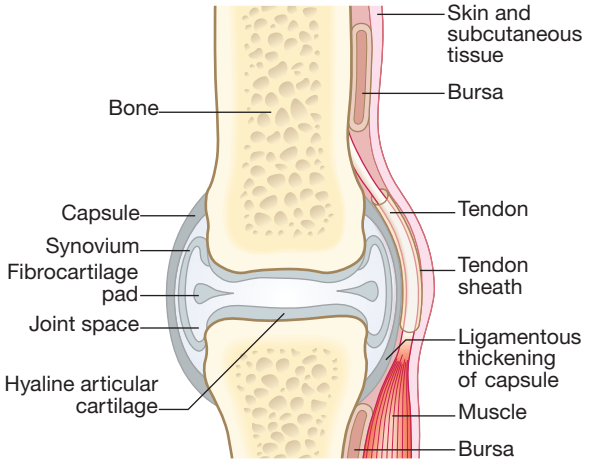

Fig. 25.3 Structure of a synovial joint.

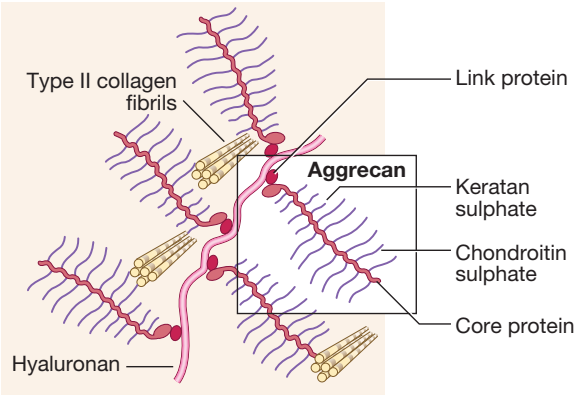

Fig. 25.4 Ultrastructure of articular cartilage.

important proteoglycan is aggrecan, which consists of a core protein to which several glycosaminoglycan (GAG) side-chains are attached (Fig. 25.4). The GAGs are polysaccharides that consist of long chains of disaccharide repeats comprising one normal sugar and an amino sugar. The most abundant GAGs in aggrecan are chondroitin sulphate and keratan sulphate. Hyaluronan is another important GAG that binds to aggrecan molecules to form very large complexes with a total molecular weight of more than 100 million. Aggrecan has a strong negative charge and avidly binds water molecules to assume a shape that occupies the maximum possible volume available. The expansive force of the hydrated aggrecan, combined with the restrictive strength of the collagen mesh, gives articular cartilage excellent shock-absorbing properties.

With ageing, the concentration of chondroitin sulphate decreases, whereas that of keratan sulphate increases, resulting in reduced water content and shock-absorbing properties. These changes differ from those found in osteoarthritis (p. 1081), where there is abnormal chondrocyte division, loss of proteoglycan from matrix and an increase in water content. Cartilage matrix is constantly turning over and in health there is a perfect balance between synthesis and degradation. Degradation of cartilage matrix is carried out by aggrecanases and matrix metalloproteinases, responsible for the breakdown of proteins and proteoglycans, and by glycosidases, responsible for the breakdown of GAGs. Pro-inflammatory cytokines, such as interleukin-1 (IL-1) and tumour necrosis factor (TNF), stimulate production of aggrecanase and metalloproteinases, which contribute to cartilage degradation in inflammatory arthritis.

Synovial fluid

The surfaces of articular cartilage are separated by a space filled with synovial fluid, a viscous liquid that lubricates the joint. It is an ultrafiltrate of plasma, into which synovial cells secrete hyaluronan and proteoglycans.

Intra-articular discs

Some joints contain fibrocartilaginous discs within the joint space that act as shock absorbers. The most clinically important are the menisci of the knee. These are avascular structures that remain viable by diffusion of oxygen and nutrients from the synovial fluid.

The synovial membrane, joint capsule and bursae

The bones of synovial joints are connected by the joint capsule, a fibrous structure richly supplied with blood vessels, nerves and lymphatics, which encases the joint. Ligaments are discrete, regional thickenings of the capsule that act to stabilise joints (see Fig. 25.3). The inner surface of the joint capsule is the synovial membrane, comprising an outer layer of blood vessels and loose connective tissue that is rich in type I collagen, and an inner layer 1–4 cells thick consisting of two main cell types. Type A synoviocytes are phagocytic cells derived from the monocyte/macrophage lineage and are responsible for removing particulate matter from the joint cavity; type B synoviocytes are fibroblast-like cells that secrete synovial fluid. Most inflammatory and degenerative joint diseases associate with thickening of the synovial membrane and infiltration by lymphocytes, polymorphs and macrophages.

Bursae are hollow sacs lined with synovium and contain a small amount of synovial fluid. They help tendons and muscles move smoothly in relation to bones and other articular structures.

Skeletal muscle

Skeletal muscles are responsible for body movements and respiration. Muscle consists of bundles of cells (myocytes) embedded in fine connective tissue containing nerves and blood vessels. Myocytes are large, elongated, multinucleated cells formed by fusion of mononuclear precursors (myoblasts) in early embryonic life. The nuclei lie peripherally and the centre of the cell contains actin and myosin molecules, which interdigitate with one another to form the myofibrils that are responsible for muscle contraction. The molecular mechanisms of skeletal muscle contraction are the same as for cardiac muscle (p. 531). Myocytes contain many mitochondria that provide the large amounts of adenosine triphosphate (ATP) necessary for muscle contraction, and are rich in the protein myoglobin, which acts as a reservoir for oxygen during contraction.

Individual myofibrils are organised into bundles (fasciculi) that are bound together by a thin layer of connective tissue (the perimysium). The surface of the muscle is surrounded by a thicker layer of connective tissue, the epimysium, which merges with the perimysium to form the muscle tendon. Tendons are tough,

fibrous structures that attach muscles to a point of insertion on the bone surface called the enthesis.

INVESTIGATION OF MUSCULOSKELETAL DISEASE

Clinical history and examination usually provide sufficient information for the diagnosis and management of most musculoskeletal diseases. Investigations are helpful in confirming the diagnosis, assessing disease activity and indicating prognosis.

Joint aspiration

Joint aspiration with examination of synovial fluid (SF) is pivotal in patients suspected of having septic arthritis, crystal arthritis or intra-articular bleeding. It should be done in all patients with acute monoarthritis, and samples sent for microbiology and clinical chemistry.

It is possible to obtain SF by aspiration from most peripheral joints, and only a small volume is required for diagnostic purposes. Normal SF is present in small volume, and is clear and either colourless or pale yellow with a high viscosity. It contains few cells. With joint inflammation, the volume increases, the cell count and the proportion of neutrophils rise (causing turbidity), and the viscosity reduces (due to enzymatic degradation of hyaluronan and aggrecan). Turbid fluid with a high neutrophil count occurs in sepsis, crystal arthritis and reactive arthritis. High concentrations of urate crystals or cholesterol can make SF appear white. Non-uniform blood-staining usually reflects needle trauma to the synovium. Uniform blood-staining is most commonly due to a bleeding diathesis, trauma or pigmented villonodular synovitis (p. 1134), but can occur in severe inflammatory synovitis. A lipid layer floating above blood-stained fluid is diagnostic of intra-articular fracture and is caused by release of bone marrow fat into the joint.

Crystals can be identified by compensated polarised light microscopy of fresh SF (to avoid crystal dissolution and post-aspiration crystallisation). Urate crystals are long and needle-shaped, and show a strong light intensity and negative birefringence (Fig. 25.5A). Calcium pyrophosphate crystals are smaller, rhomboid in shape and usually less numerous than urate, and have weak intensity and positive birefringence (Fig. 25.5B).

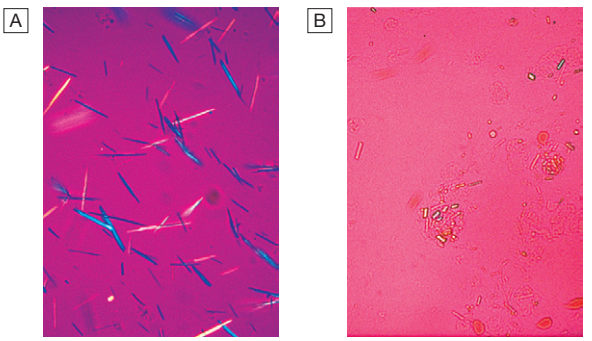

Fig. 25.5 Compensated polarised light microscopy of synovial fluids (× 400). A Monosodium urate crystals showing bright negative birefringence under polarised light and needle-shaped morphology. B Calcium pyrophosphate crystals showing weak positive birefringence under polarised light and are few in number. They are more difficult to detect than urate crystals.

Imaging

Plain radiography

Radiographs show anatomical changes that are of value in the differential diagnosis of many bone and joint diseases (Box 25.4). The bones and joints to be X-rayed are usually selected on the basis of symptoms or patterns of involvement identified at clinical assessment.

Radiographs are of diagnostic value in osteoarthritis (OA), where they demonstrate joint space narrowing that tends to be focal rather than widespread, as in inflammatory arthritis. Other features of OA detected on X-ray include osteophytes, subchondral sclerosis, bone cysts and calcified loose bodies within the synovium (see Fig. 25.20, p. 1084). Radiographs may show erosions and sclerosis of the sacroiliac joints and syndesmophytes in the spine in patients with seronegative spondyloarthritis (see Fig. 25.36, p. 1106). In peripheral joints, so-called proliferative erosions, associated with new bone formation and a periosteal reaction, may be observed. In tophaceous gout, well-defined punched-out erosions may occur (see Fig. 25.26, p. 1089). Calcification of cartilage, tendons and soft tissues or muscle may occur in chondrocalcinosis (see Fig. 25.27, p. 1090), calcific periarthritis and connective tissue diseases.

Radiographs are of limited value in the diagnosis of rheumatoid arthritis (RA) since features such as erosions, joint space narrowing and periarticular osteoporosis may only be detectable after several months or even years. The main indication for radiographs in RA is in the assessment of advanced disease, when structural damage of the joints is suspected and arthroplasty is being considered. Early evidence of articular damage in RA is more usually obtained using magnetic resonance imaging or ultrasonography.

25.4 X-ray abnormalities in selected rheumatic diseases

Rheumatoid arthritis	
• Periarticular osteoporosis • Bone erosions	• Joint space narrowing
Osteoporosis	
• Osteopenia • Vertebral fractures	• Non-vertebral fractures
Paget's disease	
• Bone expansion • Abnormal trabecular pattern • Osteolysis	• Osteosclerosis • Pseudofractures
Spondyloarthritis	
• Sacroiliitis • Syndesmophytes	• Ligament calcification • Squaring of vertebral bodies
Osteoarthritis	
• Joint space narrowing • Osteophytes • Subchondral sclerosis	• Peaking of tibial spines • Subchondral cysts

Radionuclide bone scan

This is useful in patients suspected of having metastatic bone disease and Paget's disease. It involves gamma-camera imaging following an intravenous injection of ^{99m}Tc-bisphosphonate. Early post-injection images reflect vascularity and can show increased perfusion of inflamed synovium, Pagetic bone, or primary or secondary bone tumours. Delayed images taken a few hours later reflect bone remodelling as the bisphosphonate localises to sites of active bone turnover. Scintigraphy has a high sensitivity for detecting important bone and joint pathology that is not apparent on plain X-rays (Box 25.5). Single photon emission computed tomography (SPECT) combines radionuclide imaging with computed tomography. It can provide accurate anatomical localisation of abnormal tracer uptake within the bone and is of particular value in the assessment of patients with chronic low back pain of unknown cause.

25.5 Conditions detected by isotope bone scanning

- Paget's disease of bone
- Bone metastases
- Stress fractures
- Reflex sympathetic dystrophy (algodystrophy, p. 1130)
- Hypertrophic pulmonary osteoarthropathy (p. 1132)

Magnetic resonance imaging

Magnetic resonance imaging (MRI) gives detailed information on anatomy, allowing three-dimensional visualisation of bone and soft tissues that cannot be adequately assessed by plain X-rays. The technique is valuable in the assessment and diagnosis of many musculoskeletal diseases (Box 25.6). T1-weighted sequences are useful for defining anatomy, whereas T2-weighted sequences are useful for assessing tissue water content, which is often increased in synovitis and other inflammatory disorders (Fig. 25.6). Contrast agents, such as gadolinium, can be administered to increase sensitivity in detecting erosions and synovitis.

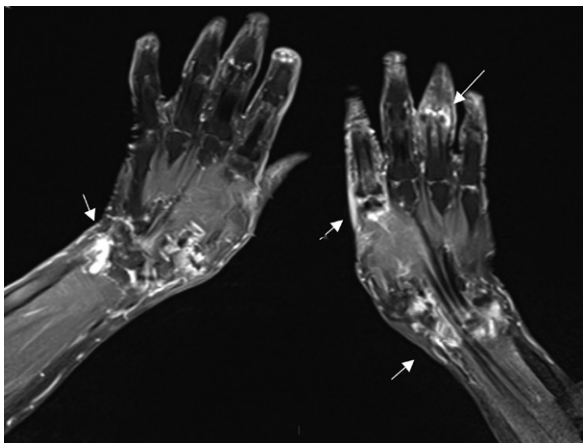

Fig. 25.6 Magnetic resonance image showing synovitis. Coronal fat-saturated post-contrast T1-weighted image shows extensive enhancement consistent with synovitis (white areas, arrowed) in both wrists and at the second metacarpophalangeal joint and proximal interphalangeal joints of the right hand.

25.6 Conditions detected by magnetic resonance imaging

- Osteonecrosis
- Intervertebral disc disease
- Nerve root entrapment
- Spinal cord compression
- Spinal stenosis
- Sepsis
- Reflex sympathetic dystrophy syndrome
- Malignancy
- Fractures
- Meniscal disease
- Synovitis
- Sacroiliitis and enthesitis
- Inflammatory myositis
- Rotator cuff tears, bursitis and tenosynovitis

Ultrasonography

Ultrasonography is a useful investigation for confirmation of small joint synovitis and erosion, for anatomical confirmation of periarticular lesions, and for guided aspiration and injection of joints and bursae. Ultrasound is more sensitive than clinical examination for the detection of early synovitis and is used increasingly in the diagnosis and assessment of patients with suspected inflammatory arthritis. In addition to locating synovial thickening and effusions, ultrasound can detect increased blood flow within synovium using power Doppler imaging, an option that is available on most modern ultrasound machines (Fig. 25.7).

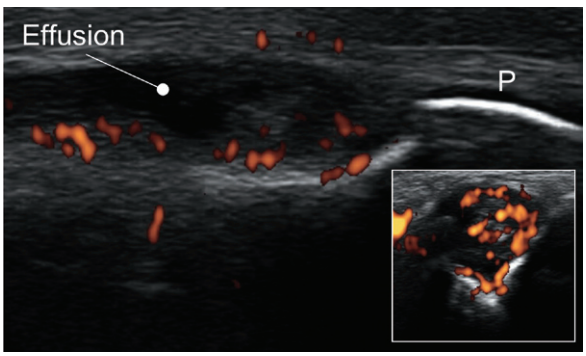

Fig. 25.7 Ultrasound image showing synovitis. Lateral image of a metacarpophalangeal joint in inflammatory arthritis. The periosteum (P) of the phalanx shows as a white line. The dark, hypo-echoic area indicates an effusion. The coloured areas demonstrated by power Doppler indicate increased vascularity. The inset shows a transverse image of the same joint.

Computed tomography

Computed tomography (CT) can be used in the assessment of patients with bone and joint disease but has largely been superseded by MRI, which gives better visualisation of soft tissue structures. CT may be used when MRI is contraindicated, or for evaluation of articular regions in which an adjacent joint replacement creates image artefacts on MRI.

Bone mineral density

Bone mineral density (BMD) measurements play a key role in the diagnosis and management of osteoporosis. The technique of choice is dual energy X-ray absorptiometry (DEXA), which is usually performed at the lumbar spine and hip, and provides images of the region studied. This technique works on the principle that calcium in

bone attenuates passage of X-ray beams through the tissue in proportion to the amount of mineral present. The greater the amount of bone mineral present, the higher the BMD value. Most DEXA scanners give a BMD readout expressed as grams of hydroxyapatite/cm^2, and as a T-score and Z-score value. The T-score is a measure of the number of standard deviations by which the patient's BMD value differs from that in a young healthy control, whereas the BMD Z-score is a measure of the number of standard deviations by which the BMD deviates from that of age-matched controls (Fig. 25.8). Osteoporosis is defined by a T-score value of 2.5 or below (shaded red in the figure), whereas osteopenia is diagnosed when the T-score lies between –1.0 and –2.5 (shaded pink). Many healthy people, especially above the age of 50, have BMD values in the osteopenic range. Values of BMD above –1.0 and below +2.5 are considered normal, whereas values above +2.5 can be found in osteosclerotic diseases and OA. Results need to be interpreted carefully. It is possible for BMD values to lie in the normal or osteopenic range in patients who have osteoporosis, due to coexisting conditions such as aortic calcification, vertebral compression fractures, degenerative disc disease and OA. These can sometimes be suspected on the basis of antero-posterior or lateral DEXA images, but abnormal appearances should be confirmed by X-ray or other imaging as appropriate.

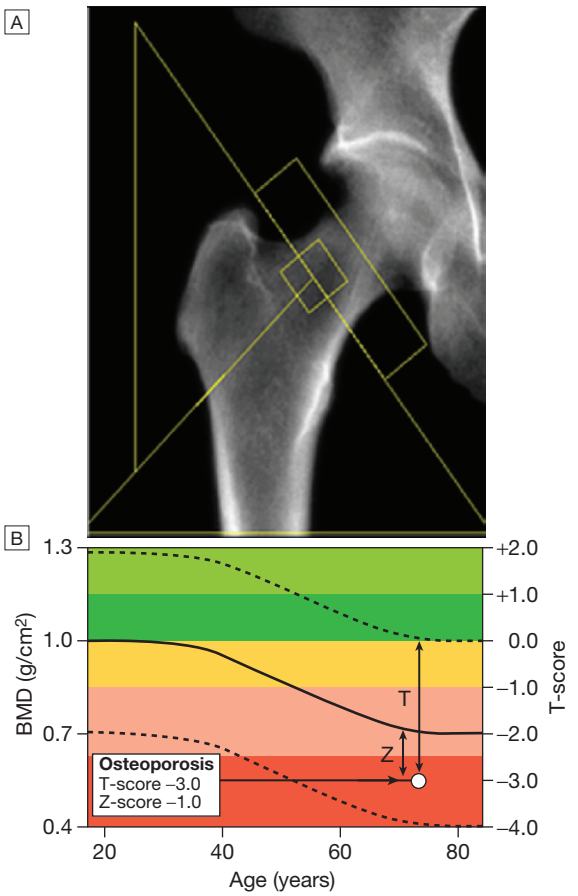

Fig. 25.8 Typical output from a dual energy X-ray absorptiometry (DEXA) scanner. A DEXA scan of the hip. B Bone mineral density (BMD) values plotted in g/cm^2 (left axis) and as the T-score values (right axis). The solid line represents the population average plotted against age, and the interrupted lines are ± 2 standard deviations from the average. The patient shown, aged 72, has an osteoporotic T-score of –3.0 but a Z-score of –1.0, which is within the 'normal range' for that age, reflecting the fact that bone is lost with age.

Blood tests

Haematology

Abnormalities in the full blood count (FBC) often occur in inflammatory rheumatic diseases but changes are usually non-specific. Examples include neutrophilia in vasculitis, acute gout and sepsis; neutropenia in lupus; and a raised erythrocyte sedimentation rate (ESR) in many inflammatory diseases. Reduced levels of haemoglobin are a common and important finding in a range of rheumatological disorders. Many disease-modifying antirheumatic drugs (DMARDs) cause marrow toxicity and require regular monitoring of the FBC.

Biochemistry

Routine biochemistry is useful for assessing metabolic bone disease, muscle diseases and gout. Several bone diseases, including Paget's disease, renal bone disease and osteomalacia, give a characteristic pattern that can be helpful diagnostically (Box 25.7). Serum levels of uric acid are usually raised in gout but a normal level does not exclude it, especially during an acute attack, when urate levels temporarily fall. Equally, an elevated serum uric acid does not confirm the diagnosis, since most hyperuricaemic people never develop gout. Levels of C-reactive protein (CRP) are a useful marker of infection and inflammation, and are more specific than the ESR. An exception is in connective tissue diseases such as systemic lupus erythematosus (SLE) and systemic sclerosis, where CRP may be normal but ESR raised in active

25.7 Biochemical abnormalities in bone disease

	Serum calcium	Serum phosphate	Serum ALP	Serum PTH	Serum 25(OH)D
Osteoporosis	N	N	N	N	N or ↓
Paget's disease	N	N	↑↑	N or ↑	N
Renal osteodystrophy	↓	↑↑	↑	↑↑	N
Vitamin D-deficient osteomalacia	N or ↓	N or ↓	↑↑	↑↑	↓
Hypophosphataemic rickets	N	↓↓	↑	N or ↑	N

(ALP = alkaline phosphatase; N = normal; PTH = parathyroid hormone; single arrow = increased or decreased; double arrow = greatly increased or decreased)

25.8 Causes of an elevated serum creatine kinase

- Inflammatory myositis ± vasculitis
- Muscular dystrophy
- Motor neuron disease
- Alcohol, drugs (N.B. statins)
- Trauma, strenuous exercise, long lie after a fall
- Myocardial infarction*
- Hypothyroidism, metabolic myopathy
- Viral myositis

*The CK-MB cardiac-specific isoform is disproportionately elevated compared with total CK.

inflammatory disease. Accordingly, an elevated CRP in a patient with lupus or scleroderma suggests an intercurrent illness such as sepsis rather than active disease. More detail on the interpretation of CRP and ESR changes is given on page 84. Serum creatine kinase (CK) levels are useful in the diagnosis of myopathy or myositis, but specificity and sensitivity are poor and raised levels may occur in some conditions (Box 25.8). Biochemical monitoring of renal and hepatic function is important in ongoing care of patients on DMARD therapy.

Autoantibodies

Autoantibody tests are widely used in the diagnosis of rheumatic diseases. False-positive results are common but high antibody titres or concentrations are generally of greater clinical significance. Whatever test is used, the results must be interpreted in light of the clinical picture and the different detection and assay systems used in different hospitals.

Rheumatoid factor

Rheumatoid factor (RF) is an antibody directed against the Fc fragment of human immunoglobulin. In routine clinical practice, IgM rheumatoid factor is usually measured, although different methodologies allow measurement of IgG and IgA RFs too. Positive RF occurs in a wide variety of diseases and some normal adults (Box 25.9), particularly with increasing age. Although the specificity is poor, about 70% of patients with RA test positive. High RF titres are associated with more severe disease and extra-articular disease.

25.9 Conditions associated with a positive rheumatoid factor

Disease	Frequency (%)
Rheumatoid arthritis with nodules and extra-articular manifestations	100
Rheumatoid arthritis (overall)	70
Sjögren's syndrome	90
Mixed essential cryoglobulinaemia	90
Primary biliary cirrhosis	50
Infective endocarditis	40
Systemic lupus erythematosus	30
Tuberculosis	15
Age > 65 yrs	20

Normal healthy people can be positive for rheumatoid factor.

Anti-citrullinated peptide antibodies

Anti-citrullinated peptide antibodies (ACPA) recognise peptides in which the amino acid arginine has been converted to citrulline by peptidylarginine deiminase, an enzyme abundant in inflamed synovium and in a variety of mucosal structures. ACPA have similar sensitivity to RF for RA (70%) but much higher specificity (> 95%), and are increasingly being used in preference to RF in the diagnosis of RA. ACPA are associated with more severe disease progression, and can be detected in asymptomatic patients several years before the development of RA. Their pathological role is still debated but it is likely that they amplify the synovial response at an inflammatory stimulus.

Antinuclear antibodies

Antinuclear antibodies (ANA) are directed against one or more components of the cell nucleus, including nucleic acids themselves, and the proteins concerned with processing of DNA or RNA. They occur in many inflammatory rheumatic diseases but are also found at low titre in normal individuals and in other diseases (Box 25.10). High titres of ANA are of greater diagnostic significance but circulating levels are not associated with disease severity or activity. The most common indication for ANA testing is in patients suspected of having SLE or connective tissue diseases. ANA has high sensitivity for SLE (virtually 100%) but low specificity (10–40%). A negative ANA virtually excludes SLE but a positive result does not confirm it.

Anti-DNA antibodies bind to double-stranded DNA and are highly specific for SLE (95%) but sensitivity is poor (30%). They can be useful in disease monitoring since very high titres are associated with more severe disease, including renal or central nervous system (CNS) involvement, and an increase in antibody titre may precede relapse.

Antibodies to extractable nuclear antigens (ENA) act as markers for certain connective tissue diseases and some complications of SLE, but sensitivity and specificity are poor (Box 25.11). For example, antibodies to Sm are found in a minority of patients with SLE but are associated with renal involvement. Antibodies to Ro occur in SLE and in Sjögren's syndrome (in association with anti-La antibodies), and are associated with a

25.10 Conditions associated with a positive antinuclear antibody

Condition	Approximate frequency
Diseases where ANA is useful in diagnosis	
Systemic lupus erythematosus	100%
Systemic sclerosis	60–80%
Sjögren's syndrome	40–70%
Dermatomyositis or polymyositis	30–80%
Mixed connective tissue disease	100%
Autoimmune hepatitis	100%
Diseases where ANA is not useful in diagnosis	
Rheumatoid arthritis	30–50%
Autoimmune thyroid disease	30–50%
Malignancy	Varies widely
Infectious diseases	Varies widely

N.B. 5% of healthy individuals have an ANA titre > 1:80.

25.11 Conditions associated with antibodies to extractable nuclear antigens

Antibody (target/other name)	Disease association
Anti-centromere antibody	CREST variant of systemic sclerosis (sensitivity 60%, specificity 98%) Occasionally found in primary Raynaud's syndrome
Anti-histone antibody	Drug-induced lupus (80%)
Anti-Jo-1 (anti-histidyl-tRNA synthetase)	Polymyositis, dermatomyositis or polymyositis–systemic sclerosis overlap (20–30%). Particularly associated with interstitial lung disease
Anti-La antibody (anti-SS-B)	Sjögren's syndrome (60%) SLE (20–60%)
Anti-ribonucleoprotein antibody (anti-RNP)	Mixed connective tissue disease (100%) SLE (25–50%), usually in conjunction with anti-Sm antibodies
Anti-Ro antibody (anti-SS-A)	SLE (35–60%): associated with photosensitivity, thrombocytopenia and subacute cutaneous lupus Maternal anti-Ro antibodies associated with neonatal lupus and congenital heart block Sjögren's syndrome (40–80%)
Anti-RNA polymerase	Diffuse systemic sclerosis (15%)
Anti Sm (anti-Smith antibody)	SLE (15–30%); associated with renal disease
Anti-Scl-70 (anti-topoisomerase I antibody)	Diffuse systemic sclerosis (15%); associated with more severe organ involvement, including pulmonary fibrosis

(CREST = calcinosis, Raynaud's, oesophageal dysmotility, sclerodactyly, telangiectasia)

photosensitive rash and congenital heart block. Antibodies to ribonuclear protein (RNP) occur in SLE and also in mixed connective tissue disease, where features of lupus, myositis and systemic sclerosis coexist. Anti-topoisomerase 1 (also termed Scl-70) antibodies occur in diffuse systemic sclerosis, whereas anti-centromere antibodies are more specific for limited systemic sclerosis.

Antiphospholipid antibodies

Antiphospholipid antibodies bind to a number of phospholipid binding proteins, but the most clinically relevant are those that target beta$_2$-glycoprotein 1 (β_2GP1). They may be detected in SLE and other connective tissue diseases or can be present in isolation or in the antiphospholipid antibody syndrome (p. 1055).

Antineutrophil cytoplasmic antibodies

Antineutrophil cytoplasmic antibodies (ANCA) are IgG antibodies directed against the cytoplasmic constituents of granulocytes and are useful in the diagnosis and monitoring of systemic vasculitis. Two common patterns are described by immunofluorescence: cytoplasmic fluorescence (c-ANCA), which is caused by antibodies to proteinase-3 (PR3); and perinuclear fluorescence (p-ANCA), which is caused by antibodies to myeloperoxidase (MPO) and other proteins such as lactoferrin and elastase. These antibodies are not specific for vasculitis and positive results may be found in autoimmune liver disease, malignancy, infection (bacterial and human immunodeficiency virus, HIV), inflammatory bowel disease, rheumatoid arthritis, SLE and pulmonary fibrosis.

Tissue biopsy

Tissue biopsy is useful in confirming the diagnosis in certain musculoskeletal diseases.

Synovial biopsy can be useful in selected patients with chronic inflammatory monoarthritis or tenosynovitis to rule out chronic infectious causes, especially mycobacterial infections. Characteristic changes on MRI can obviate the need for biopsy in many cases of suspected tumour. Whatever the indication, synovial biopsy can be obtained arthroscopically (by conventional means or via use of needle arthroscope) or using ultrasound guidance under local anaesthetic.

Temporal artery biopsy can be of value in patients suspected of having temporal arteritis, especially when the presentation is atypical, but a negative result does not exclude the diagnosis. Biopsies of affected tissues, such as skin, lung, nasopharynx, gut, kidney and muscle, can be of value in the diagnosis of systemic vasculitis and granulomatosis with polyangiitis (also known as Wegener's granulomatosis).

Muscle biopsy plays an important role in the investigation of myopathy and inflammatory myositis. It is usually taken from the quadriceps or deltoid through a small skin incision under local anaesthetic. Since myositis can be patchy in nature, MRI is sometimes used to localise the best site for biopsy. Immunohistochemical staining, together with plain histology, gives information on primary and secondary muscle and neuromuscular disease. Repeat biopsies are sometimes used to monitor the response to treatment.

Bone biopsy is occasionally required where non-invasive tests give inconclusive results and in the diagnosis of infiltrative disorders, chronic infections and malignancy. If a systemic disorder of mineralisation, such as osteomalacia, is suspected, the biopsy can be taken from the iliac crest using a large-diameter (8-mm) trephine needle under local anaesthetic, and processed without demineralisation. For focal lesions, the biopsy should be taken under X-ray guidance or at open surgery, from an affected site.

Electromyography

Electromyography (p. 1152) is of value in the investigation of suspected myopathy and inflammatory myositis, when it shows the diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganised outline
- repetitive bouts of high-voltage oscillations on needle contact with diseased muscle.

PRESENTING PROBLEMS IN MUSCULOSKELETAL DISEASE

Acute monoarthritis

This term is used to describe sudden pain and swelling in a single joint. The most important causes are crystal arthritis, sepsis and reactive arthritis. Other potential causes are shown in Box 25.12.

Clinical assessment

The clinical history, pattern of joint involvement, speed of onset, and age and gender of the patient all give clues to the most likely diagnosis. Reactive arthritis (p. 1107) is the most common cause in young men, gout in middle-aged men and pseudogout in older women. Gout classically affects the first metatarsophalangeal (MTP) joint, whereas the wrist and shoulder are typical sites for pseudogout. A very rapid onset (6–12 hours) is suggestive of gout or pseudogout; joint sepsis develops more slowly and continues to progress until treated. Haemarthrosis typically causes a large effusion, in the absence of periarticular swelling or skin change, in a patient who has suffered an injury. Pigmented villonodular synovitis (p. 1134) also presents with synovial swelling and a large effusion, although the onset is gradual. A previous diarrhoeal illness or recent sexual contact suggests reactive arthritis, whereas intercurrent illness, dehydration or surgery may act as a trigger for crystal-induced arthritis. Rheumatoid arthritis seldom presents with monoarthritis and a sudden increase in pain and swelling involving a single joint in a patient with pre-existing RA is strongly suggestive of sepsis. Osteoarthritis can present with pain and stiffness affecting a single joint, but the onset is gradual and there is seldom evidence of significant joint swelling.

Investigations

Aspiration of the affected joint is mandatory. The fluid should be sent for culture and Gram stain to seek the presence of organisms, and should be checked by microscopy for crystals. Blood cultures should also be taken in patients suspected of having septic arthritis. CRP levels and ESR are raised in sepsis, crystal arthritis and reactive arthritis, and this can be useful in assessing the response to treatment. Serum uric acid measurements may be raised in gout but a normal level does not exclude the diagnosis.

Management

If there is any suspicion of sepsis, intravenous antibiotics (Box 25.52, p. 1095) should be given promptly, pending the results of cultures. Otherwise, management should be directed towards the underlying cause.

25.12 Causes of acute monoarthritis

Common

- Septic arthritis
- Gout
- Pseudogout
- Reactive arthritis
- Trauma
- Haemarthrosis
- Seronegative spondyloarthritis
  - Psoriatic arthritis
  - Ankylosing spondylitis
  - Enteropathic arthritis

Less common

- Erythema nodosum
- Rheumatoid arthritis
- Juvenile idiopathic arthritis
- Pigmented villonodular synovitis
- Foreign body reaction
- Other infection
  - Gonococcal
  - Tuberculosis
- Leukaemia*
- Osteomyelitis*

*In children, both leukaemia and osteomyelitis may present with monoarthritis.

Polyarthritis

This term is used to describe pain and swelling affecting five or more joints or joint groups. The possible causes are listed in Box 25.13.

25.13 Causes of polyarthritis

Cause	Characteristics
Common	
Rheumatoid arthritis	Symmetrical, small and large joints, upper and lower limbs
Viral arthritis	Symmetrical, small joints; may be associated with rash and prodromal illness; self-limiting
Osteoarthritis	Symmetrical, targets PIP, DIP and first CMC joints in hands, knees, hips, back and neck; associated with Heberden's and Bouchard's nodes
Psoriatic arthritis	Asymmetrical, targets PIP and DIP joints of hands and feet (sausage appearance on examination), nail pitting, large joints also affected
Ankylosing spondylitis and enteropathic arthritis	Tends to affect large joints, lower more than upper limbs, possible history of inflammatory back pain
SLE	Symmetrical, typically affecting small joints, clinical evidence of synovitis unusual
Less common	
Juvenile idiopathic arthritis	Symmetrical, small and large joints, upper and lower limbs
Chronic gout	Affects distal more than proximal joints, history of acute attacks
Chronic sarcoidosis (p. 709)	Symmetrical, small and large joints
Polymyalgia rheumatica	Symmetrical, small and large joints
Rare	
Systemic sclerosis and polymyositis	Small and large joints
Hypertrophic osteoarthropathy	Small joints, clubbing
Haemochromatosis (p. 972)	Small and large joints
Acromegaly (p. 792)	Mainly large joints and spine

(CMC = carpometacarpal; DIP = distal interphalangeal; PIP = proximal interphalangeal)

Clinical assessment

The hallmarks of inflammatory arthritis are early morning stiffness and worsening of symptoms with inactivity, along with synovial swelling and tenderness on examination. Clinical features in other systems can be helpful in determining the underlying cause (Box 25.14). The most important diagnosis to consider is rheumatoid arthritis, which is characterised by symmetrical involvement of the small joints of the hands and feet, often in association with other joints. Viral arthritis should also be considered. This presents with an acute symmetrical inflammatory polyarthritis affecting small and large joints of upper and lower limbs, often with a rash.

The pattern of involvement can be helpful in reaching a diagnosis (Fig. 25.9). Asymmetry, lower limb predominance and greater involvement of large joints are characteristic of seronegative spondyloarthritis. Other extra-articular features may also be present, giving a clue to the diagnosis. In psoriatic arthritis, the small joints of the hand and feet are often affected, but with involvement of the proximal and distal interphalangeal (PIP and DIP) joints, as opposed to the metacarpophalangeal (MCP) and PIP joints in RA. The pattern of involvement also tends to be asymmetrical in psoriatic arthritis, and other clues such as nail pitting and a rash may be present. SLE can be associated with polyarthritis but more usually causes polyarthralgia and tenosynovitis (p. 1110).

Investigations

Blood samples should be taken for routine haematology, biochemistry, ESR, CRP, viral serology and an immunological screen, including ANA, RF and ACPA. Ultrasound examination or MRI may be required to confirm the presence of synovitis if this is not obvious clinically.

25.14 Extra-articular features of inflammatory arthritis

Clinical feature	Disease association
Skin, nails and mucous membranes	
Psoriasis, nail pitting and dystrophy	Psoriatic arthritis
Raynaud's phenomenon	SLE, systemic sclerosis
Photosensitivity	SLE
Livedo reticularis	SLE
Splinter haemorrhages, nail-fold infarcts	Vasculitis
Oral ulcers	SLE, reactive arthritis, Behçet's syndrome
Large nodules (mainly extensor surfaces)	RA, gout
Clubbing	Enteropathic arthritis, metastatic lung cancer, endocarditis
Eyes	
Uveitis	Seronegative spondyloarthritis
Conjunctivitis	Reactive arthritis
Episcleritis, scleritis	RA, vasculitis
Heart, lungs	
Pleuro-pericarditis	SLE, RA
Fibrosing alveolitis	RA, SLE, other connective tissue disease
Abdominal organs	
Hepatosplenomegaly	RA, SLE
Haematuria, proteinuria	SLE, vasculitis, systemic sclerosis
Urethritis	Reactive arthritis
Fever, lymphadenopathy	Infection, systemic juvenile idiopathic arthritis

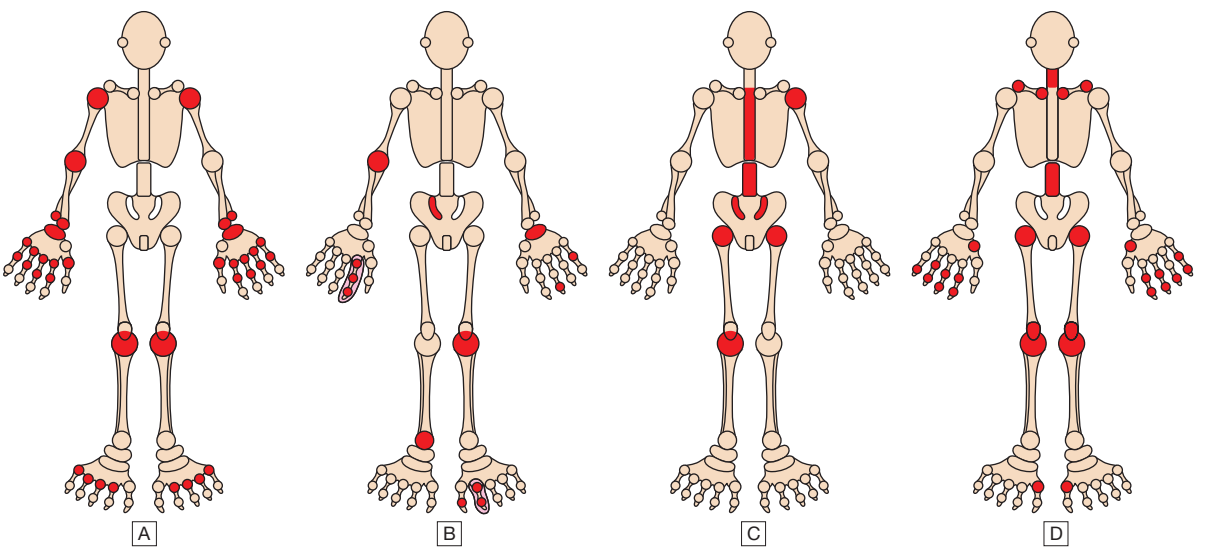

Fig. 25.9 Patterns of joint involvement in different forms of polyarthritis. A Rheumatoid arthritis typically targets the metacarpophalangeal and proximal interphalangeal joints of the hands and metatarsophalangeal joints of the feet, as well as other joints, in a symmetrical pattern. B Psoriatic arthritis targets proximal and distal interphalangeal joints of the hands and larger joints in an asymmetrical pattern. Sacroiliitis (often asymmetrical) may occur. C Ankylosing spondylitis targets the spine, sacroiliac joints and large peripheral joints in an asymmetrical pattern. D Osteoarthritis targets the proximal and distal interphalangeal joints of the hands, first carpometacarpal joint at the base of the thumb, knees, hips, lumbar and cervical spine.

Management

Management should be directed at the underlying condition, but treatment with non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics may be required for symptom control until a diagnosis has been made.

Fracture

Fractures are a common presenting symptom of osteoporosis, but they also occur in other bone diseases, in osteopenia and in some patients with normal bone.

Clinical assessment

The presentation is with localised bone pain, which is worsened by movement of the affected limb or region. There is usually a history of trauma but spontaneous fractures can occur in the absence of trauma in those with severe osteoporosis. Fractures can be divided into several subtypes, based on the precipitating event and presence or absence of an underlying disease (Box 25.15). The main differential diagnosis is soft tissue injury, but fracture should be suspected when there is marked pain and swelling, abnormal movement of the affected limb, crepitus or deformity. Femoral neck fractures typically produce a shortened, externally rotated leg that is painful to move.

Investigations

Radiographs of the affected site should be taken in at least two planes and examined for discontinuity of the cortical outline (Box 25.16). In addition to demonstrating the fracture, X-rays may also show evidence of an underlying disorder, such as osteoporosis, Paget's disease or osteomalacia. If the X-ray fails to show evidence of a fracture but clinical suspicion remains high, MRI should be performed, since this can demonstrate fractures that are radiographically occult. Patients who are over the age of 50 and present with fragility fractures should be screened for the presence of osteoporosis by DEXA.

Management

Management of fracture in the acute stage requires adequate pain relief, with opiates if necessary, reduction of the fracture to restore normal anatomy, and immobilisation of the affected limb to promote healing. This can be achieved either by the use of an external cast or splint or by internal fixation. Femoral neck fractures present a special management problem since non-union and avascular necrosis are common. This is especially true with intracapsular hip fractures, which should be treated by joint replacement surgery. Following the fracture, rehabilitation is required with physiotherapy and a supervised exercise programme (this is especially important in older patients to prevent muscle-wasting and loss of mobility). Elderly patients with hip fracture also benefit from nutritional supplementation. Patients with high-energy and fatigue fractures generally require no further investigation or treatment once the fracture has healed. If the DEXA examination or other investigation shows evidence of osteoporosis or other metabolic bone disease, this should be treated appropriately (p. 172).

25.15 Characteristics of different fracture types

Fracture type	Precipitation factor	Disease
Fragility fracture	Fall from standing height or less	Osteoporosis Osteopenia
Vertebral fracture	Bending, lifting, falling	Osteoporosis
Stress fracture	Running, excessive training	Normal
High-energy fracture	Major trauma	Normal
Pathological fracture	Spontaneous, minimal trauma	Malignancy Paget's disease Osteomalacia

25.16 How to investigate a suspected fracture

- Order X-rays in two projections at right angles to one another
- Include the whole bone and the joints at either end (this may reveal an additional unsuspected fracture)
- Check for evidence of displacement
- Check for a break in the cortex
- In suspected vertebral fracture, check for depression of the end plate
- If clinical suspicion is high but no fracture is seen, request MRI

Generalised musculoskeletal pain

Clinical assessment

Clinical history and examination can often indicate the underlying cause (Box 25.17). Relentlessly progressive pain occurring in association with weight loss suggests malignant disease with bone metastases. Generalised bone pain may also occur in Paget's disease if the disease is widespread, but Pagetic pain is usually more focal and localised to the site of involvement (p. 1128). Widespread pain can occur in OA but this also tends to be localised to sites of involvement, such as the lumbar spine, hips, knees and hands. Signs of OA may be apparent on clinical examination. Osteomalacia (p. 1125) can cause generalised bone pain that is associated with bone tenderness and limb girdle weakness. Fibromyalgia can present with generalised pain particularly affecting the trunk, back and neck. Accompanying features include fatigue, poor concentration and focal areas of hyperalgesia. Another potential cause is joint hypermobility, the features of which should be apparent on clinical examination (p. 1134).

25.17 Causes of generalised pain

- Metastatic bone disease
- Fibromyalgia (p. 1092)
- Joint hypermobility
- Osteomalacia (p. 1125)
- Osteoarthritis
- Paget's disease
- Polymyalgia rheumatica (p. 1117)
- Myositis (p. 1114)

Investigations

Radionuclide bone scanning is of value in patients suspected of having bone metastases and Paget's disease, along with further imaging as appropriate. Myeloma (p. 1046) should be excluded by plasma and urinary protein electrophoresis. If these results are positive, a radiological skeletal survey should be performed, since the isotope bone scan may be normal in myeloma. Routine biochemistry, vitamin D levels and PTH measurement should be performed if osteomalacia is suspected. In Paget's disease, ALP may be elevated but can be normal in localised disease. Laboratory investigations are normal in patients with fibromyalgia and benign hypermobility.

Management

Management should be directed towards the underlying cause. Chronic pain of unknown cause and that associated with fibromyalgia responds poorly to analgesics and NSAID, but may respond partially to antineuropathic agents such as amitriptyline, duloxetine, gabapentin and pregabalin.

Back pain

Back pain is a common symptom that affects 60–80% of people at some time in their lives. Although the prevalence has not increased, reported disability from back pain has risen significantly in the last 30 years. In Western countries, back pain is the most common cause of sickness-related work absence. In the UK, 7% of adults consult their GP each year with back pain. The most important causes are summarised in Box 25.18.

25.18 Causes of low back pain

- Mechanical back pain
- Prolapsed intervertebral disc
- Osteoarthritis
- Vertebral fracture (p. 1071)
- Spinal stenosis
- Paget's disease
- Spondylolysis (p. 1133)
- Bone metastases
- Spondylolisthesis (p. 1133)
- Arachnoiditis
- Scheuermann's disease (p. 1130)

Clinical assessment

The main purpose of clinical assessment is to differentiate the self-limiting disorder of acute mechanical back pain from serious spinal pathology, as summarised in Figure 25.10. Mechanical back pain is the most common cause of acute back pain in people aged 20–55. This accounts for more than 90% of episodes, and is usually acute and associated with lifting or bending. It is exacerbated by activity and is generally relieved by rest (Box 25.19). It is usually confined to the lumbar–sacral region, buttock or thigh, is asymmetrical, and does not radiate beyond the knee (which would imply nerve root irritation). On examination, there may be asymmetric local paraspinal muscle spasm and tenderness, and painful restriction of some but not all movements. Low back pain is more common in manual workers, particularly those in occupations that involve heavy lifting and twisting. The prognosis is generally good. After 2 days,

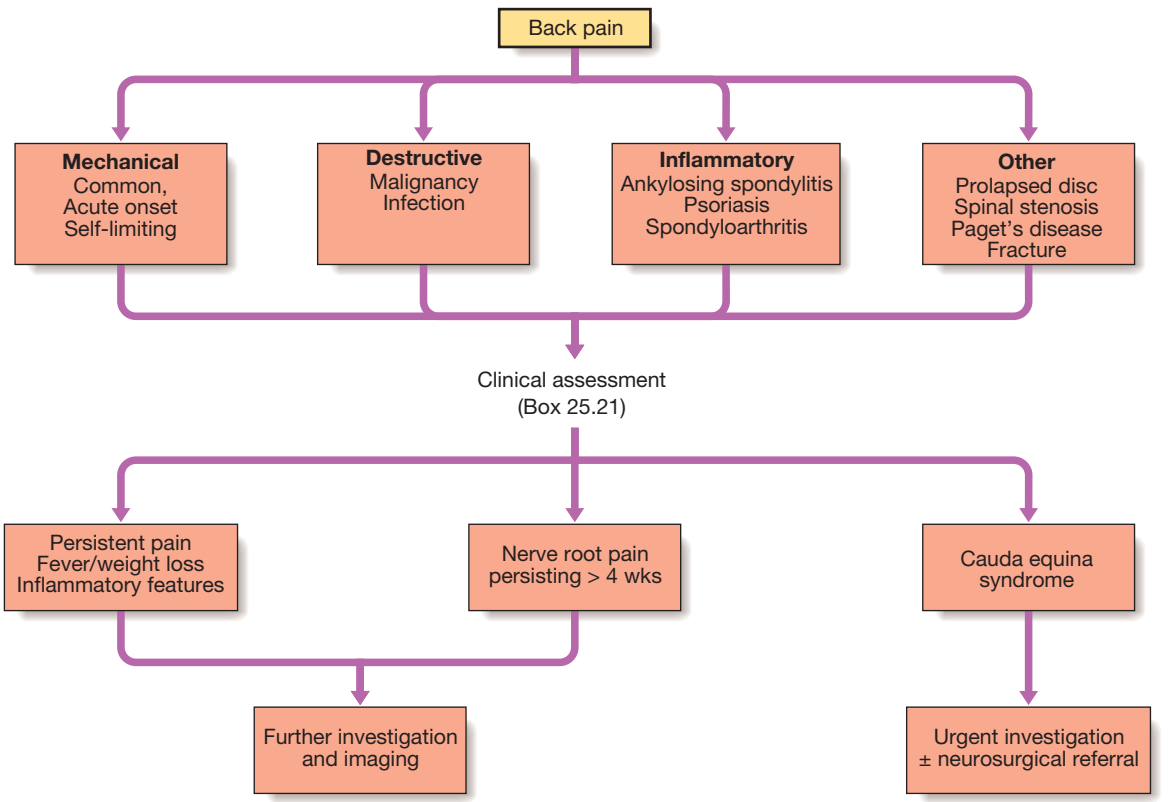

Fig. 25.10 Initial triage assessment of back pain.

25.19 Features of mechanical low back pain

- Pain varies with physical activity (improved with rest)
- Sudden onset, precipitated by lifting or bending
- Recurrent episodes
- Pain limited to back or upper leg
- No clear-cut nerve root distribution
- No systemic features
- Prognosis good (90% recovery at 6 wks)

25.20 Red flags for possible spinal pathology

History

- Age: presentation < 20 yrs or > 55 yrs
- Character: constant, progressive pain unrelieved by rest
- Location: thoracic pain
- Past medical history: carcinoma, tuberculosis, HIV, systemic corticosteroid use, osteoporosis
- Constitutional: systemic upset, sweats, weight loss
- Major trauma

Examination

- Painful spinal deformity
- Severe/symmetrical spinal deformity
- Saddle anaesthesia
- Progressive neurological signs/muscle-wasting
- Multiple levels of root signs

25.21 Clinical features of radicular pain

Nerve root pain

- Unilateral leg pain worse than low back pain
- Pain radiates beyond knee
- Paraesthesia in same distribution
- Nerve irritation signs (reduced straight leg raising that reproduces leg pain)
- Motor, sensory or reflex signs (limited to one nerve root)
- Prognosis reasonable (50% recovery at 6 wks)

Cauda equina syndrome

- Difficulty with micturition
- Loss of anal sphincter tone or faecal incontinence
- Saddle anaesthesia
- Gait disturbance
- Pain, numbness or weakness affecting one or both legs

30% are better and 90% have recovered by 6 weeks. Recurrences of pain may occur and about 10–15% of patients go on to develop chronic back pain that may be difficult to treat. Psychological elements, such as job dissatisfaction, depression and anxiety, are important risk factors for the transition to chronic pain and disability.

Back pain secondary to serious spinal pathology has different characteristics (Box 25.20). If there is clinical evidence of spinal cord or nerve root compression, or a cauda equina lesion (Box 25.21), urgent investigation is needed. Spinal stenosis presents with leg discomfort on walking that is relieved by rest (pseudoclaudication). Bending forwards or walking uphill may also relieve the pain. Common causes include Paget's disease, in which enlargement of the vertebrae may encroach on the spinal canal, and osteoarthritis of the spine, in which osteophytes can have the same effect. Patients may adopt a characteristic simian posture, with a forward stoop and slight flexion at hips and knees.

Degenerative disc disease is a common cause of chronic low back pain. Prolapse of an intervertebral disc presents with nerve root pain, which can be accompanied by a sensory deficit, motor weakness, and asymmetrical reflexes. Examination may reveal a positive sciatic or femoral stretch test. About 70% of patients improve by 4 weeks. Inflammatory back pain due to seronegative spondyloarthritis has a gradual onset and almost always occurs before the age of 40. It is associated with morning stiffness and improves with movement. Spondylolisthesis (p. 1133) may cause back pain that is typically aggravated by standing and walking. Occasionally, diffuse idiopathic skeletal hyperostosis (DISH; p. 1133) can cause back pain but it is usually asymptomatic. Arachnoiditis is a rare cause of chronic severe low back pain. It is due to chronic inflammation of the nerve root sheaths in the spinal canal and can complicate meningitis, spinal surgery, or myelography with oil-based contrast agents.

Investigations

Investigations are not required in patients with acute mechanical back pain. Those with persistent pain (> 6 weeks) or red flags (see Box 25.20) should undergo further investigation. MRI is the investigation of choice since it can demonstrate spinal stenosis, cord compression or nerve root compression, as well as inflammatory changes in spondyloarthropathy, and infectious causes such as spinal abscess. Plain radiographs can be of value in patients suspected of having vertebral compression fractures, OA and degenerative disc disease. If metastatic disease is suspected, radionuclide bone scan or SPECT should be considered. Additional investigations that may be required include routine biochemistry and haematology with measurement of ESR and CRP (to screen for sepsis and inflammatory disease), protein and urinary electrophoresis (for myeloma) and prostate specific antigen (for prostate carcinoma).

Management

Education is important in patients with mechanical back pain. It should emphasise the self-limiting nature of the condition and the fact that exercise is helpful rather than damaging. Regular analgesia and/or NSAIDs may be required to improve mobility and facilitate exercise. Return to work and normal activity should take place as soon as possible. Bed rest is not helpful and may increase the risk of chronic disability. Referral for physiotherapy or manipulation should be considered if a return to normal activities has not been achieved by 6 weeks. Low-dose tricyclic antidepressant drugs may help pain, sleep and mood.

Other treatment modalities that are occasionally used include epidural and facet joint injection, traction and lumbar supports, though there is little evidence to support their use (Box 25.22). Malignant disease, osteoporosis, Paget's disease and spondyloarthropathies require specific treatment of the underlying condition.

Surgery is required in less than 1% of patients with low back pain but may be needed in spinal stenosis, in spinal cord compression and in some patients with nerve root compression.

EBM 25.22 Management of low back pain

- Reassure patients (favourable prognosis)
- Advise patients to stay active
- Prescribe medication if necessary (preferably at fixed time intervals)
- Paracetamol
- NSAID
- Consider opioids, muscle relaxants
- Discourage bed rest
- Consider spinal manipulation for pain relief
- Do not advise lumbar supports, back-specific exercises, traction, acupuncture, epidural or facet injections.

- Koes BW. BMJ 2006; 332:1430–1434.

Regional musculoskeletal pain

Regional musculoskeletal pain is a common presenting complaint, usually occurring as the result of age-related degenerative disease of tendons and ligaments, OA and repetitive strain injuries due to overuse.

Neck pain

Neck pain is a common symptom that can occur following injury (for example, whiplash), after falling asleep in an awkward position, as a result of stress, or in association with OA of the spine. The causes are shown in Box 25.23. Most cases resolve spontaneously or with a short course of NSAID or analgesics, and a soft collar. Patients with persistent pain that follows a nerve root distribution and those with neurological signs and symptoms should be investigated by MRI scan, and if necessary referred for a neurosurgical opinion.

25.23 Causes of neck pain

Mechanical	
• Postural	• Disc prolapse
• Whiplash injury	• Cervical spondylosis
Inflammatory	
• Infections	• RA
• Spondylitis	• Polymyalgia rheumatica
• Juvenile idiopathic arthritis	
Metabolic	
• Osteoporosis	• Paget's disease
• Osteomalacia	
Neoplasia	
• Metastases	• Lymphoma
• Myeloma	• Intrathecal tumours
Other	
• Fibromyalgia	• Torticollis
Referred pain	
• Pharynx	• Aortic aneurysm
• Cervical lymph nodes	• Pancoast tumour
• Teeth	• Diaphragm
• Angina pectoris	

Shoulder pain

Shoulder pain is a common complaint in both genders over the age of 40, and is most often due to degenerative disease of tendons in the rotator cuff (Box 25.24). Varying pain patterns associated with common lesions are shown in Figure 25.11. Management is symptomatic, with analgesics, NSAID, local corticosteroid injections and physiotherapy aimed at restoring normal movement and function. Surgery may be required in patients who have debilitating symptoms in association with rotator cuff tears. Adhesive capsulitis (frozen shoulder) presents with upper arm pain that can progress over 4–10 weeks before subsiding over a similar time course. Restriction of glenohumeral movement is characteristic. In the early phase, there is marked anterior joint/capsular tenderness and stress pain in a capsular pattern; later there is painless restriction, often of all movements. Frozen shoulder is more common in diabetes mellitus, but may also be triggered by a rotator cuff tear, local trauma, myocardial infarction or hemiplegia. Treatment in the early stage is with analgesia, intra- and extracapsular steroid injection, and regular 'pendulum' exercises of the arm to prevent the capsule from over-tightening. Mobilising and strengthening exercises are the sole treatment in the painless 'frozen' stage. The natural

25.24 Clinical findings in shoulder pain

Rotator cuff lesion

- Pain reproduced by resisted active movement:
  Abduction: supraspinatus
  External rotation: infraspinatus, teres minor
  Internal rotation: subscapularis

Subacromial bursitis

- Pain on full abduction but no pain on resisted active abduction

Bicipital (long head) tendinitis

- Tender over bicipital groove
- Pain reproduced by resisted active wrist supination or elbow flexion

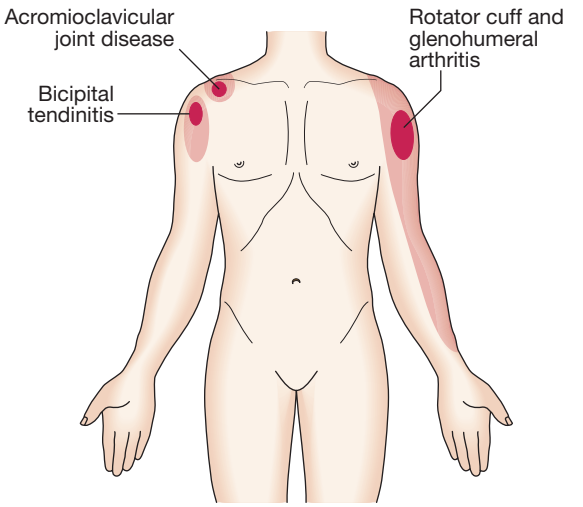

Fig. 25.11 Pain patterns around the shoulder. The dark shading indicates sites of maximum pain.

history is for slow but complete recovery, sometimes taking up to 2 years.

Elbow pain

The most common causes are repetitive strain injury affecting the lateral epicondyle (tennis elbow) and medial epicondyle (golfer's elbow) (Box 25.25). Management is by rest, analgesics and topical or systemic NSAID. Symptoms may also respond to local application of glyceryl trinitrate patches. Local corticosteroid injections may be required in resistant cases. Olecranon bursitis can also follow local repetitive trauma but other causes include infections, gout and RA.

25.25 Local causes of elbow pain

Lesion	Pain	Examination findings
Tennis elbow	Lateral epicondyle Radiation to extensor forearm	Tender over epicondyle Pain reproduced by resisted active wrist extension
Golfer's elbow	Medial epicondyle Radiation to flexor forearm	Tender over epicondyle Pain reproduced by resisted active wrist flexion
Olecranon bursitis	Olecranon	Fluctuant tender swelling over olecranon

Hand and wrist pain

Pain from hand or wrist joints is well localised to the affected joint, except for pain from the first metacarpal joint, commonly targeted by OA; although maximal at the thumb base, the pain often radiates down the thumb and to the radial aspect of the wrist. Non-articular causes of hand pain include:

- Tenosynovitis: flexor or extensor (pain and swelling, with or without fine crepitus on volar or extensor aspect). De Quervain's tenosynovitis involves the tendon sheaths of abductor pollicis longus and extensor pollicis brevis, and produces pain maximal over the radial aspect of the distal forearm and wrist. It usually occurs as the result of a repetitive strain injury. There is tenderness (with or without warmth, linear swelling and fine crepitus) over the distal radius and marked pain on forced ulnar deviation of the wrist with the thumb held across the patient's palm (Finkelstein's sign).
- Raynaud's phenomenon (p. 602).
- C8/T1 radiculopathy.
- Reflex sympathetic dystrophy (p. 1130).

Hip pain

Pain from the hip joint is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin (Fig. 25.12). Trochanteric bursitis is a common cause (Box 25.26), typically affecting obese women, and occurring in isolation or secondary to an abnormal gait, such as in hip or knee OA. Pain in the hip region may also be referred from the back. Root entrapment can cause pain in the lateral thigh (T12–L1) or the inguinal region and lateral thigh (L2–4), but is worsened by coughing and straining more than by movement and is often accompanied by sensory disturbance. Other less common causes include psoas abscess, retroperitoneal haemorrhage or pelvic inflammation, which can cause inguinal and lateral thigh pain that is aggravated by resisted hip flexion.

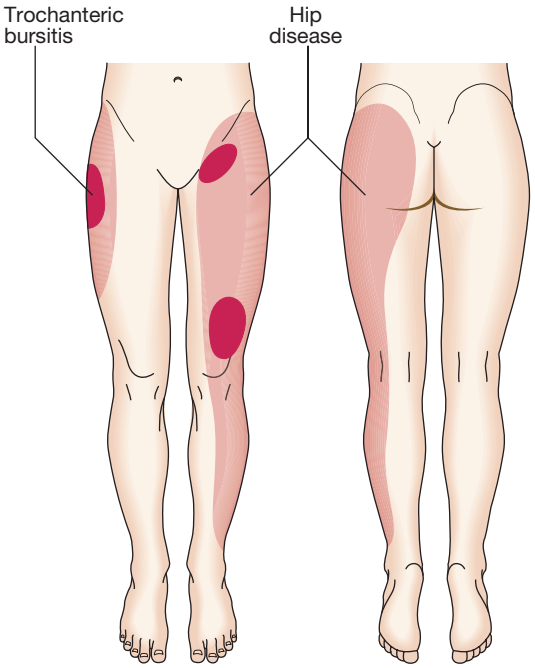

Fig. 25.12 Pain patterns of hip disease and trochanteric bursitis. The dark shading indicates sites of maximum pain.

25.26 Local causes of hip pain

Lesion	Pain	Examination findings
Trochanteric bursitis	Upper lateral thigh, worse on lying on that side at night	Tender over greater trochanter
Gluteal enthesopathy	Upper lateral thigh, worse on lying on that side at night	Tender over greater trochanter Pain reproduced by resisted active hip abduction
Adductor tendinitis	Upper inner thigh Usually clearly sports-related	Tender over adductor origin/tendon/muscle Pain reproduced by resisted active hip adduction
Ischiogluteal bursitis	Buttock, worse on sitting	Tender over ischial prominence
Iliopectineal bursitis	Anterior groin	Tender (± fluctuant swelling) lateral to femoral pulse, not worsened by internal rotation of hip (cf. hip pain)

Knee pain

The most common cause of knee pain is OA, the features of which are described on page 1082. Pain that is associated with locking of the knee (sudden painful inability to extend fully) is usually due to a meniscal tear or osteochondritis dissecans. Referred pain from the hip

25.27 Local causes of knee pain

Lesion	Pain	Examination findings
Pre-patellar bursitis	Anterior patella	Tender fluctuant swelling in front of patella
Superficial and deep infrapatellar bursitis	Anterior knee, inferior to patella	Tender fluctuant swelling in front of (superficial) or behind (deep) patella tendon
Anserine bursitis	Upper medial tibia	Tenderness (± warmth, swelling) over upper medial tibia
Inferior medial collateral ligament enthesopathy	Upper medial tibia	Localised tenderness of upper medial tibia Pain reproduced by valgus stress on partly flexed knee
Popliteal cyst (Baker's cyst)	Popliteal fossa	Tender swelling of popliteal fossa, usually reducible by massage with knee in mid-flexion
Patella tendon enthesopathy	Anterior upper tibia	Tenderness and firm swelling of tibial tubercle
Osteochondritis (Osgood–Schlatter disease)	Anterior upper tibia	Affects adolescents Pain on resisted active knee extension

may present at the knee and is reproduced by hip not knee movement. Pain from periarticular lesions is well localised to the involved structure (Box 25.27). Anterior knee pain may be due to bursitis occurring as the result of repetitive occupational kneeling, as well as infection and gout. Anterior knee pain, aggravated by sports, may occur in adolescent girls but is usually self-limiting. Rarely, anterior knee pain may be the result of chondromalacia patellae, in which degenerative changes of the articular cartilage occur.

Ankle and foot pain

Pain from the mortice joint of the ankle (the tibiofibular–talar joint) is felt between the malleoli and is worse on weight-bearing. Pain from the subtalar joint is also worse on weight-bearing on uneven surfaces. The mortice joint is commonly affected by OA, whereas RA tends to affect the subtalar joint. Pain under the heel can arise from plantar fasciitis or subcalcaneal bursitis. Pain affecting the back of the heel may be due to Achilles tendinitis or bursitis. Patients with seronegative spondyloarthritis may develop enthesopathy affecting this region, resulting in plantar fasciitis, which presents with pain and tenderness under the heel, or as Achilles enthesitis, which presents with pain at the tendon insertion into the calcaneus. The MTP joints of the feet are commonly involved in RA. The presentation is with pain on walking below the metatarsal heads, often described as 'walking on marbles'. Patients with active inflammation of the MTP joints have pain when the forefoot is squeezed (p. 1059). Involvement of the first MTP joint is common in OA and is associated with a valgus deformity (hallux valgus). This joint is also a classical target in acute gout. Claw foot (pes cavus) can be associated with anterior foot pain and is characterised by a high arch and clawing of the toes. It may be an isolated phenomenon or secondary to neurological disorders such as Friedreich's ataxia (p. 1199) or spina bifida (p. 1222). Management should follow the general principles outlined on page 1077. Bursitis and enthesitis resistant to standard measures may respond to local steroid injections. Morton's neuroma is the name given to an entrapment neuropathy of the interdigital nerves of the feet, which presents with shooting pain that is usually located between the third and fourth metatarsal heads. Women are most commonly affected. Local sensory loss and a palpable tender swelling between the metatarsal heads may be detected. Footwear adjustment, with or without a local corticosteroid injection, often helps but surgical decompression may be required if symptoms persist.

Muscle pain and weakness

Muscle pain and weakness can arise from a variety of causes. It is important to distinguish between a subjective feeling of generalised weakness or fatigue, and an objective weakness with loss of muscle power and function. The former is a non-specific manifestation of many diseases, including depression, whereas the latter is often a sign of primary muscle disease.

Clinical assessment

Proximal muscle weakness suggests the presence of a myopathy or myositis, which typically causes difficulty with standing from a seated position, squatting and lifting overhead. The causes are shown in Box 25.28. Worsening of symptoms on exercise and post-exertional cramps suggest a metabolic myopathy, such as glycogen storage disease (p. 450). A strong family history and onset in childhood or early adulthood suggests muscular dystrophy (p. 1228). Alcohol excess can cause an inflammatory myositis and atrophy of type 2 muscle fibres. Proximal myopathy may be a complication of corticosteroid therapy and of osteomalacia. Myopathy and myositis can also occur in association with statin use and viral infections, including HIV infection, when it may be due to HIV itself or treatment with zidovudine. Clinical examination should document the presence, pattern and severity of muscle weakness, and the latter should be assessed using the Medical Research Council (MRC) scale, in which muscle strength is graded on a six-point scale ranging from no power (0) to full power (5).

Investigations

Investigations should include routine biochemistry and haematology, ESR, and measurement of CRP and CK. Serum 25(OH) vitamin D levels and PTH should be checked in suspected osteomalacia. Raised CK levels suggest muscle pathology but do not establish the cause. The ESR and CRP may be raised in inflammatory myositis. Muscle biopsy and electromyography (EMG) are usually required to make the diagnosis, but MRI can be used to identify focal areas of muscle abnormality and increase the diagnostic yield from muscle biopsies.

Management

Management is determined by the cause but all patients with muscle disease may benefit from physiotherapy and graded exercises to maximise muscle function.

25.28 Causes of proximal muscle pain or weakness

Inflammatory

- Polymyositis
- Dermatomyositis
- Inclusion body myositis
- Polymyalgia rheumatica

Endocrine (Ch. 20)

- Hypothyroidism
- Hyperthyroidism
- Cushing's syndrome
- Addison's disease

Metabolic (Ch. 16)

- Myophosphorylase deficiency
- Phosphofructokinase deficiency
- Hypokalaemia
- Carnitine deficiency
- Myoadenylate deaminase deficiency
- Osteomalacia (p. 1125)

Drugs/toxins

- Alcohol
- Cocaine
- Fibrates
- Statins
- Penicillamine
- Zidovudine

Infections (Ch. 13)

- Viral (HIV, cytomegalovirus, rubella, Epstein–Barr, echo)
- Parasitic (schistosomiasis, cysticercosis, toxoplasmosis)
- Bacterial (*Clostridium perfringens*, staphylococci, tuberculosis, *Mycoplasma*)

PRINCIPLES OF MANAGEMENT OF MUSCULOSKELETAL DISORDERS

Although management of musculoskeletal disease depends on the underlying diagnosis, certain aspects of management are common to many disorders. The general aims of management are to:

- educate the patient
- control pain
- optimise function
- modify the disease process where this is possible
- identify and treat related comorbidity.

These aims are interrelated and success in one area often benefits others. Successful management requires careful assessment of the person as a whole, as well as his or her musculoskeletal system. The management plan should be individualised and patient-centred, should involve all necessary members of the multidisciplinary team, and should be agreed and understood by both the patient and involved practitioners. It must also take into account:

- the person's daily activity requirements, and work and recreational aspirations
- risk factors and associations of the musculoskeletal condition (obesity, muscle weakness, non-restorative sleep)
- the person's perceptions and knowledge of the condition
- medications and coping strategies already tried by the patient
- comorbid disease and its therapy
- the availability, costs and logistics of appropriate evidence-based interventions.

25.29 Core interventions for patients with rheumatic diseases

Core

- Education
- Exercise
  - Aerobic conditioning
  - Strengthening
- Simple analgesia
- Reduction of adverse mechanical factors
  - Pacing of activities
  - Appropriate footwear
- Weight reduction if obese

Other options

- Other analgesic drugs
  - Oral NSAIDs
  - Topical agents
  - Opioid analgesics
  - Amitriptyline
  - Gabapentin/pregabalin
- Disease-modifying therapy
- Local corticosteroid injections
- Physical treatments
  - Heat, cold, aids, appliances
- Surgery
- Coping strategies

Simple and safe interventions should be tried first. Symptoms and signs will change with time, so the plan requires regular review and re-adjustment. Effective management may require the expertise of a variety of health professionals, with a coordinated multidisciplinary team approach.

Core interventions that should be considered for everyone with a painful musculoskeletal condition are listed in Box 25.29. There are also other non-pharmacological and drug options, the choice depending largely on the nature and severity of the diagnosis.

Education and lifestyle interventions

Education

Patients must always be informed about the nature of their condition and its investigation, treatment and prognosis, as education can improve outcome. Information and therapist contact can reduce pain and disability, improve self-efficacy and reduce the health-care costs of many musculoskeletal conditions, including OA and RA. The mechanisms are unclear but in part may result from improved adherence. Benefits are modest but potentially long-lasting, safe and cost-effective (Box 25.30). Education can be provided through one-to-one discussion, written literature, patient-led group education classes and interactive computer programs. Inclusion of the patient's partner or carer is often appropriate; this is essential for childhood conditions but also helps in many chronic adult conditions, such as RA or fibromyalgia.

Exercise

Two types of exercise should be prescribed (Box 25.30):

- Aerobic fitness training can produce long-term reduction in pain and disability. It improves well-being, encourages restorative sleep and benefits common comorbidity such as obesity, diabetes, chronic heart failure and hypertension.
- Local strengthening exercise for muscles that act over compromised joints also reduces pain and disability, with improvements in the reduced muscle strength, proprioception, coordination and

EBM 25.30 Education and exercise in the management of arthritis

'Both patient education and exercise regimens have a modest, yet clinically important influence on patients' well-being.'

'Both aerobic walking and home-based quadriceps-strengthening exercises reduce pain and disability from knee osteoarthritis.'

- Devos-Combey L, et al. J Rheumatol 2006; 33:744–756.
- Roddy E, et al. Ann Rheum Dis 2005; 64:544–548.

balance that associate with chronic arthritis. 'Small amounts often' of strengthening exercise are better than protracted sessions performed infrequently.

Joint protection

Excessive impact-loading and adverse repetitive use of a compromised joint or periarticular tissue can often be reduced: for example, cessation of contact sports, or altered use of machinery or tools at the workplace. Simple 'pacing' of activities – dividing physically onerous tasks into shorter segments with brief breaks in between – is helpful. Use of shock-absorbing footwear with thick soft soles can reduce impact-loading through feet, knees, hips and back, and improve symptoms at these sites. A walking stick held on the contralateral side takes the weight off a painful hip, knee or foot.

Weight loss

Obesity aggravates pain at most sites of the body through increased mechanical strain and is a risk factor for more rapid progression of joint damage in patients with arthritis. This should be explained to obese patients and strategies offered on how to lose and then maintain an appropriate weight (p. 117).

Pharmacological treatment

Analgesics

Paracetamol (1 g up to 4 times daily) is the oral analgesic of first choice and, if successful, the preferred long-term oral analgesic. It inhibits prostaglandin synthesis in the brain but has less effect on peripheral prostaglandin production. It is generally well tolerated and has few adverse effects and drug interactions. There is a possible increased risk of both gastrointestinal events and cardiovascular disease with chronic usage, but it is uncertain whether this is due to the underlying disease or the drug itself. If paracetamol fails to achieve an adequate response, it can be used in combination with opioids such as codeine and dihydrocodeine in compound analgesic preparations like co-codamol (codeine and paracetamol) or co-dydramol (dihydrocodeine and paracetamol). Although these are more effective than paracetamol, side-effects include constipation, headache and confusion, especially in the elderly. The centrally acting analgesics tramadol and meptazinol may be useful for temporary control of severe pain unresponsive to other measures. Both may cause nausea, bowel upset, dizziness and somnolence, and withdrawal symptoms after chronic use. The non-opioid analgesic nefopam (30–90 mg 3 times daily) can help moderate pain, though side-effects (nausea, anxiety, dry mouth) often limit its use. Patients with severe or intractable pain may require stronger opioid analgesics such as oxycodon and morphine.

Non-steroidal anti-inflammatory drugs

These are among the most widely prescribed drugs, but their use has declined over recent years because of concerns about an increased risk of cardiovascular disease. Oral NSAIDs are particularly useful in the management of pain that has an inflammatory component, and a long-acting NSAID taken in the evening may help reduce early morning stiffness. There is marked variability in individual tolerance and response; patients who do not respond to one NSAID may still gain relief from another. The mechanism of NSAID action is through inhibition of prostaglandin H synthase and cyclo-oxygenase (COX) enzymes. Arachidonic acid, derived from membrane phospholipids, is metabolised to produce prostaglandins and leukotrienes by the COX and 5-lipoxygenase pathways respectively (Fig. 25.13). There are two isoforms of COX, encoded by different genes. COX-1 is constitutively expressed and fulfils a 'housekeeping' function in the gastric mucosa, platelets and kidneys. The COX-2 enzyme is largely induced at sites of inflammation, producing prostaglandins that cause local pain and inflammation, but COX-2 is also up-regulated in the CNS, where it plays a role in the central mediation of pain and fever. Traditional NSAIDs, such as ibuprofen, diclofenac and naproxen, inhibit both COX enzymes, whereas newer NSAIDs, such as celecoxib and etoricoxib, selectively inhibit COX-2. Whilst NSAIDs have anti-inflammatory activity, they are not thought to have a disease-modifying effect in either OA or inflammatory rheumatic diseases.

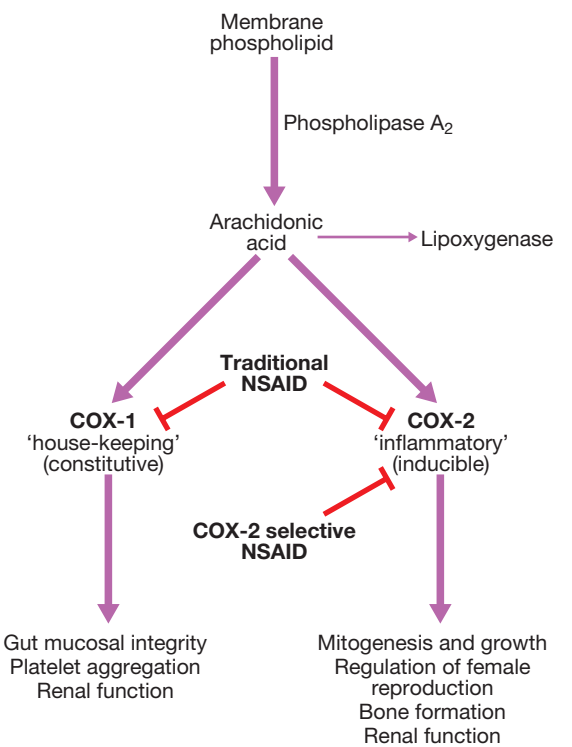

Fig. 25.13 COX-1 and COX-2 pathways.

25.31 Commonly used NSAIDs and their relative risk of gastrointestinal bleeding and perforation

Drug	Daily adult dose	Doses/ day	Idiosyncratic side-effects, comments
Very low risk			
Celecoxib	100–200 mg	1–2	Selective COX-2 inhibitor
Etoricoxib	60–120 mg	1	Selective COX-2 inhibitor
Low risk			
Ibuprofen	600–1600 mg	3–4	Weak anti-inflammatory effect at this dose
Etodolac	600 mg	1	Partially selective COX-2 inhibitor
Meloxicam	7.5–15 mg	1	Partially selective COX-2 inhibitor
Nabumetone	1–2 g	1–2	Partially selective COX-2 inhibitor
Medium risk			
Ibuprofen	1600–2400 mg	3–4	
Naproxen	500–1000 mg	1–2	
Diclofenac	75–150 mg	2–3	Abnormal liver function tests
High risk			
Indometacin	50–200 mg	3–4	High incidence of dyspepsia and CNS side-effects (headache, dizziness, confusion)
Ketoprofen	100–200 mg	2–4	
Highest risk			
Piroxicam	20–30 mg	1–2	Restricted use in those > 60 yrs
Azapropazone	600–200 mg	2–4	Uricosuric action. Restricted use in those > 60 yrs

25.32 Risk factors for NSAID-induced ulcers

- Age > 60 yrs*
- Past history of peptic ulcer*
- Past history of adverse event with NSAID
- Concomitant corticosteroid use
- High-dose or multiple NSAID
- High-risk NSAID (see Box 25.31)

*The most important risk factors.

25.33 Recommendations for the use of NSAID

- Use with caution in patients with cardiovascular disease
- Use the lowest dose for the shortest time possible to control symptoms
- Avoid NSAID in patients on warfarin
- Allow 2–3 weeks to assess efficacy. If response is inadequate, consider trial of another NSAID
- Never prescribe more than one NSAID at a time
- Co-prescribe proton pump inhibitor for patients with risk factors for gastrointestinal adverse effects (see Box 25.32)

25.34 Use of oral NSAID in old age

- **Gastrointestinal complications**: age is a strong risk factor for bleeding and perforation and peptic ulceration. Elderly patients are more likely to die if they suffer NSAID-associated bleeding or perforation.
- **Cardiovascular disease**: use NSAID with caution in patients with cardiovascular disease. Therapy with NSAID may exacerbate hypertension and heart failure.
- **Renal disease**: use of NSAID may cause renal impairment.

Non-selective NSAIDs can damage the gastric and duodenal mucosal barrier and are associated with an increased risk of upper gastrointestinal ulceration, bleeding and perforation. The adjusted increased risk (odds ratio) of bleeding or perforation from all NSAIDs is 4–5, though differences exist between NSAIDs (Box 25.31). Dyspepsia is a poor guide to the presence of NSAID-associated ulceration and bleeding, and the principal risk factors are shown in Box 25.32. Co-prescription of omeprazole (20 mg daily) or misoprostol (200 µg twice or 3 times daily) reduces but does not eliminate NSAID-induced ulceration and bleeding, but H_2-antagonists in standard doses are ineffective. The COX-2 selective NSAIDs celecoxib and etoricoxib are much less likely to cause gastrointestinal toxicity but benefit is attenuated in patients on low-dose aspirin. In the UK, National Institute for Health and Clinical Excellence (NICE) guidelines advise that a proton pump inhibitor (PPI) should be co-prescribed with all NSAIDs, including COX-2 selective NSAIDs, even though the risk of gastrointestinal events with these is low. Since chronic PPI therapy is associated with an increased risk of hip fracture, the merits of giving PPI therapy with a COX-2 selective drug need to be weighed up carefully.

Other side-effects of NSAID include fluid retention and renal impairment due to inhibition of renal prostaglandin production, non-ulcer-associated dyspepsia, abdominal pain and altered bowel habit, and rashes. Interstitial nephritis, asthma and anaphylaxis can also occur but are rare. Recommendations for NSAID prescribing are summarised in Box 25.33. Because of the risk of adverse effects, NSAIDs should be used with great care in the elderly (Box 25.34).

Topical agents

Topical NSAID creams and gels and capsaicin (chilli extract; 0.025%) cream can help in the treatment of OA and superficial periarticular lesions affecting hands, elbows and knees. They may be used as monotherapy or as an adjunct to oral analgesics. Topical NSAIDs can penetrate superficial tissues and even reach the joint capsule, though intrasynovial levels mainly reflect blood-borne drug delivery. Capsaicin selectively binds to the protein transient receptor potential vanilloid type 1 (TRPV1), which is a heat-activated calcium channel on the surface of peripheral type C nociceptor

fibres. Initial application causes a burning sensation but continued use depletes presynaptic substance P, with subsequent pain reduction that is optimal after 1–2 weeks.

Non-pharmacological interventions

Physical and occupational therapy

Local heat, ice packs, wax baths and other local external applications can induce muscle relaxation and temporary relief of symptoms in a range of rheumatic diseases.

Hydrotherapy induces muscle relaxation and facilitates enhanced movement in a warm, pain-relieving environment without the restraints of gravity and normal load-bearing. Various manipulative techniques may also help improve restricted movement. The combination of these with education and therapist contact enhances their benefits.

Splints can give temporary rest and support for painful joints and periarticular tissues, and prevent harmful involuntary postures during sleep. Prolonged rest, however, must be avoided.

Orthoses are more permanent appliances used to reduce instability and excessive abnormal movement. They include working wrist splints, knee orthoses, and iron and T-straps to control ankle instability. Orthoses are particularly suited to severely disabled patients in whom a surgical option is inappropriate, and often need to be custom-made for the individual.

Aids and appliances can provide dignity and independence to patients with respect to activities of daily living. Common examples are a raised toilet seat, raised chair height, extended handles on taps, a shower instead of a bath, thick-handled cutlery, and extended 'hands' to pull on tights and socks. Full assessment and advice from an occupational therapist maximise the benefits of these.

Surgery

A variety of surgical interventions can relieve pain and conserve or restore function in patients with bone, joint and periarticular disease (Box 25.35). Soft tissue release and tenosynovectomy may reduce inflammatory symptoms, improve function and prevent or retard tendon damage for variable periods, sometimes indefinitely. Synovectomy of joints does not prevent disease progression but may be indicated for pain relief when drugs, physical therapy and intra-articular injections have provided insufficient relief. The main approaches for damaged joints are osteotomy (cutting bone to alter joint mechanics and load transmission), excision arthroplasty (removing part or all of the joint), joint replacement (insertion of prosthesis in place of the excised joint) and arthrodesis (joint fusion). Surgical fixation of fractures is frequently required in patients with osteoporosis and other bone diseases.

The main aims of surgery are to provide pain relief and improve function and quality of life. If surgery is to be successful, the aims and consequences of each operation should be considered as part of an integrated programme of management and rehabilitation, by multidisciplinary teams of surgeons, allied health professionals and physicians, and carefully explained to the patient. Assessment of motivation, social support and environment is no less important than careful consideration of patients' general health, their risks for major surgery, the extent of disease in other joints, and their ability to mobilise following surgery. For some severely compromised people, pain relief and functional independence are better served by provision of a suitable wheelchair, home adjustments and social services than by surgery that is technically successful but following which the patient cannot mobilise.

25.35 Surgical procedures in rheumatology and bone disease

Procedure	Indication
Soft tissue release	
Carpal tunnel	Median nerve compression
Tarsal tunnel	Posterior tibial nerve entrapment
Flexor tenosynovectomy	Relief of 'trigger' fingers
Ulnar nerve transposition	Ulnar nerve entrapment at elbow
Fasciotomy	Severe Dupuytren's contracture
Tendon repairs and transfers	
Hand extensor tendons	Extensor tendon rupture
Thumb and finger flexor tendons	Flexor tendon rupture
Synovectomy	
Wrist and extensor tendon sheath (+ excision of radial head)	Pain relief and prevention of extensor tendon rupture in RA, resistant inflammatory synovitis
Knee synovectomy	Resistant inflammatory synovitis
Osteotomy	
Femoral osteotomy	Early OA of hip
Tibial osteotomy	Unicompartmental knee OA Deformed tibia in OA or Paget's disease
Excision arthroplasty	
First metatarsophalangeal joint (Keller's procedure)	Painful hallux valgus
Radial head	Painful distal radio-ulnar joint
Lateral end of clavicle	Painful acromioclavicular joint
Metatarsal head	Painful subluxed metatarsophalangeal joints
Joint replacement arthroplasty	
Knee, hip, shoulder, elbow	Painful damaged joints in OA and RA
Arthrodesis	
Wrist	Damaged joint: pain relief, improvement of grip
Ankle/subtalar joints	Damaged joint: pain relief, stabilisation of hindfoot
Fracture repair	
Hip arthroplasty	Fractured neck of femur
External fixation	Multiple fractures, open fractures
Intramedullary nailing	Tibial and femur fractures
Screw, plating and wiring	Wrist and other fractures
Other procedures	
Nerve root decompression	Spinal stenosis, nerve entrapment
Kyphoplasty	Painful vertebral fracture
Vertebroplasty	Painful vertebral fracture

Self-help and coping strategies

These help patients to cope better with, and adjust to, chronic pain and disability. They may be useful at any

25.36 Self-help and coping strategies

- Yoga and relaxation techniques to reduce stress
- Avoiding negative situations or activities that produce stress, and increasing pleasant activities that give satisfaction
- Information and discussion to alter beliefs about and perspectives on disease
- Reducing or avoiding catastrophising and maladaptive pain behaviour
- Imagery and distraction techniques for pain
- Expanding social contact and better use of social services

stage but are particularly so for patients with incurable problems, who have tried all available treatment options. The aim is to increase self-management through self-assessment and problem-solving, so that patients can recognise negative but potentially remediable aspects of their mood (stress, frustration, anger or low self-esteem) and their situation (physical, social, financial). These may then be addressed by changes in attitude and behaviour, as shown in Box 25.36.

Involvement of the spouse or partner in mutual goal-setting can improve partnership adjustment. Such approaches are often an element of group education classes and pain clinics, but may require more formal clinical psychological input.

OSTEOARTHRITIS

Osteoarthritis (OA) is by far the most common form of arthritis. It is strongly associated with ageing and is a major cause of pain and disability in older people. Osteoarthritis is characterised by focal loss of articular cartilage, subchondral osteosclerosis, osteophyte formation at the joint margin, and remodelling of joint contour with enlargement of affected joints. Inflammation can occur but is not a prominent feature. Joint involvement in OA follows a characteristic distribution, mainly targeting the hips, knees, PIP and DIP joints of the hands, neck and lumbar spine (see Fig. 25.9). The prevalence of OA rises progressively with age and it has been estimated that 45% of all people develop knee OA and 25% hip OA at some point during life. Although some of these patients are asymptomatic, the lifetime risk of having a total hip or knee replacement for OA in someone aged 50 is about 11% in women and 8% in men. Symptoms attributable to OA are more prevalent in women, except at the hip, where men are equally affected.

Pathophysiology

OA is a complex disorder with both genetic and environmental components (Fig. 25.14). Repetitive adverse loading of joints during occupation or competitive sports is also an important predisposing factor in farmers (hip OA), miners (knee OA) and elite or professional athletes (knee OA). For most people, however, participation in recreational sport does not appear to increase the risk of OA, unless there has been significant joint trauma. Congenital abnormalities of the joint, such as slipped femoral epiphysis, are also associated with a high risk of OA, presumably due to abnormal load distribution

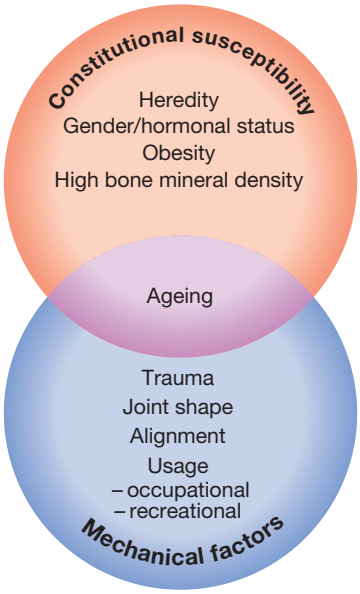

Fig. 25.14 Risk factors for the development of osteoarthritis.

within the joint, and this is also thought to be the explanation for the increased risk of OA in Paget's disease of bone. Obesity is another strong risk factor. Although this is likely to be due in part to increased mechanical loading of the joints, it has been speculated that cytokines released from adipose tissue may also play a role. The increased incidence of OA in women has led to speculation that sex hormones may play a causal role. While there is no evidence to suggest that circulating sex hormone levels or reproductive history predispose to OA, some studies have shown a lower prevalence of OA in women who use hormone replacement therapy (HRT), as compared with non-users. Genetic factors play a key role in the pathogenesis of OA, and family-based studies have estimated that the heritability of OA ranges between about 43% at the knee to between 60% and 65% at the hip and hand, respectively. Recent genome-wide association studies have identified several loci that predispose to OA, but many others remain to be discovered.

Major alterations in cartilage structure are characteristic of OA. Chondrocytes divide to produce nests of metabolically active cells (Fig. 25.15A). Initially, matrix components are produced at an increased rate, but at the same time there is increased degradation of the major structural components of cartilage, including aggrecan and type II collagen (see Fig. 25.4, p. 1063). Eventually, the concentration of aggrecan in matrix falls and makes the cartilage vulnerable to load-bearing injury. Fissuring of the cartilage surface ('fibrillation') then occurs, leading to the development of deep vertical clefts (Fig. 25.15B), localised chondrocyte death and decreased cartilage thickness; this is focal rather than generalised in nature and mainly affects the maximum load-bearing part of the joint, although, eventually, large parts of the cartilage surface can be damaged. Calcium pyrophosphate and basic calcium phosphate crystals often become deposited in the abnormal cartilage.

The subchondral bone is also abnormal, with osteosclerosis and subchondral cyst formation (Fig. 25.15C).

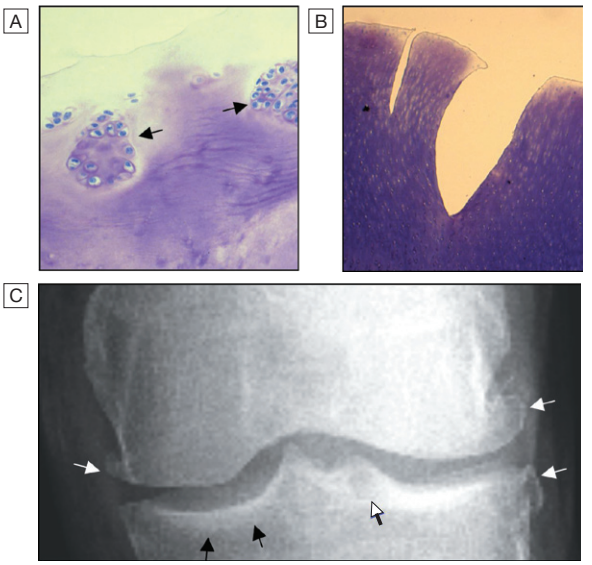

Fig. 25.15 Pathological changes in osteoarthritis. A Abnormal nests of proliferating chondrocytes (arrows) interspersed with matrix devoid of normal chondrocytes. B Fibrillation of cartilage in OA. C Radiograph of knee joint affected by OA, showing osteophytes at joint margin (white arrows), subchondral sclerosis (black arrows) and subchondral cyst (open arrow).

Fibrocartilage is produced at the joint margin, which undergoes endochondral ossification to form osteophytes. Bone remodelling and cartilage thinning slowly alter the shape of the OA joint, increasing its surface area. Patients with OA also have higher BMD values at sites distant from the joint, and this is particularly related to osteophyte formation. The reason for this is not completely understood but it may reflect the fact that common signalling pathways are involved in the regulation of bone and cartilage metabolism.

The synovium undergoes variable degrees of hyperplasia, and inflammatory changes may sometimes be observed, although to a much lesser extent than in RA and other inflammatory arthropathies. Osteochondral bodies commonly occur within the synovium, reflecting chondroid metaplasia or secondary uptake and growth of damaged cartilage fragments. The outer capsule also thickens and contracts, usually retaining the stability of the remodelling joint. The muscles surrounding affected joints commonly show evidence of wasting and non-specific type II fibre atrophy.

Clinical features

The main presenting symptoms are pain and functional restriction in a patient over the age of 45, but more often over 60 years. The causes of pain in OA are not completely understood but may relate to increased pressure in subchondral bone (mainly causing night pain), trabecular microfractures, capsular distension and low-grade synovitis, or may result from bursitis and enthesopathy secondary to altered joint mechanics. Typical OA pain has the characteristics listed in Box 25.37. For many people, functional restriction of the hands, knees or hips is an equal, if not greater, problem than pain. The clinical findings vary according to severity but are principally those of joint damage.

25.37 Symptoms and signs of osteoarthritis

Pain

- Insidious onset over months or years
- Variable or intermittent over time ('good days, bad days')
- Mainly related to movement and weight-bearing, relieved by rest
- Only brief (< 15 mins) morning stiffness and brief (< 5 mins) 'gelling' after rest
- Usually only one or a few joints painful

Clinical signs

- Restricted movement due to capsular thickening, or blocking by osteophyte
- Palpable, sometimes audible, coarse crepitus due to rough articular surfaces
- Bony swelling around joint margins
- Deformity, usually without instability
- Joint-line or periarticular tenderness
- Muscle weakness and wasting
- Synovitis mild or absent

The correlation between the presence of structural change, pain and disability varies markedly according to site. It is stronger at the hip than the knee, and poor at most small joints. Risk factors for pain and disability may differ from those for structural change. At the knee, for example, reduced quadriceps muscle strength and adverse psychosocial factors (anxiety, depression) correlate more strongly with pain and disability than the degree of radiographic change.

Radiological evidence of OA is very common in middle-aged and older people, and the disease may coexist with other conditions, so it is important to remember that pain in a patient with OA may be due to another cause. Generalised OA, knee OA, hip OA and spine OA (spondylosis) will be considered individually.

Generalised nodal OA

Characteristics of this common form of OA are shown in Box 25.38. Some patients are asymptomatic whereas others develop pain, stiffness and swelling of one or more PIP joints of the hands from the age of about 40 years onward. Gradually, these develop posterolateral swellings on each side of the extensor tendon that slowly enlarge and harden to become Heberden's (DIP) and Bouchard's (PIP) nodes (Fig. 25.16). Typically, each joint goes through a phase of episodic symptoms (1–5 years) while the node evolves and OA develops. Once OA is fully established, symptoms may subside and hand function often remains good. Affected joints are enlarged as the result of osteophyte formation and

25.38 Characteristics of generalised nodal osteoarthritis

- Polyarticular finger interphalangeal joint OA
- Heberden's (± Bouchard's) nodes
- Marked female preponderance
- Peak onset in middle age
- Good functional outcome for hands
- Predisposition to OA at other joints, especially knees
- Strong genetic predisposition

Fig. 25.16 Nodal osteoarthritis. Heberden's nodes and lateral (radial/ulnar) deviation of distal interphalangeal joints, with mild Bouchard's nodes at the proximal interphalangeal joints.

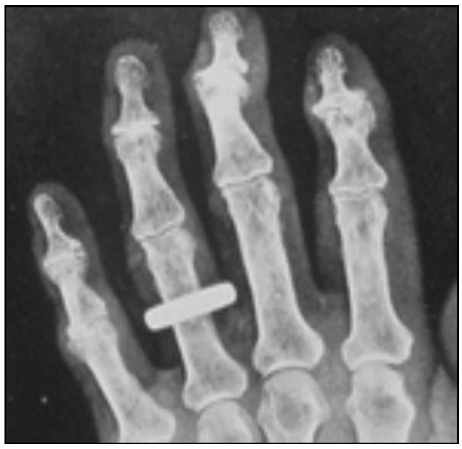

Fig. 25.17 X-ray appearances in hand osteoarthritis. There is marked loss of joint space at all of the distal interphalangeal joints, with osteophyte formation most marked at the first and second DIP joints. The fifth proximal interphalangeal joint also shows loss of joint space with osteophyte formation.

often show characteristic lateral deviation, reflecting the asymmetric focal cartilage loss of OA (Fig. 25.17). Involvement of the first carpometacarpal joint (CMC) is also common, leading to pain on trying to open bottles and jars and functional impairment. Clinically, it may be detected by the presence of crepitus on joint movement, and squaring of the thumb base.

Generalised nodal OA has a very strong genetic component: the daughter of an affected mother has a 1 in 3 chance of developing nodal OA herself. People with nodal OA are at increased risk of OA at other sites, especially the knee.

Knee OA

OA principally targets the patello-femoral and medial tibio-femoral compartments at this site but eventually spreads to affect the whole of the joint (Fig. 25.18). It may be isolated or occur as part of generalised nodal OA. Most patients, particularly women, have bilateral and symmetrical involvement. With men, trauma is a more important risk factor and may result in unilateral OA.

The pain is usually localised to the anterior or medial aspect of the knee and upper tibia. Patello-femoral pain is usually worse going up and down stairs or inclines.

Fig. 25.18 X-ray appearances in knee osteoarthritis. There is almost complete loss of joint space affecting both compartments, and sclerosis of subchondral bone.

Fig. 25.19 Typical varus deformity resulting from marked medial tibio-femoral osteoarthritis.

Posterior knee pain suggests the presence of a complicating popliteal cyst (Baker's cyst). Prolonged walking, rising from a chair, getting in or out of a car, or bending to put on shoes and socks may be difficult. Local examination findings may include:

- a jerky, asymmetric (antalgic) gait with less time weight-bearing on the painful side
- a varus (Fig. 25.19), less commonly valgus, and/or fixed flexion deformity
- joint-line and/or periarticular tenderness (secondary anserine bursitis and medial ligament enthesopathy (see Box 25.27, p. 1076), causing tenderness of the upper medial tibia)
- weakness and wasting of the quadriceps muscle
- restricted flexion/extension with coarse crepitus
- bony swelling around the joint line.

Calcium pyrophosphate dihydrate (CPPD) crystal deposition in association with OA is most common at the knee. This may result in a more overt inflammatory component (stiffness, effusions) and super-added acute attacks of synovitis ('pseudogout', p. 1090), which

may predict more rapid radiographic and clinical progression.

Hip OA

Hip OA most commonly targets the superior aspect of the joint (Fig. 25.20). This is often unilateral at presentation, frequently progresses with superolateral migration of the femoral head, and has a poor prognosis. The less common central (medial) OA shows more central cartilage loss and is largely confined to women. It is often bilateral at presentation and may associate with generalised nodal OA. It has a better prognosis than superior hip OA and progression to axial migration of the femoral head is uncommon.

The hip shows the best correlation between symptoms and radiographic change. Hip pain is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin. Lateral hip pain, worse on lying on that side with tenderness over the greater trochanter, suggests secondary trochanteric bursitis. Common functional difficulties are the same as for knee OA; in addition, restricted hip abduction in women may cause pain on intercourse. Examination may reveal:

- an antalgic gait
- weakness and wasting of quadriceps and gluteal muscles
- pain and restriction of internal rotation with the hip flexed – the earliest and most sensitive sign of hip OA; other movements may subsequently be restricted and painful
- anterior groin tenderness just lateral to the femoral pulse
- fixed flexion, external rotation deformity of the hip
- ipsilateral leg shortening with severe joint attrition and superior femoral migration.

Although obesity is not a major risk factor for development of hip OA, it is associated with more rapid progression.

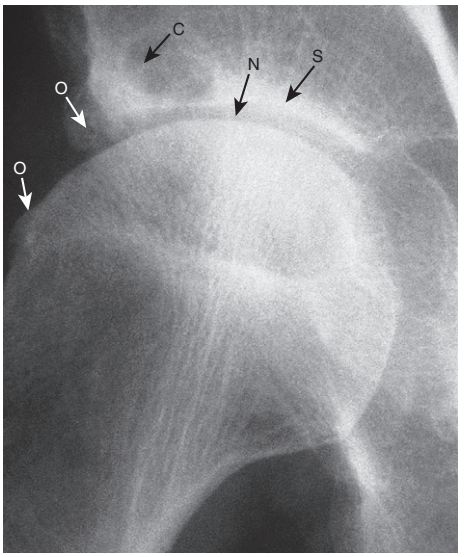

Fig. 25.20 X-ray of hip showing changes of osteoarthritis. Note the superior joint space narrowing (N), subchondral sclerosis (S), marginal osteophytes (white arrows) and cysts (C).

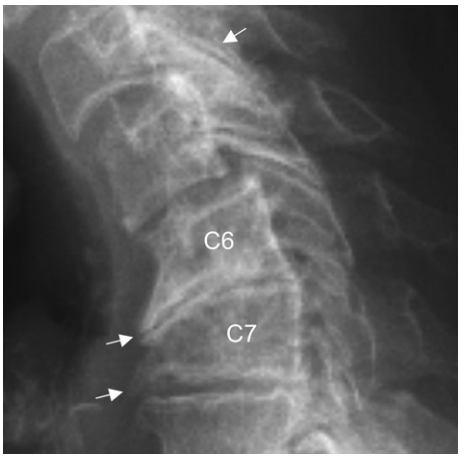

Fig. 25.21 X-ray of spine showing typical changes of osteoarthritis. Cervical spondylosis showing disc space narrowing between C6 and C7, osteophytes at the anterior vertebral body margins (arrows) and osteosclerosis at the apophyseal joints.

Spine OA

The cervical and lumbar spine are predominantly targeted by OA, then referred to as cervical spondylosis and lumbar spondylosis, respectively (Fig. 25.21). Spine OA may occur in isolation or as part of generalised OA. The typical presentation is with pain localised to the low back region or the neck, although radiation of pain to the arms, buttocks and legs may also occur due to nerve root compression. The pain is typically relieved by rest and worse on movement. On physical examination, the range of movement may be limited and loss of lumbar lordosis is typical. The straight leg-raising test or femoral stretch test may be positive and neurological signs may be seen in the legs where there is complicating spinal stenosis or nerve root compression.

Early-onset OA

Unusually, typical symptoms and signs of OA may present before the age of 45. In most cases, a single joint is affected and there is a clear history of previous trauma. However, specific causes of OA need to be considered in people with early-onset disease affecting several joints, especially those not normally targeted by OA, rare causes need to be considered (Box 25.39). Kashin–Beck disease is a rare form of OA that occurs in children, typically between the ages of 7 and 13, in some regions

25.39 Causes of early-onset osteoarthritis

Monoarticular

- Previous trauma, localised instability

Pauciarticular or polyarticular

- Juvenile idiopathic arthritis (p. 1103)
- Metabolic or endocrine disease
  - Haemochromatosis (p. 972)
  - Ochronosis
  - Acromegaly (p. 792)
- Spondylo-epiphyseal dysplasia
- Late avascular necrosis
- Neuropathic joint
- Kashin–Beck disease

of China. The cause is unknown but suggested predisposing factors are selenium deficiency and contamination of cereals with mycotoxin-producing fungi.

Erosive OA

This term is used to describe rare patients with hand OA who have a more prolonged symptom phase, more overt inflammation, more disability and worse outcome than those with nodal OA. Distinguishing features include preferential targeting of PIP joints, subchondral erosions on X-rays, occasional ankylosis of affected joints and lack of association with OA elsewhere. It is unclear whether erosive OA is part of the spectrum of hand OA or a discrete subset.

Investigations

A plain X-ray of the affected joint should be performed and often this will show one or more of the typical features of OA (see Figs 25.17–25.21). In addition to providing diagnostic information, X-rays are used to assess the severity of structural change, which is useful if joint replacement surgery is being considered. Non-weight-bearing postero-anterior views of the pelvis are adequate for assessing hip OA. Patients with suspected knee OA should have standing antero-posterior radiographs taken to assess tibio-femoral cartilage loss, and a flexed skyline view to assess patello-femoral involvement. Spine OA can often be diagnosed on plain X-ray, which typically shows evidence of disc space narrowing and osteophytes. If nerve root compression or spinal stenosis is suspected, MRI should be performed.

Routine biochemistry, haematology and autoantibody tests are usually normal. Synovial fluid aspirated from an affected joint is viscous with a low cell count. Radioisotope bone scans performed for other reasons often show, as an incidental finding, discrete increased uptake in OA joints due to increased bone remodelling.

Unexplained early-onset OA requires additional investigation, guided by the suspected underlying condition. X-rays may show typical features of dysplasia or avascular necrosis, widening of joint spaces in acromegaly, multiple cysts and chondrocalcinosis in haemochromatosis (p. 972), or disorganised architecture in neuropathic joints.

Management

Treatment follows the principles outlined on pages 1077–1081 and in Box 25.40. Measures that are pertinent in older people are summarised in Box 25.41.

Education and other general measures

It is important to explain the nature of the condition fully, outlining the role of relevant risk factors (obesity, heredity, trauma) and the fact that established structural changes are permanent but that pain and function can improve. The prognosis should also be discussed (good for nodal hand OA, more optimistic for knee than hip OA), as should how appropriate action can improve the prognosis of large-joint OA. Exercise has beneficial effects in OA, including both strengthening and aerobic exercise, preferably with reinforcement by a physiotherapist (see Box 25.30, p. 1078). Quadriceps strengthening exercises are particularly beneficial in knee OA. Weight loss can have a substantial beneficial effect on symptoms if the patient is obese and is probably one of the most effective treatments for reducing pain, particularly in OA of the lower limbs. Shock-absorbing footwear, pacing of activities, use of a walking stick for painful knee or hip OA, or provision of built-up shoes to equalise leg lengths can all improve symptoms.

Analgesics and anti-inflammatory drugs

If symptoms do not respond to non-pharmacological measures, paracetamol should be given. Addition of a topical NSAID, and then capsaicin, for knee and hand OA can also be helpful. Oral NSAID should be considered in patients who remain symptomatic. These drugs are significantly more effective than paracetamol and can be successfully combined with paracetamol or compound analgesics such as co-codamol if the pain is severe. Opiates may occasionally be required. For temporary benefit of moderate to severe pain, intra-articular injection of corticosteroids can be helpful (see below). Local physical therapies such as heat or cold can sometimes give temporary relief. Acupuncture and transcutaneous electrical nerve stimulation (TENS) have also been shown to be effective in knee OA. Antineuropathic drugs, such as amitriptyline, gabapentin and pregabalin, are sometimes used in patients with symptoms that are difficult to control, but the evidence base for their use is poor.

EBM 25.40 Management of osteoarthritis

'The following measures have been shown to be effective:
- weight loss (if overweight)
- quadriceps strengthening exercises (knee OA)
- paracetamol and/or topical NSAID
- oral NSAID
- joint replacement surgery for disabling symptoms.'

For further information www.nice.org.uk/CG59

25.41 Osteoarthritis in old age

- **Pain and disability**: OA is the principal cause in old age.
- **Calcium phosphate deposition disease**: may cause acute attacks of synovitis (pseudogout) on a background of chronic OA.
- **Falls**: reduced muscle strength and pain associated with lower limb OA increase the risk.
- **Muscle strengthening exercises**: safely reduce the pain and disability of knee OA with accompanying improvements in balance and reduced tendency to fall.
- **Oral paracetamol and topical NSAID**: safe in older people, with no important drug interactions or contraindications.
- **Intra-articular injection of corticosteroid**: a very safe and often effective treatment, particularly useful for tiding a patient over a special event.
- **Total joint replacement**: an excellent cost-effective treatment for severe disabling knee or hip OA in older people. There is no age limit for joint replacement surgery.

Corticosteroid injections

Intra-articular corticosteroid injections are effective in the treatment of knee OA and are also used for symptomatic relief in the treatment of OA at the first CMC joint. The duration of effect is usually short but trials of serial corticosteroid injections every 3 months in knee OA have shown efficacy for up to 1 year.

Chondroitin and glucosamine

Chondroitin sulphate and glucosamine sulphate have been used alone and in combination for the treatment of knee OA. There is evidence from randomised controlled trials that these agents can improve knee pain to a small extent (3–5%), as compared with placebo. Although NICE did not consider these differences to be clinically significant, the beneficial effects of paracetamol in knee OA are equally small.

Hyaluronan injections

In knee OA, intra-articular injection of one of several forms of hyaluronan (polymers of hyaluronate), usually given as a course of weekly injections for 3–5 weeks, may give modest pain relief for several months. However, evidence for efficacy is heterogeneous and the expense of this treatment and the common requirement for serial injection mean that hyaluronan injections are not recommended for OA by NICE.

Disease-modifying therapies

There are no licensed drugs that can halt the progression of OA. Glucosamine sulphate was shown in one study to slow the rate of radiological progression in knee OA and to reduce the number of subjects who progressed to joint replacement but the study has been criticised on methodological grounds. A recent randomised controlled trial suggested that strontium ranelate might also be effective in reducing the rate of progression of knee OA but it is not licensed for this indication.

Surgery

Surgery should be considered for patients with OA whose pain, stiffness and reduced function impact significantly on their quality of life and are refractory to other treatments. Osteotomy can prolong the life of malaligned joints and relieve pain by reducing intraosseous pressure, but is performed infrequently. Total joint replacement surgery is by far the most common surgical procedure for patients with OA. It can transform the quality of life for people with severe knee or hip OA and is indicated when there is significant structural damage on X-ray, and pain and functional impairment are limiting quality of life despite the use of medical therapy. Although surgery should not be undertaken at an early stage during the development of OA, it is important to consider it before functional limitation has become advanced since this may compromise the surgical outcome. Patient-specific factors, such as age, gender, smoking and presence of obesity, should not be barriers to referral for joint replacement.

Only a small proportion of patients with OA progress to the extent that total joint replacement is required, but OA is by far the most frequent indication for a total joint replacement. Over 95% of joint replacements continue to function well into the second decade after surgery and most provide life-long, pain-free function. However, some 20% of patients are not satisfied with the outcome, and a few experience little or no improvement in pain.

CRYSTAL-INDUCED ARTHRITIS

A variety of crystals can deposit in and around joints and cause an acute inflammatory arthritis, as well as a

25.42 Crystal-associated arthritis and deposition in connective tissue

Crystal	Associations
Common	
Monosodium urate monohydrate	Acute gout Chronic tophaceous gout
Calcium pyrophosphate dihydrate	Acute 'pseudogout' Chronic (pyrophosphate) arthropathy Chondrocalcinosis
Basic calcium phosphates	Calcific periarthritis Calcinosis
Uncommon	
Cholesterol	Chronic effusions in RA
Calcium oxalate	Acute arthritis in dialysis patients
Extrinsic crystals/semi-crystalline particles	
Synthetic crystals	Acute synovitis
Plant thorns/sea urchin spines	Chronic monoarthritis, tenosynovitis

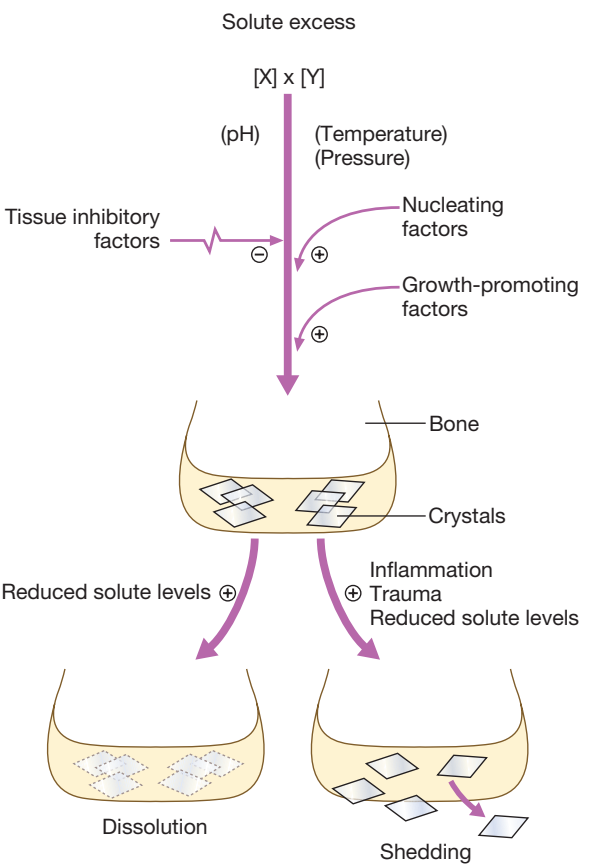

Fig. 25.22 Factors affecting the balance of crystal formation and tissue concentration.

more chronic arthritis associated with progressive joint damage (Box 25.42). Crystals can be the primary pathogenic agent, as in gout, or an accessory factor, as in calcium pyrophosphate deposition disease, in which crystals are deposited in joints that are already abnormal. Several factors influence crystal formation (Fig. 25.22). There must be sufficient concentration of the chemical components (ionic product), but whether a crystal then forms depends on the balance of tissue factors that promote and inhibit crystal nucleation and growth. Many tissues are supersaturated for the various products but depend on natural inhibitors to prevent crystallisation. The inflammatory potential of crystals resides in their physical irregularity and high negative surface charge, which can induce inflammation and damage cell membranes. Crystals may also cause mechanical damage to tissues and act as wear particles at the joint surface. Crystals can paradoxically reside in cartilage or tendon for years without causing inflammation or symptoms, and it is only when they are released that they trigger inflammation. This may occur spontaneously but can also result from local trauma, changes in the concentration of the components that form crystals, or be part of an acute phase response due to intercurrent illness or surgery.

Gout

Gout is an inflammatory disease caused by deposition of monosodium urate monohydrate crystals in and around synovial joints.

Epidemiology

The prevalence of gout varies between populations but is approximately 1–2%, with a greater than 5:1 male preponderance. It is the most common inflammatory arthritis in men and in older women. The risk of developing gout increases with age and with serum uric acid (SUA) levels, which are normally distributed in the general population. Levels are higher in men, increase with age and are associated with body weight. Levels are higher in some ethnic groups (such as Maoris and Pacific islanders). Hyperuricaemia is defined as an SUA level greater than 2 standard deviations above the mean for the population. Gout has become more common over recent years in parallel with increased longevity and the higher prevalence of metabolic syndrome, of which hyperuricaemia is an integral component. Although hyperuricaemia is an independent risk factor for hypertension, vascular disease, renal disease and cardiovascular events, only a minority of hyperuricaemic people develop gout. There is currently no evidence to support the use of urate-lowering therapy in patients with asymptomatic hyperuricaemia.

Pathophysiology

About one-third of the body uric acid pool is derived from dietary sources and two-thirds from endogenous purine metabolism (Fig. 25.23). The concentration of uric acid in body fluids depends on the balance between endogenous synthesis, and elimination by the kidneys (two-thirds) and gut (one-third). Purine nucleotide synthesis and degradation are regulated by a network of enzyme pathways. Xanthine oxidase catalyses the end conversion of hypoxanthine to xanthine and then xanthine to uric acid.

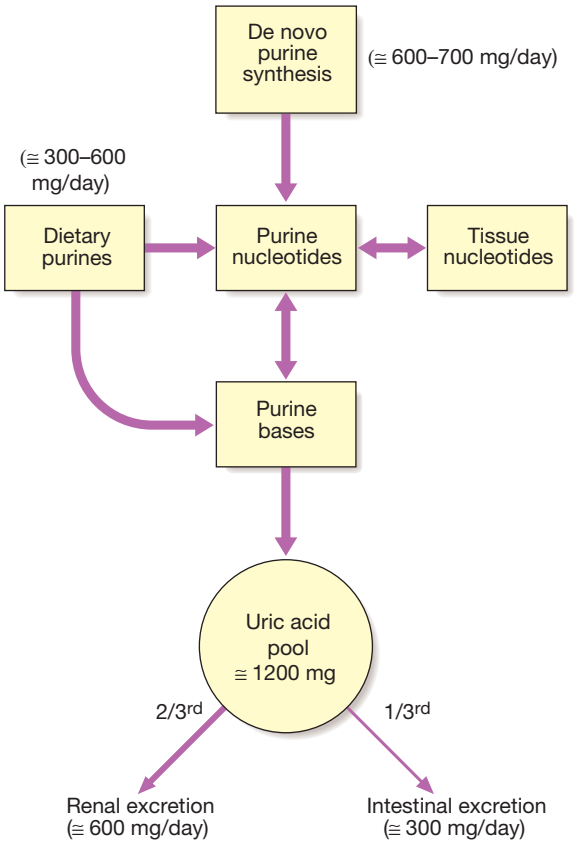

Fig. 25.23 The uric acid pool. Origins and disposal of uric acid.

25.43 Causes of hyperuricaemia and gout

Diminished renal excretion	
• Increased renal tubular reabsorption*	• Drugs Thiazide and loop diuretics Low-dose aspirin Ciclosporin Pyrazinamide
• Renal failure	
• Lead toxicity	
• Lactic acidosis	
• Alcohol	
Increased intake	
• Red meat • Seafood	• Offal
Over-production of uric acid	
• Myeloproliferative and lymphoproliferative disease • Psoriasis • High fructose intake • Glycogen storage disease (p. 450)	• Inherited disorders Lesch–Nyhan syndrome (HPRT mutations) Phosphoribosyl pyrophosphate synthetase 1 mutations

*Usually genetically determined (see text).
(HPRT = hypoxanthine guanine phosphoribosyl transferase)

The causes of hyperuricaemia are shown in Box 25.43. In over 90% of patients, the main abnormality is reduced uric acid excretion by the renal tubules, which impairs the body's ability to respond to a purine load. In many cases, this is genetically determined and recent studies

have identified polymorphisms in several genes that are associated with gout, the most important of which is *SLC2A9*, which regulates urate excretion by the kidney. Impaired renal excretion of urate also accounts for the occurrence of hyperuricaemia in chronic renal failure, and for the association between hyperuricaemia and treatment with thiazide diuretics.

Other risk factors for gout include metabolic syndrome (p. 805), high alcohol intake (predominantly beer, which contains guanosine), generalised osteoarthritis, a diet relatively high in red meat or fructose or relatively low in vitamin C or coffee, and lead poisoning (saturnine gout). The association between OA and gout is thought to be due to reduction in levels of proteoglycan and other inhibitors of crystal formation in osteoarthritic cartilage, predisposing to crystal formation.

Some patients develop gout because they overproduce uric acid. The mechanisms are poorly understood, except in the case of a few rare disorders, in which gout is inherited in a Mendelian manner as the result of mutations in genes responsible for purine synthesis (see Box 25.43). Lesch–Nyhan syndrome for example, is an X-linked recessive form of gout that is also associated with mental retardation, self-mutilation and choreoathetosis. Such conditions should be suspected if other clinical features are present or there is an early age at onset with a positive family history. Severe hyperuricaemia can also occur in patients with leukaemia undergoing chemotherapy due to increased purine turnover.

Clinical features

The classical presentation is with an acute monoarthritis, which in over 50% of cases affects the first MTP joint (Fig. 25.24). Other common sites are the ankle, midfoot, knee, small joints of hands, wrist and elbow. The axial skeleton and large proximal joints are rarely involved. Typical features include:

- rapid onset, reaching maximum severity in 2–6 hours, and often waking the patient in the early morning
- severe pain, often described as the 'worst pain ever'
- extreme tenderness, such that the patient is unable to wear a sock or to let bedding rest on the joint
- marked swelling with overlying red, shiny skin
- self-limiting over 5–14 days, with complete resolution.

During the attack, the joint shows signs of marked synovitis, swelling and erythema. There may be accompanying fever, malaise and even confusion, especially if a large joint such as the knee is involved. As the attack subsides, pruritus and desquamation of overlying skin are common. The main differential diagnosis is septic arthritis, infective cellulitis or reactive arthritis. Acute attacks may also manifest as bursitis, tenosynovitis or cellulitis, which have the same clinical characteristics. Many patients describe milder episodes lasting just a few days. Some have attacks in more than one joint. Others have further attacks in other joints a few days later (cluster attacks), the first possibly acting as a trigger. Simultaneous polyarticular attacks are unusual.

Some people never have a second episode after an acute attack. In others, several years may elapse before the next attack. In many, however, a second attack occurs within 1 year and may progress to chronic gout, with chronic pain and joint damage, and occasionally severe deformity and functional impairment. Patients with uncontrolled hyperuricaemia who suffer multiple attacks of acute gout may also progress to chronic gout.

Crystals may be deposited in the joints and soft tissues to produce irregular firm nodules called tophi. These have a predilection for the extensor surfaces of fingers, hands, forearm, elbows, Achilles tendons and sometimes the helix of the ear. Tophi have a white colour, differentiating them from rheumatoid nodules (Fig. 25.25). Tophi can ulcerate, discharging white gritty material, become infected or induce a local inflammatory response, with erythema and pus in the absence of secondary infection. They are usually a feature of long-standing gout but can sometimes develop within

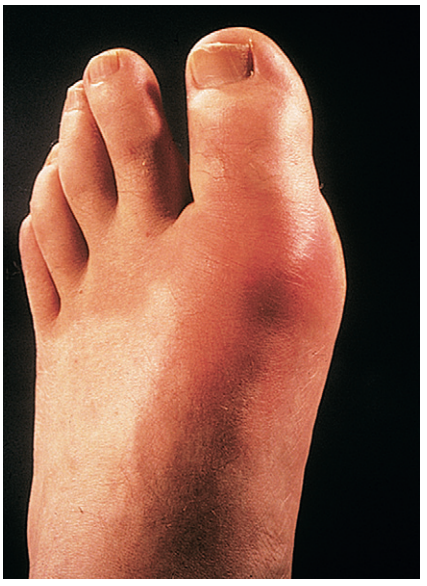

Fig. 25.24 Podagra. Acute gout causing swelling, erythema and extreme pain and tenderness of the first metatarsophalangeal joint.

Fig. 25.25 Tophus with white monosodium urate monohydrate crystals visible beneath the skin. Diuretic-induced gout in a patient with pre-existing nodal OA.

12 months in patients with chronic renal failure. Occasionally, tophi may develop in the absence of previous acute attacks, especially in patients on thiazide therapy who have coexisting OA.

In addition to causing musculoskeletal disease, chronic hyperuricaemia may be complicated by renal stone formation (p. 507) and, if severe, renal impairment due to the development of interstitial nephritis as the result of urate deposition in the kidney. This is particularly common in patients with chronic tophaceous gout who are on diuretic therapy.

Investigations

The diagnosis of gout can be confirmed by the identification of urate crystals in the aspirate from a joint, bursa or tophus (see Fig. 25.5A, p. 1064). In acute gout, synovial fluid shows increased turbidity due to the greatly elevated cell count (> 90% neutrophils). In chronic gout, the appearance is more variable but occasionally the fluid appears white due to the high crystal load. Between attacks, aspiration of an asymptomatic first MTP joint or knee may still reveal crystals.

A biochemical screen, including renal function, uric acid, glucose and lipid profile, should be performed because of the association with metabolic syndrome. Although hyperuricaemia is usually present, this does not confirm the diagnosis. Conversely, normal uric acid levels during an attack do not exclude gout, as serum urate falls during the acute phase response. Elevated ESR and CRP and a neutrophilia are typical of acute gout, and they return to normal as the attack subsides. Tophaceous gout may be accompanied by a modest but chronic elevation in ESR and CRP.

Radiographs are usually normal in acute gout but well-demarcated erosions may be seen in patients with chronic or tophaceous gout (Fig. 25.26). Tophi may also be visible on X-rays as soft tissue swellings. In late disease, destructive changes may occur similar to those in other forms of advanced inflammatory arthritis.

Management

Oral NSAIDs are effective for pain relief in the acute attack and are the standard treatment, but have to be prescribed with caution in old age. Local ice packs can also be used for symptomatic relief. Patients with recurrent episodes can keep a supply of an NSAID and take it as soon as the first symptoms occur, continuing until the attack resolves. Oral colchicine, which works by inhibiting microtubule assembly in neutrophils, is also very effective. It is usually given in doses of 0.5 mg twice or 3 times daily. The most common adverse effects are nausea, vomiting and diarrhoea. Joint aspiration can give pain relief, and may be combined with an intra-articular steroid injection if the diagnosis is clear and infection can be excluded. A short course of oral or intramuscular corticosteroids can also be highly effective in treating acute attacks.

Patients who have more than one acute attack within 12 months and those with complications should be offered urate-lowering therapy (Box 25.44). The long-term therapeutic aim is to prevent attacks occurring by bringing uric acid levels below the level at which monosodium urate monohydrate crystals form. A therapeutic target of 360 µmol/L (6 mg/dL) is recommended in the British Society of Rheumatology guidelines, whereas the European League Against Rheumatism guidelines recommend a threshold of 300 µmol/L (5 mg/dL).

Allopurinol is the drug of first choice. It is a xanthine oxidase inhibitor, which reduces the conversion of hypoxanthine and xanthine to uric acid. The recommended starting dose is 100 mg daily, or 50 mg in older patients and in renal impairment. The dose of allopurinol should be increased by 100 mg every 4 weeks (50 mg in the elderly and those with renal impairment) until the target uric acid level is achieved, side-effects occur or the maximum recommended dose is reached (900 mg/day). Acute flares of gout often occur following initiation of urate-lowering therapy. The patient should be warned about this and told to continue therapy, even if an attack occurs. The risk of flares can be reduced by administration of oral colchicine (0.5 mg twice daily) or NSAID therapy for the first few months. In the longer term, annual monitoring of uric acid levels is recommended. In most patients, urate-lowering therapy needs to be continued indefinitely.

Febuxostat is a xanthine oxidase inhibitor that is useful in patients who fail to respond adequately to allopurinol, and those in whom it is contraindicated or has been poorly tolerated. It undergoes hepatic metabolism and so no dose adjustment is required for renal impairment. It is more effective than allopurinol at reducing uric acid levels and, as a result, commonly provokes attacks at the recommended starting dose (80 mg daily). In view of this, treatment with colchicine or NSAID should be considered for the initial 6 months.

Uricosuric drugs, such as probenecid or sulfinpyrazone, can be effective but require several doses each day and maintenance of a high urine flow to avoid uric

Fig. 25.26 Erosive arthritis in chronic gout. Punched-out erosions are visible (arrows), in association with a destructive arthritis affecting the first metatarsophalangeal joint.

25.44 Indications for urate-lowering drugs

- Recurrent attacks of acute gout
- Tophi
- Evidence of bone or joint damage
- Renal impairment
- Nephrolithiasis
- Very high levels of serum uric acid

25.45 Gout in old age

- **Aetiology**: a higher proportion of older patients have gout secondary to diuretic use and chronic kidney disease. Gout is often associated with OA.
- **Presentation**: may be atypical, with painful tophi and chronic symptoms, rather than acute attacks. Joints of the upper limbs are more frequently affected.
- **Management**: acute attacks are best treated by aspiration and intra-articular injection of corticosteroids, followed by early mobilisation. NSAID and colchicine should be used with caution because of increased risk of toxicity. Low doses of allopurinol (50 mg/day) should be given, and increased gradually to avoid toxicity.

25.46 Risk factors for chondrocalcinosis

Common

- Age
- Osteoarthritis*
- Primary hyperparathyroidism

Rare

- Familial*
- Haemochromatosis*
- Hypophosphatasia
- Hypomagnesaemia
- Wilson's disease

*May be associated with structural damage to affected joints.

acid crystallisation in renal tubules. Salicylates antagonise the uricosuric action of these drugs and should be avoided. Uricosurics are contraindicated in overproducers, those with renal impairment and in urolithiasis (they increase stone formation). The uricosuric benzbromarone can be very effective and safe in mild to moderate renal impairment, but can cause hepatotoxicity. It is not licensed in the UK for the treatment of hyperuricaemia.

Pegloticase is a biological treatment in which the enzyme uricase has been conjugated to monomethoxypolyethylene glycol. It is indicated for the treatment of tophaceous gout resistant to standard therapy and is administered as an intravenous infusion every 2 weeks for up to 6 months. It is highly effective at controlling hyperuricaemia and causes regression of tophi. The main adverse effects are infusion reactions (which can be treated with antihistamines or steroids) and flares of gout during the first 3 months of therapy. A limiting factor for longer-term treatment is the development of antibodies to pegloticase, which occur in a high proportion of cases and are associated with an impaired therapeutic response.

In addition to drug treatment, predisposing factors should be corrected if possible. Patients should be advised to lose weight where appropriate and to reduce excessive alcohol intake, especially beer. Thiazide diuretics should be stopped if possible and substituted with angiotensin-converting enzyme (ACE) inhibitors, as these have a uricosuric effect. Patients should be advised to avoid large amounts of seafood and offal, which have a high purine content, but a highly restrictive diet is not necessary.

Calcium pyrophosphate dihydrate crystal deposition disease

This condition is associated with deposition of calcium pyrophosphate dihydrate (CPPD) crystals within articular and hyaline cartilage and is sometimes known as 'pseudogout'. It is rare under the age of 55, but occurs in 10–15% of people between the ages of 65 and 75 years and in 30–60% of those over 85. The knee (hyaline cartilage and menisci) is by far the most common site, followed by the wrist (triangular fibrocartilage) and pelvis (symphysis pubis). Risk factors are shown in Box 25.46. In many patients, chondrocalcinosis is asymptomatic

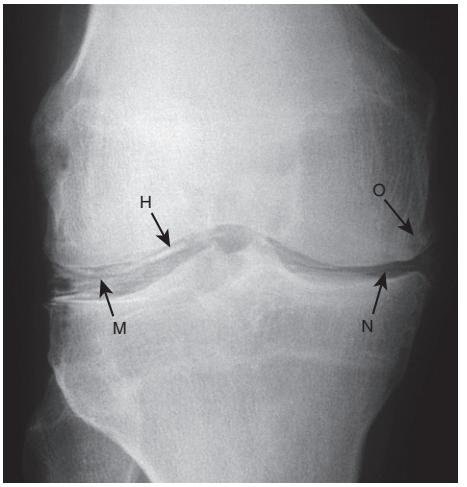

Fig. 25.27 Chondrocalcinosis of the knee. The X-ray shows calcification of the fibrocartilaginous menisci (M) and articular hyaline cartilage (H). There is also narrowing (N) and osteophyte (O) of the medial tibio-femoral compartment.

and an incidental finding on X-ray examination, but others present with an acute inflammatory arthritis (pseudogout) or a chronic inflammatory arthropathy superimposed on a background of OA, especially at the knee (Fig. 25.27), associated with joint damage and functional limitation.

Pathophysiology

The underlying mechanisms of crystal deposition are poorly understood. Clinical studies have shown that pyrophosphate levels are raised in patients with CPPD crystal deposition disease, possibly due to over-production, but why this occurs is unclear. In hypophosphatasia, the predisposing factor is thought to be impaired degradation of pyrophosphate due to mutations in the genes that encode ALP. OA is thought to predispose to CPPD crystal deposition disease because of a reduction in the amounts of proteoglycan and other natural inhibitors of crystal formation in the abnormal cartilage.

Clinical features

A common presentation is with an acute inflammatory arthritis that resembles acute gout, sometimes termed 'pseudogout'. Examination reveals a warm, tender

erythematous joint with signs of a large effusion. Fever is common and the patient may appear confused and ill. The knee is most commonly affected, followed by the wrist, shoulder, ankle and elbow. Trigger factors include trauma, intercurrent illness and surgery. Sepsis and gout are the main differential diagnoses.

Chronic arthropathy may also occur in association with CPPD crystal deposition disease, affecting the same joints that are involved in acute pseudogout. The presentation is with chronic pain, early morning stiffness, inactivity gelling and functional impairment. Acute attacks of pseudogout may be superimposed. Affected joints usually show features of OA, with varying degrees of synovitis. Effusion and synovial thickening are usually most apparent at knees and wrists; wrist involvement may result in carpal tunnel syndrome. Inflammatory features may be sufficiently pronounced to suggest RA, but tenosynovitis and extra-articular involvement are absent, and large and medium rather than small joints are targeted. Severe damage and instability of knees or shoulders may occasionally lead to consideration of a neuropathic joint, but no neurological abnormalities will be found.

Investigations

Examination of synovial fluid using compensated polarised microscopy will demonstrate CPPD crystals (see Fig. 25.5B, p. 1064) and permit distinction from gout. The aspirated fluid is often turbid and may be uniformly blood-stained, reflecting the severity of inflammation. Since sepsis and pseudogout can coexist, Gram stain and culture of the fluid should be performed to exclude sepsis, even if CPPD crystals are identified in synovial fluid.

X-rays of the affected joint may show evidence of calcification in hyaline cartilage and/or fibrocartilage, although absence of calcification does not exclude the diagnosis. Signs of OA are frequently present. Screening for secondary causes (see Box 25.46) should be undertaken, especially in patients who present under the age of 25 and those with polyarticular disease.

Management

Joint aspiration can often provide symptomatic relief in pseudogout and sometimes no further treatment is required. Patients with persistent symptoms can be treated with intra-articular corticosteroids, colchicine or NSAID. Since most patients with pseudogout are elderly, NSAID must be used with caution. Early active mobilisation is also important. Chronic pyrophosphate-induced arthropathy should be managed as for OA (p. 1085).

Basic calcium phosphate deposition disease

Basic calcium phosphate (BCP) deposition disease is caused by the deposition of hydroxyapatite or apatite crystals and other basic calcium phosphate salts (octacalcium phosphate, tricalcium phosphate) in soft tissues. The main affected sites are tendons, ligaments and hyaline cartilage in patients with degenerative disease, and skeletal muscle and subcutaneous tissues in connective tissue diseases.

25.47 Rheumatic diseases associated with basic calcium phosphate deposition

Disease	Site of calcification
Calcific periarthritis	Tendons and ligaments
Dermatomyositis and polymyositis	Subcutaneous tissue
Systemic sclerosis and CREST syndrome	Subcutaneous tissue
Mixed connective tissue disease	Subcutaneous tissue
Paget's disease of bone	Blood vessels
Ankylosing spondylitis	Ligaments
Fibrodysplasia ossificans progressiva	Subcutaneous tissues and muscle
Milwaukee shoulder syndrome	Tendons and ligaments
Albright's hereditary osteodystrophy	Muscle

(CREST = calcinosis, Raynaud's, oesophageal dysmotility, sclerodactyly, telangiectasia)

Pathophysiology

Under normal circumstances, inhibitors of mineralisation, such as pyrophosphate and proteoglycans, inhibit calcification of soft tissues. When these protective mechanisms break down, abnormal calcification occurs. There are many causes (Box 25.47). In most situations, calcification is of no consequence, but when the crystals are released, an inflammatory reaction may be initiated, causing local pain and inflammation.

Calcific periarthritis

Deposition of BCP in tendons may result in an acute inflammatory response. The most commonly affected site is the supraspinatus tendon (Fig. 25.28) but other sites may also be affected, including the tendons around the hip, feet and hands. The presentation is with acute pain, swelling and local tenderness that develops rapidly

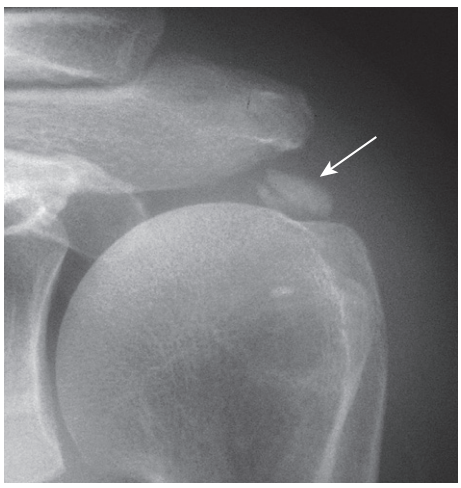

Fig. 25.28 Shoulder X-ray showing supraspinatus tendon calcification (arrow).

over 4–6 hours. The overlying skin may be hot and red, raising the possibility of infection. Attacks sometimes occur spontaneously but can also be triggered by trauma. Modest systemic upset and fever are common. X-rays show tendon calcification. If the affected joint or bursa is aspirated, inflammatory fluid containing many calcium-staining (alizarin red S) aggregates may be obtained. During an acute attack, there may be a neutrophilia with an elevation in ESR and CRP. Routine biochemistry is normal. Treatment is with analgesics and NSAID. Attacks may also respond to a local injection of corticosteroid. The condition usually resolves spontaneously over 1–3 weeks and this is often accompanied by dispersal and disappearance of small to medium-sized BCP deposits on X-ray. Large deposits sometimes accumulate, causing limitation of joint movement, and may require surgical removal.

Acute inflammatory arthritis

Deposition of BCP occurs commonly in OA, both alone and in combination with CPPD crystals, when it is referred to as mixed crystal deposition disease. It may present with pseudogout or be an incidental finding.

Milwaukee shoulder syndrome

This is a rare syndrome, in which extensive deposition of BCP crystals in large joints is associated with progressive joint destruction. It is more common in women than in men. The onset is gradual with joint pain, sometimes precipitated by injury or overuse. The disease progresses over a few months to cause severe pain and disability, associated with joint destruction. X-rays show joint space narrowing, osteophytes and calcification. Aspiration yields large volumes of relatively non-inflammatory fluid containing abundant BCP aggregates and often cartilage fragments. The differential diagnosis is end-stage avascular necrosis, chronic sepsis or neuropathic joint. There is no acute phase response and synovial fluid cultures are negative.

Treatment is with analgesics, intra-articular injection of corticosteroids, local physical treatments and physiotherapy. The clinical outcome is poor, however, and most patients require joint replacement. The cause is incompletely understood but it has been speculated that deposition of BCP crystals activates collagenase and other proteases in articular cells, which are responsible for the tissue damage.

Connective tissue disease

Deposition of BCP may occur in the subcutaneous tissues and muscle of patients with scleroderma and other connective tissue disease. Usually, the deposits are asymptomatic but can be associated with pain and local ulceration. There is no specific treatment.

FIBROMYALGIA

This is a common cause of generalised regional pain and disability, and is frequently associated with medically unexplained symptoms in other systems (p. 236). The prevalence in the UK and US is about 2–3%. Although fibromyalgia can occur at any age, including adolescence, it increases in prevalence with age, to reach a peak of 7% in women aged over 70. There is a strong female predominance of around 10:1. Risk factors include life events that cause psychosocial distress, such as marital disharmony, alcoholism in the family, injury or assault, low income and self-reported childhood abuse (Box 25.48). It occurs in a wide variety of races and cultures.

EBM 25.48 Predisposing factors for fibromyalgia

'Epidemiological studies show that widespread body pain, fatigue, psychological distress and multiple hyperalgesic tender sites cluster together and associate with stressful life events.'

- Wolfe F, et al. Arthritis Rheum 1995; 38:19–28.
- Croft P, et al. BMJ 1994; 309:696–699.

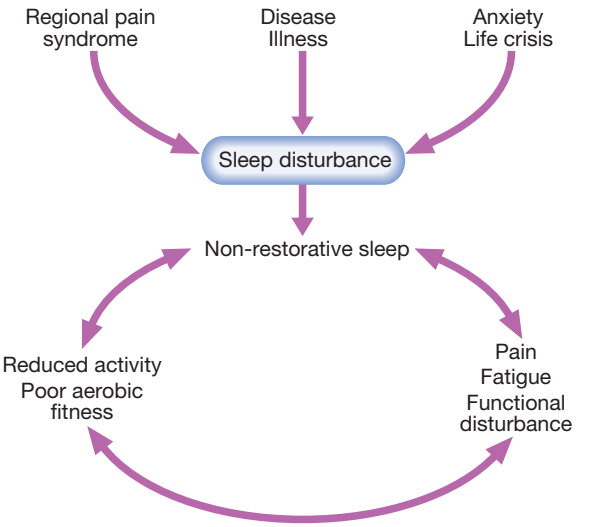

Fig. 25.29 Possible causative mechanisms in fibromyalgia.

Pathophysiology

The cause of fibromyalgia is poorly understood but two abnormalities that may be interrelated (Fig. 25.29) have been consistently reported in affected patients.

Sleep abnormality

Delta waves are characteristic of deep stages of non-rapid eye movement (non-REM) sleep, usually occurring in the first few hours and thought to have an important restorative function. People with fibromyalgia have reduced delta sleep in a pattern distinct from that seen with depression. Furthermore, deprivation of delta but not REM sleep in normal volunteers produces the symptoms and signs of fibromyalgia, supporting it as a non-restorative sleep disorder.

Abnormal peripheral and central pain processing

A reduced threshold of pain perception and tolerance at characteristic sites throughout the body is characteristic of fibromyalgia. Affected people have peripheral sensitisation and spinal cord 'wind-up' (pain amplification), with an exaggerated skin flare response to topically applied capsaicin, and frequent occurrence of dermatographism and allodynia (normally non-noxious stimuli become painful). Abnormal central pain processing is suggested by altered cerebrospinal fluid levels of substance P (increased) and serotonin (reduced); reduced basal levels of regional cerebral blood flow in the

caudate and thalamus with an augmented processing response on functional MRI; low basal free cortisol and reduction in evening trough; and altered descending inhibition via the hypothalamic–pituitary–adrenal and growth hormone somatomedin axes.

Clinical features

The main presenting feature is widespread pain, which is often worst in the neck and back (Box 25.49). The pain is characteristically diffuse and unresponsive to analgesics and NSAID. Physiotherapy often makes it worse. Fatiguability, most prominent in the morning, is another major problem and disability is often marked. Although people can usually dress, feed and groom themselves, they may be unable to perform tasks such as shopping or housework. They may have experienced major difficulties at work or even retire because of pain and fatigue.

Examination is unremarkable, apart from the presence of hyperalgesia on moderate digital pressure in multiple sites (Fig. 25.30). The tenderness can be quantitated using metered dolorimeters but moderate digital pressure, enough just to whiten the nail, is sufficient for clinical diagnosis. Patients with other musculoskeletal diseases can develop fibromyalgia and it is important to determine to what extent symptoms are related to fibromyalgia or a coexisting disease.

Investigations and management

There are no abnormalities on routine blood tests or imaging, but it is important to screen for other conditions that could contribute to some of the patient's symptoms (Box 25.50).

The aims of management are to educate the patient about the condition, achieve pain control and improve sleep. Wherever possible, education should include the

25.49 Clinical features in fibromyalgia

Usual symptoms

- Multiple regional pain
- Marked fatigability
- Marked disability
- Broken, non-restorative sleep
- Low affect, irritability, weepiness
- Poor concentration, forgetfulness

Variable locomotor symptoms

- Early morning stiffness
- Swelling of hands, fingers
- Numbness, tingling of all fingers

Additional, variable, non-locomotor symptoms

- Non-throbbing bifrontal headache (tension headache)
- Colicky abdominal pain, bloating, variable bowel habit (irritable bowel syndrome)
- Bladder fullness, nocturnal frequency (irritable bladder)
- Hyperacusis, dyspareunia, discomfort when touched (allodynia)
- Frequent side-effects with drugs (chemical sensitivity)

25.50 Minimum investigation screen in fibromyalgia

Test	Condition screened
Full blood count	Anaemia, lymphopenia of SLE
Erythrocyte sedimentation rate, C-reactive protein	Inflammatory disease
Thyroid function	Hypothyroidism
Calcium, alkaline phosphatase	Hyperparathyroidism, osteomalacia
Antinuclear antibodies	SLE

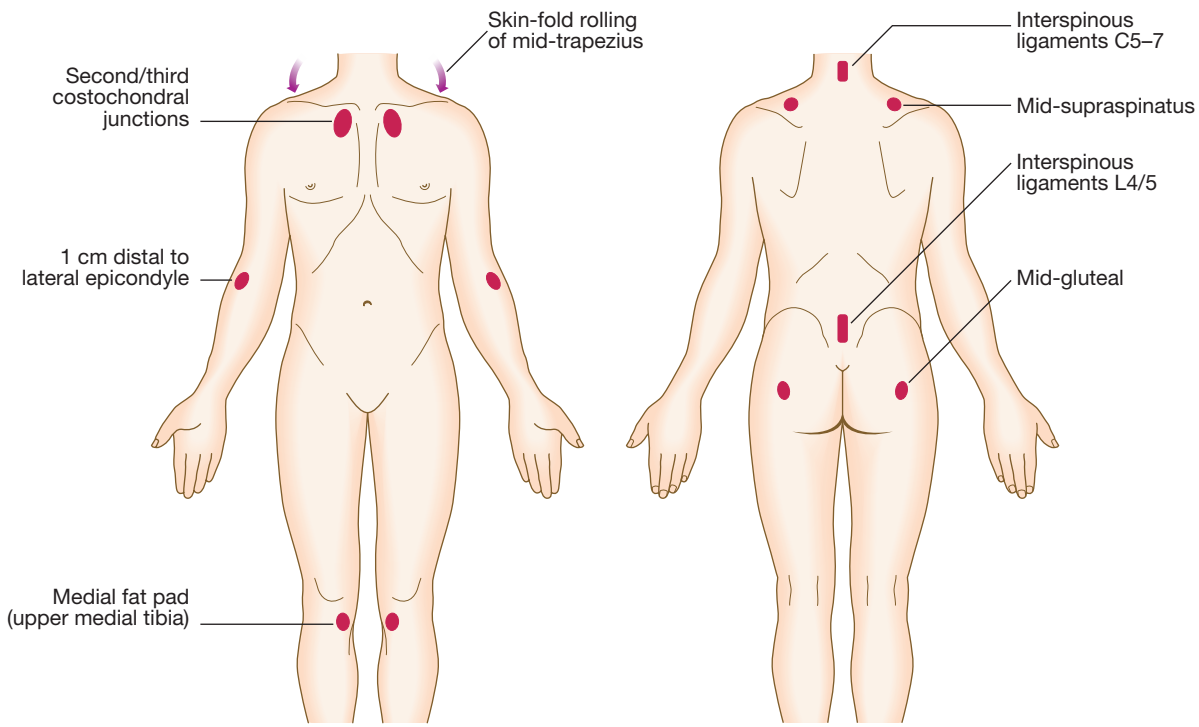

Fig. 25.30 Typical tender spots in fibromyalgia.

spouse, family or carer. It should be acknowledged that the cause of fibromyalgia is not fully understood but the widespread pain does not reflect inflammation, tissue damage or disease. The model of a self-perpetuating cycle of poor sleep and pain (see Fig. 25.29) is a useful framework for problem-based management. Understanding the diagnosis can often help the patient come to terms with the symptoms. Repeat or drawn-out investigation may reinforce beliefs in occult serious pathology and should be avoided.

Low-dose amitriptyline (10–75 mg at night), with or without fluoxetine, may help by encouraging delta sleep and reducing spinal cord wind-up. Many people with fibromyalgia, however, are intolerant of even small doses of amitriptyline. There is limited evidence for the use of tramadol, serotonin–noradrenaline (norepinephrine) re-uptake inhibitors (SNRIs) such as duloxetine, and the anticonvulsants pregabalin and gabapentin. A graded increase in aerobic exercise can improve well-being and sleep quality. The use of self-help strategies and a cognitive behavioural approach with relaxation techniques should be encouraged. Sublimated anxiety relating to distressing life events should be specifically explored with appropriate counselling. There are patient organisations that provide additional information and support.

The prognosis for hospital-diagnosed fibromyalgia is poor. Although treatment may improve quality of life and ability to cope, most people do not lose their symptoms over 5 years. Subjects diagnosed in primary care, or who have sublimated anxiety that can be successfully addressed, may fare better.

BONE AND JOINT INFECTION

Septic arthritis

Septic arthritis is the most rapid and destructive joint disease, and is associated with significant morbidity and a mortality of 10%. This has not improved over the last 20 years, despite advances in antimicrobial therapy. The incidence is 2–10 per 100 000 in the general population, and 30–70 per 100 000 in those with pre-existing joint disease or joint replacement.

Septic arthritis is usually due to haematogenous spread from either skin or upper respiratory tract; infection from direct puncture wounds or secondary to joint aspiration is uncommon. Risk factors include increasing age, pre-existing joint disease (principally RA), diabetes mellitus, immunosuppression (by drugs or disease) and intravenous drug misuse. In RA, the skin is a frequent portal of entry because of maceration of skin between the toes due to joint deformity and difficulties with foot hygiene due to hand deformity. Box 25.51 describes the particular considerations in old age.

Clinical features

The usual presentation is with acute or subacute monoarthritis and fever. The joint is usually swollen, hot and red, with pain at rest and on movement. Although any joint can be affected, lower limb joints, such as the knee and hip, are commonly targeted. Patients with pre-existing arthritis may present with multiple joint involvement.

25.51 Joint and bone infection in old age

- **Vertebral infection**: more common. Recognition may be delayed, as symptoms may be attributed to compression fractures caused by osteoporosis.
- **Peripheral vascular disease**: leads to more frequent involvement of the bones of the feet, and diabetic foot ulcers are also commonly complicated by osteomyelitis.
- **Prosthetic joint infections**: now more common because of the increased frequency of prosthetic joint insertion in older people.
- **Gram-negative bacilli**: more frequent pathogens than in younger people.

In adults, the most likely organism is *Staphylococcus aureus*, particularly in patients with RA and diabetes. In young, sexually active adults, disseminated gonococcal infection occurs in up to 3% of untreated gonorrhoea, usually presenting with migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of oligo- or monoarthritis. Painful pustular skin lesions may also be present. Amongst the elderly and intravenous drug users, Gram-negative bacilli or group B, C and G streptococci are important causes. Group A streptococci, pneumococci, meningococci and *Haemophilus influenzae* are occasionally isolated.

Investigations

The pivotal investigation is joint aspiration but blood cultures should also be taken. The synovial fluid is usually turbid or blood-stained but may appear normal. If the joint is not readily accessible, aspiration should be performed under imaging guidance or in theatre. Prosthetic joints should only be aspirated in theatre.

Synovial fluid should be sent for Gram stain and culture; cultures are positive in around 90% of cases, but the Gram stain is positive in only 50%. In contrast, synovial fluid culture is positive in only 30% of gonococcal infections, making it important to obtain concurrent cultures from the genital tract (positive in 70–90% of cases). There is a leucocytosis with raised ESR and CRP in most patients, but these features may be absent in elderly or immunocompromised patients, or early in the disease course. Serial measurements of CRP and ESR are useful in following the response to treatment.

Management

The principles of management are summarised in Box 25.52. The patient should be admitted to hospital for pain relief and administration of parenteral antibiotics. Flucloxacillin (2 g IV 4 times daily) is the antibiotic of first choice pending the results of cultures, since it will cover most staphylococcal and streptococcal infections. If there is reason to suspect a Gram-negative infection, then a cephalosporin or gentamicin should be added. Microbiology advice should be sought in complicated situations such as intravenous drug users, patients in intensive care and those who might be colonised by resistant organisms. It is traditional to continue intravenous antibiotics for 2 weeks and to follow this with oral treatment for another 4 weeks, but there is no evidence to support the optimal duration of treatment. Joint aspiration should be performed using a large-bore needle once or twice daily. If this is not possible,

25.52 Emergency management of suspected septic arthritis

Admit patient to hospital

Perform urgent investigations

- Aspirate joint
  - Send synovial fluid for Gram stain and culture
  - Use imaging guidance if required (e.g. for hip)
- Send blood for culture, routine biochemistry and haematology, including ESR and CRP
- Consider sending other samples (sputum, urine, wound swab) for culture, depending on patient history, to determine primary source of infection

Commence intravenous antibiotic

- Flucloxacillin 2 g 4 times daily
- If penicillin-allergic, give clindamycin 450–600 mg 4 times daily
- If at high risk of Gram-negative sepsis (elderly, frail, recurrent urinary tract infection), add a cephalosporin (cefuroxime 1.5 g 3 times daily)

Relieve pain

- Oral and/or intravenous analgesics
- Consider local ice-packs

Aspirate joint

- Perform serial needle aspiration to dryness (1–3 times/day or as required)
- Consider arthroscopic drainage if needle aspiration difficult

Arrange physiotherapy

- Early regular passive movement, progressing to active movements once pain controlled and effusion not re-accumulating

arthroscopic or open surgical drainage may need to be undertaken. Regular passive movement should be undertaken from the outset, and active movements encouraged once the condition has stabilised. Infected prosthetic joints require management by the orthopaedic team, but often prolonged antibiotic treatment on its own is ineffective and removal of the prosthesis is required for eradication of the infection.

Arthritis may be a feature of Lyme disease caused by members of the *Borrelia* species of microorganisms. It is generally a late manifestation, which usually affects large joints. Brucellosis presents with an acute febrile illness, followed in some cases by the development of localised infection, which can result in arthritis, bursitis, osteomyelitis, sacroiliitis and paravertebral or psoas abscesses. These conditions are discussed on pages 332 and 333.

Viral arthritis

The usual presentation is with acute polyarthritis, following a febrile illness, which may be accompanied by a rash. Most cases of viral arthritis are self-limiting and settle down within 4–6 weeks. Human parvovirus (mainly B19, p. 315) arthropathy is the most common in Europe; adults may not have the characteristic 'slapped cheek' facial rash seen in children. The diagnosis can be confirmed by a rise in specific IgM. Polyarthritis may also occur rarely with hepatitis B and C, rubella (including rubella vaccination) and HIV infection. A variety of

25.53 Musculoskeletal manifestations of HIV

• Non-specific arthralgia	Most common; intermittent and polyarticular
• Reactive arthritis • Psoriatic arthritis • Idiopathic lower limb inflammatory oligoarthritis	Especially in men who have sex with men
• Osteonecrosis • Myositis • Vasculitis • Sjögren's-like disease	Unclear if related to HIV or its treatment, or intercurrent disease

mosquito-borne viruses may cause epidemics of acute polyarthritis, including Ross River (Australia, Pacific), Chikungunya and O'nyongnyong (Asia, Africa), and Mayaro viruses (South America). A wide variety of articular symptoms have been associated with HIV, mainly in the later stages of infection (Box 25.53). Management is symptomatic, with NSAID and analgesics.

Osteomyelitis

In osteomyelitis, the primary site of infection is bone and bone marrow. Any part of a bone may be involved but there is preferential targeting of the juxta-epiphyseal regions of long bones adjacent to joints. The usual source is through haematogenous spread, although directly introduced infection may complicate trauma or orthopaedic surgery. The organisms most frequently implicated are staphylococci, *Pseudomonas* and *Mycobacterium tuberculosis*. Osteomyelitis occurs most commonly in childhood and adolescence. Risk factors include diabetes mellitus (especially involving the foot), compromised immunity (including AIDS) and sickle cell disease, which particularly increases the risk of *Salmonella* infection. The infection often results in a florid inflammatory response, with a greatly increased intraosseous pressure. If untreated, the condition may cause localised areas of osteonecrosis, leading to the development of a fragment of necrotic bone that is called a sequestrum. Eventual perforation of the cortex by pus stimulates local new bone formation (involucrum) in the periosteum, often leading to the development of sinuses that discharge through the skin.

Clinical features and investigations

The presentation is with localised bone pain and tenderness, often accompanied by malaise, night sweats and pyrexia. The adjacent joint may be painful to move and may develop a sterile effusion or secondary septic arthritis. X-rays may show evidence of osteopenia, localised osteolysis and osteonecrosis, but the imaging modality of choice is MRI, which is much more sensitive for detecting early changes. Cultures should be performed, where possible, by open or imaging-guided biopsy. Blood cultures should be taken, which may also reveal the causative organism.

Management

Early recognition and management is critical; once osteomyelitis becomes established and chronic, it may prove very hard to eradicate the infection with

antibiotics alone. The principles are those followed for septic arthritis, with parenteral antibiotics for at least 2 weeks, followed by oral antibiotics for at least 4 weeks. Resection of the infected bone and subsequent reconstruction are often required. Complications of chronic osteomyelitis include secondary amyloidosis (p. 86) and skin malignancy at the margin of a discharging sinus (Marjolin's ulcer).

Tuberculosis

Tuberculosis can affect the musculoskeletal system, usually targeting the spine (Pott's disease) or large joints such as the hip, knee or ankle. The presentation is with pain, swelling and fever. The X-ray changes are non-specific and mycobacteria are seldom identified in the synovial fluid, so tissue biopsy is required for a definite diagnosis. Medical management is described on page 693. In some cases, surgical débridement may be required for extensive joint disease, and spinal involvement may require surgical stabilisation and decompression.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is the most common persistent inflammatory arthritis, occurring throughout the world and in all ethnic groups. The prevalence is lowest in black Africans and Chinese, and highest in Pima Indians. In Caucasians, approximately 0.8–1.0% are affected, with a female to male ratio of 3:1. The clinical course is prolonged, with intermittent exacerbations and remissions. Patients with RA have an increased mortality when compared with age-matched controls, primarily due to an increased risk of cardiovascular disease. This is most marked in those with severe disease, with a reduction in expected lifespan by 8–15 years. Around 40% of RA patients are registered as disabled within 3 years of onset, and around 80% are moderately to severely disabled within 20 years. Functional capacity decreases most rapidly at the beginning of disease and the functional status of patients within their first year of RA is often predictive of long-term outcome. Factors that associate with a poorer prognosis are disability at presentation, female gender, involvement of MTP joints, radiographic damage at presentation, smoking and a positive RF or ACPA. It is likely that the prognosis of RA will improve as more effective treatment regimens are introduced in patients with early disease. In former years, around 25% of patients required a large joint replacement but rates are now falling, probably reflecting more aggressive and effective medical therapy.

Pathophysiology

Genetic, epigenetic and environmental factors are implicated in the pathogenesis of RA. The concordance rate of RA is higher in monozygotic (12–15%) than in dizygotic twins (3%), and there is an increased frequency of disease in first-degree relatives of patients. Genome-wide association studies have detected more than 30 loci that are associated with the risk of developing RA or with severity of disease once it is established. Many of the risk genes are involved in the function of the immune system, and include major histocompatibility complex (MHC) class II, *PTPN22*, *CD40L* and *CTLA4*. The MHC class II gene, *HLA-DR4*, is the major susceptibility haplotype in most ethnic groups, occurring in 50–75% of Caucasian patients with RA, compared to 20–25% of the normal population. However, *DR1* is more important in Indians and Israelis, and *DW15* in Japanese. It has long been thought that RA may be triggered by an infectious agent in a genetically susceptible host, but a specific pathogen has not been identified. Periodontal disease and oral pathogens have been implicated, as have gastrointestinal organisms, and viruses such as Epstein–Barr and cytomegalovirus. Cigarette smoking is a strong risk factor for developing RA, especially in people with *HLA-DR4*, and is also associated with greater disease severity and reduced responsiveness to DMARD and biological treatment. Susceptibility is increased postpartum and by breastfeeding, indicating that hormone/immune interactions may be important.

The clinical onset of RA is characterised by infiltration of the synovial membrane with lymphocytes, plasma cells, dendritic cells and macrophages. $CD4^+$ T lymphocytes, including Th1 cells (interferon-gamma (IFN-γ) producers) and Th17 cells (IL-17A, IL-17F and IL-22 producers), play a central role by interacting with other cells in the synovium. Lymphoid follicles form within the synovial membrane in which T cell–B cell interactions lead B cells to produce cytokines and autoantibodies, including RF and ACPA. Synovial macrophages are activated by immune complexes and local damage-associated molecules acting via Toll-like receptors, to produce pro-inflammatory cytokines, including TNF, IL-1, IL-6 and IL-15. These act on synovial fibroblasts, to promote swelling of the synovial membrane and damage to soft tissues and cartilage. Fibroblasts, in particular, form a rich source of inflammatory cytokines, chemokines, leukotrienes and matrix metalloproteinases that drive local tissue damage and remodelling. Similarly, activation of osteoclasts by RANKL and chondrocytes by cytokines such as IL-1 and TNF drives destruction of bone and cartilage respectively (Fig. 25.31). The RA joint is hypoxic and this promotes new blood vessel formation (neoangiogenesis). Thus the inflamed synovium becomes vascularised, with highly activated endothelial cells supporting the recruitment of yet more leucocytes to perpetuate the inflammatory process. Amongst the range of inflammatory mediators present in the RA joint, TNF plays an important role by regulating production of other cytokines, whose actions are shown in Figure 25.31, and by activating the endothelium. IL-6 similarly plays a critical inflammatory role within the joint and also in regulating the systemic effects of RA by inducing the acute phase response, anaemia of chronic disease, fatigue and reduced cognitive function.

The inflammatory granulation tissue (pannus) formed by the above sequence of events spreads over and under the articular cartilage, which is progressively eroded and destroyed. Maturation of osteoclasts in the synovial membrane and in adjacent bone combine to erode bony structures. Later, fibrous or bony ankylosis may occur. Muscles adjacent to inflamed joints atrophy and may be infiltrated with lymphocytes. This leads to progressive biomechanical dysfunction and may further amplify destruction.

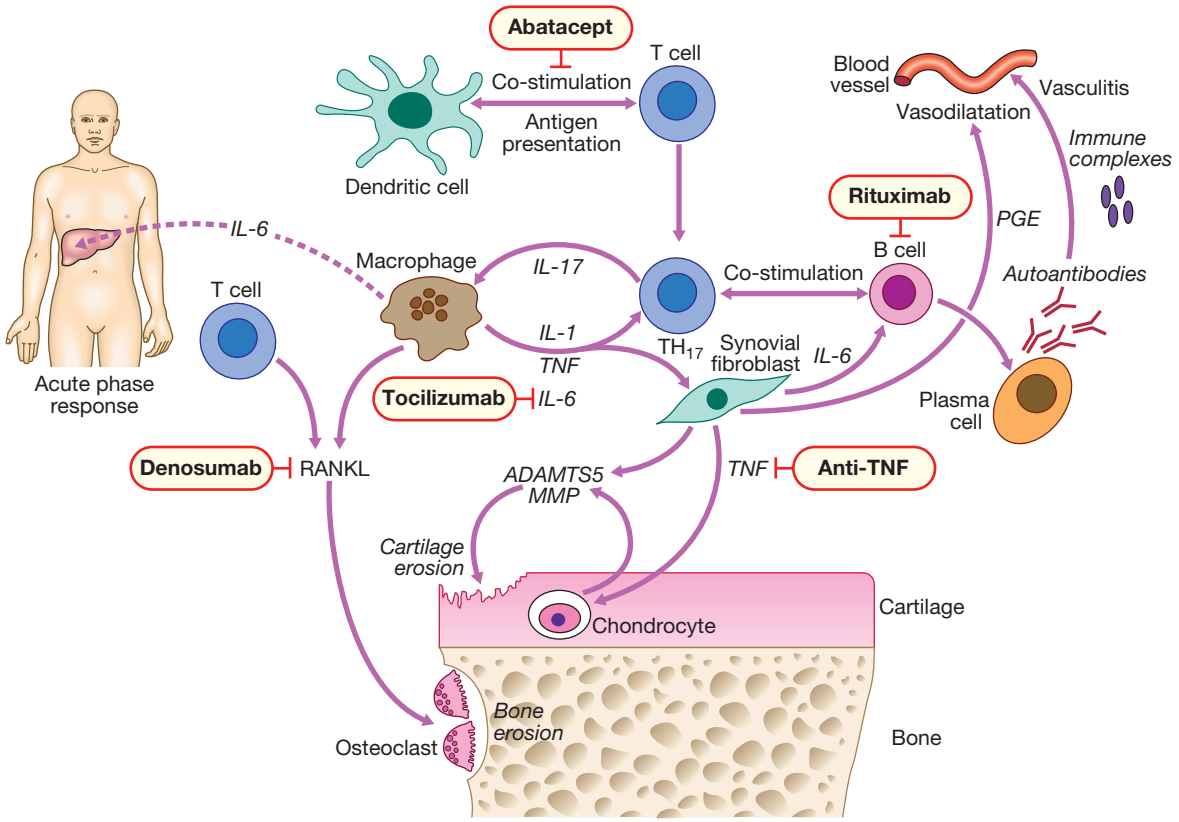

Fig. 25.31 Pathophysiology of rheumatoid arthritis. Some of the cytokines and cellular interactions believed to be important in RA are shown, along with the targets for currently available biological drugs. (ADAMTS5 = aggrecanase; IL = interleukin; MMP = matrix metalloproteinases; PGE = prostaglandin E; TNF = tumour necrosis factor; RANKL = RANK ligand)

Rheumatoid nodules consist of a central area of fibrinoid material surrounded by a palisade of proliferating mononuclear cells. Similar granulomatous lesions may occur in the pleura, lung, pericardium and sclera. Lymph nodes in RA are often hyperplastic, showing many lymphoid follicles with large germinal centres and numerous plasma cells in the sinuses and medullary cords. Immunofluorescence confirms RF and ACPA synthesis by plasma cells in synovium and lymph nodes. The bone marrow in RA is similarly hyperplastic, with evidence of lymphocyte activation and proliferation and local cytokine production. The bone marrow forms a selective survival niche for plasma cells that, in turn, produce autoantibodies. Importantly, these plasma cells are CD20-negative and, as such, escape therapies that target CD20, such as rituximab (see below).

Clinical features

The typical presentation is with pain, joint swelling and stiffness affecting the small joints of the hands, feet and wrists. Large joint involvement, systemic symptoms and extra-articular features may also occur. Clinical criteria for the diagnosis of RA are shown in Box 25.54.

Sometimes RA has a very acute onset, with florid morning stiffness, polyarthritis and pitting oedema. This occurs more commonly in old age. Other patients may present with proximal muscle stiffness mimicking

25.54 Criteria for diagnosis of rheumatoid arthritis*

Criterion	Score
Joints affected	
1 large joint	0
2–10 large joints	1
1–3 small joints	2
4–10 small joints	5
Serology	
Negative RF and ACPA	0
Low positive RF or ACPA	2
High positive RF or ACPA	3
Duration of symptoms	
< 6 wks	0
> 6 wks	1
Acute phase reactants	
Normal CRP and ESR	0
Abnormal CRP or ESR	1
Patients with a score ≥ 6 are considered to have definite RA.	

*European League Against Rheumatism/American College of Rheumatology 2010 Criteria.
(ACPA = anti-citrullinated peptide antibodies; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor)

polymyalgia rheumatica (p. 1117). Occasionally, the onset is palindromic, with relapsing and remitting episodes of pain, stiffness and swelling that last for only a few hours or days.

Examination reveals typical features of symmetrical swelling of the MCP and PIP joints. These and other joints are tender on pressure when actively inflamed and have stress pain on passive movement. Erythema is unusual and its presence suggests coexistent sepsis. Characteristic deformities may develop with long-standing uncontrolled disease, including 'swan neck' deformity, the boutonnière or 'button hole' deformity, and a Z deformity of the thumb (Fig. 25.32B). Dorsal subluxation of the ulna at the distal radio-ulnar joint is common and may contribute to rupture of the fourth and fifth extensor tendons. Triggering of fingers may occur because of nodules in the flexor tendon sheaths. Deformities of the hand are less common now, as a result of more aggressive treatment.

In the foot, dorsal subluxation of the MTP joints may result in 'cock-up' toe deformities. This causes pain on weight-bearing on the exposed MTP heads and development of secondary adventitious bursae and callosities. In the hindfoot, calcaneovalgus (eversion) is the most common deformity, reflecting damage to the ankle and subtalar joint. This is often associated with loss of the longitudinal arch (flat foot) due to rupture of the tibialis posterior tendon.

Popliteal ('Baker's') cysts may occur in combination with knee synovitis, where synovial fluid communicates with the cyst but is prevented from returning to the joint by a valve-like mechanism. Rupture, often induced by knee flexion in the presence of a large effusion, leads to calf pain and swelling that may mimic a deep venous thrombosis (DVT).

Fig. 25.32 The hand in rheumatoid arthritis. A Ulnar deviation of the fingers with wasting of the small muscles of the hands and synovial swelling at the wrists, the extensor tendon sheaths, the metacarpophalangeal and proximal interphalangeal joints. B 'Swan neck' deformity of the fingers.

Extra-articular features

Anorexia, weight loss and fatigue are common and may occur throughout the disease course. Generalised osteoporosis and muscle-wasting result from systemic inflammation. Extra-articular features are most common in patients with long-standing seropositive erosive disease but may occasionally occur at presentation, especially in men. Most are due to serositis, granuloma and nodule formation or vasculitis (Box 25.55).

Cutaneous and vascular features

Rheumatoid nodules occur almost exclusively in seropositive patients, usually at sites of pressure or friction, such as the extensor surfaces of the forearm (Fig. 25.33), sacrum, Achilles tendon and toes. They may be complicated by ulceration and secondary infection. Rheumatoid vasculitis may occur in older seropositive patients and is indicated by systemic symptoms (fatigue, fever) and multiple extra-articular features. Vasculitis can vary

25.55 Extra-articular manifestations of rheumatoid disease

Systemic
- Fever
- Weight loss
- Fatigue
- Susceptibility to infection

Musculoskeletal
- Muscle-wasting
- Tenosynovitis
- Bursitis

from relatively benign nail-fold infarcts to widespread cutaneous ulceration and skin necrosis. Rarely, involvement of medium-sized arteries can lead to mesenteric, renal or coronary artery occlusion.

Ocular involvement

The most common symptom is dry eyes (keratoconjunctivitis sicca) due to secondary Sjögren's syndrome (p. 1114). Painless episcleritis frequently accompanies nodular seropositive disease; it may cause intense redness of superficial vessels but sight is unimpaired. Scleritis is more serious and potentially sight-threatening; the eye is red and painful, vision is impaired, and the sclera shows a deep red blush beneath the individual red superficial vessels (p. 1058). Scleromalacia is painless bilateral thinning of the sclera, with the affected area appearing blue or grey (the colour of the underlying choroid). Corneal melting is a rare but devastating manifestation. It occurs in long-standing disease and is associated with systemic vasculitis. It causes pain, redness and blurred vision with corneal thinning. If it is untreated, progression to perforation is common, so urgent high-dose steroid and immunosuppressive therapy is indicated.

Cardiac and pulmonary involvement

Cardiac involvement occurs in up to 30% of patients with seropositive RA but is usually asymptomatic. Symptomatic pericardial effusions and constrictive pericarditis are rare. Occasionally, granulomatous lesions can cause heart block, cardiomyopathy, coronary artery occlusion or aortic regurgitation. Serositis is commonly asymptomatic but may present as pleurisy or breathlessness. Pulmonary fibrosis can occur in advanced RA and may cause dyspnoea (p. 712). In addition to the above manifestations, which are due to the direct effects of the inflammatory process, the risk of atheroma and cardiovascular disease is increased in RA. This is caused by a combination of conventional risk factors, such as high cholesterol, smoking, hypertension and reduced physical activity, and the effects of inflammatory factors, such as immune complexes, cytokines and chemokines, on the endothelium and adipose tissue. The risk of cardiovascular disease may be increased by NSAID and corticosteroids, whereas there is some evidence that DMARD and biological medicines are protective.

Neurological complications

Peripheral entrapment neuropathies may result from compression by hypertrophied synovium or by joint subluxation. Median nerve compression in the carpal tunnel is most common and bilateral compression can occur as an early presenting feature of RA. Other syndromes include ulnar nerve compression at the elbow or wrist, compression of the lateral popliteal nerve at the head of the fibula, and tarsal tunnel syndrome (entrapment of the posterior tibial nerve in the flexor retinaculum), which causes burning, tingling and numbness in the distal sole and toes. Diffuse symmetrical peripheral neuropathy and mononeuritis multiplex may occur in patients with rheumatoid vasculitis.

Cervical cord compression can result from subluxation of the cervical spine at the atlanto-axial joint or at a subaxial level (Fig. 25.34). Atlanto-axial subluxation is a common finding in long-standing RA and is due to erosion of the transverse ligament posterior to the odontoid peg. If unrecognised, it can lead to cord compression or sudden death following minor trauma or manipulation. Atlanto-axial subluxation should be suspected in any RA patient who describes new onset of occipital headache, particularly if symptoms of paraesthesia or electric shock are present in the arms. The onset is often insidious, with subtle loss of function that is initially attributed to active disease. Reflexes and power can be very difficult to assess in the presence of marked joint damage and therefore sensory or upper motor signs are most important. Patients with spinal cord compression may require operative stabilisation and fixation, though the outcome is poor if the patient already has tetraparesis.

Other complications

Amyloidosis is a rare complication of prolonged active disease and usually presents with nephrotic syndrome. Microcytic anaemia can occur due to iron deficiency resulting from NSAID-induced gastrointestinal blood loss, and normochromic, normocytic anaemia with thrombocytosis is present in active disease. Felty's syndrome is the association of splenomegaly and

25.56 Felty's syndrome

Risk factors

- Age of onset 50–70 yrs
- Female > male
- Caucasians > blacks
- Long-standing RA
- Deforming but inactive disease
- Seropositive for RF

Common clinical features

- Splenomegaly
- Lymphadenopathy
- Weight loss
- Skin pigmentation
- Keratoconjunctivitis sicca
- Vasculitis, leg ulcers
- Recurrent infections
- Nodules

Laboratory findings

- Normochromic, normocytic anaemia
- Neutropenia
- Abnormal liver function
- Thrombocytopenia
- Impaired T- and B-cell immunity

neutropenia with RA (Box 25.56). Generalised and local lymphadenopathy affecting nodes draining actively inflamed joints may both occur. Patients with persistent lymphadenopathy should be biopsied since there is an increased risk of lymphoma in patients with long-standing RA.

Investigations

The diagnosis of RA is based on clinical grounds but investigations are useful in confirming the diagnosis and assessing disease activity (Box 25.57). The ESR and CRP are usually raised but normal results do not exclude the diagnosis. ACPA are positive in about 70% of cases and are highly specific for RA, occurring in many patients before clinical onset of the disease. Similarly RF is positive in about 70% of cases, many of whom also test positive for ACPA. Low titres of RF are found in about 10% of the normal population and in other diseases (p. 1067).

Ultrasound examination and MRI are not routinely required in patients with obvious clinical signs. Their main value is in patients with symptoms suggestive of an inflammatory arthritis, where there is uncertainty about the presence of synovitis. They are also a sensitive means of detecting early erosions. Plain X-rays of the hands, wrist and feet are of limited value in early RA but certain changes are characteristic, including periarticular osteoporosis and marginal joint erosions. The main indication for X-ray is in the assessment of patients with problem joints to determine if significant structural damage has occurred. Patients who are suspected of having atlanto-axial disease should have lateral X-rays taken in flexion and extension, and the degree of cord compression should be established with MRI. In patients with Baker's cyst, ultrasound may be required to establish the diagnosis, since DVT and Baker's cyst may coexist.

The DAS28 score is widely used to assess disease activity, the response to treatment and the need for biological therapy. It involves counting the number of swollen and tender joints in the upper limbs and knees, and combining this with the ESR and the patient's assessment of his/her general health on a visual analogue scale, to generate a numerical score. The higher the value, the more active the disease (Box 25.58).

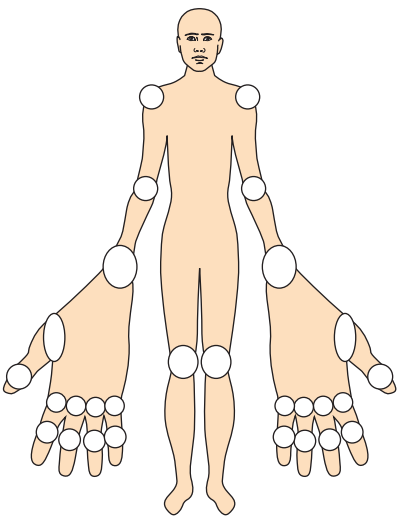
25.57 Investigations and monitoring of rheumatoid arthritis

To establish diagnosis

- Clinical criteria
- ESR and CRP
- Ultrasound or MRI
- Rheumatoid factor and anti-citrullinated peptide antibodies

To monitor disease activity and drug efficacy

- Pain (visual analogue scale)
- Early morning stiffness (minutes)
- Joint tenderness
- Joint swelling
- DAS28 score
- ESR and CRP
- Ultrasound



To monitor disease damage

- X-rays
- Functional assessment

To monitor drug safety

- Urinalysis
- Full blood count
- Urea, creatinine and liver function tests

25.58 How to calculate the DAS28 score

- Count the number of tender joints
- Count the number of swollen joints
- Measure the ESR
- Ask the patient to rate global activity of arthritis during the past week from 0 (no symptoms) to 100 (very severe)
- Enter data into an online calculator[1] or work out using a formula[2]

[1] www.4s-dawn.com/DAS28.
[2] DAS28 = 0.56 × square root (tender joints) + 0.28 × square root (swollen joints) + 0.70 × $\log_e$(ESR) + 0.014 (global activity score)

Management

The mainstay of treatment in RA comprises the early use of small-molecule disease-modifying antirheumatic drugs (DMARDs), and corticosteroids for induction of

remission. There is evidence that early use of DMARD therapy improves clinical outcome in RA. Partial or non-response to DMARD therapy should prompt escalation of the dose or use of an additional DMARD, with progression to biological drugs if necessary (Fig. 25.35). Regular monitoring of DMARD therapy is essential because of the risk of liver and haematological toxicity. Some DMARDs are contraindicated in pregnancy, especially during the first trimester (Box 25.59). Patients who wish to become pregnant should be counselled to stop DMARD treatment while they try to conceive. Since RA almost always undergoes remission during pregnancy, it is usually possible to manage the condition without DMARD therapy over this period. Details of the dose regimens, toxicity and monitoring requirements are shown in Box 25.60.

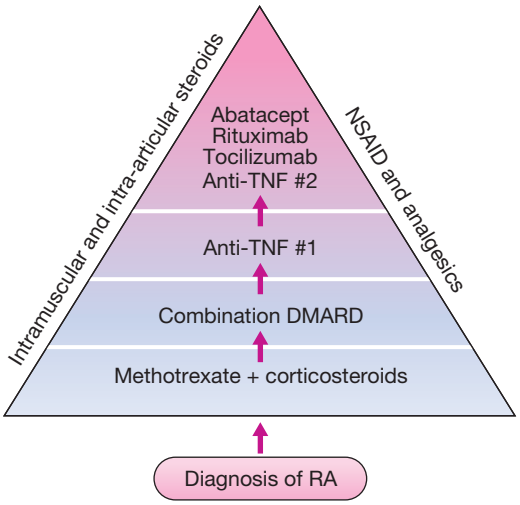


Fig. 25.35 Management of early rheumatoid arthritis. See text for details of each drug. (DMARD = disease-modifying antirheumatic drug; NSAID = non-steroidal anti-inflammatory drug; TNF = tumour necrosis factor)

25.59 Rheumatoid arthritis in pregnancy

- **Immunological changes in pregnancy**: most patients with RA go into remission during pregnancy.
- **Conception**: methotrexate and leflunomide should be discontinued for at least 3 months before trying to conceive.
- **Paracetamol**: the oral analgesic of choice during pregnancy.
- **Oral NSAIDs and selective COX-2 inhibitors**: can be used after implantation up until the last trimester.
- **Corticosteroids**: may be used to control disease flares; the main maternal risks are hypertension, glucose intolerance and osteoporosis.
- **DMARDs that may be used**: sulfasalazine, hydroxychloroquine, azathioprine or ciclosporin if required to control inflammation.
- **DMARDs that must be avoided**: methotrexate, leflunomide, cyclophosphamide, gold and penicillamine.
- **Biological therapies**: safety during pregnancy is currently unclear.
- **Breastfeeding**: methotrexate, leflunomide, cyclophosphamide, ciclosporin, azathioprine, sulfasalazine and hydroxychloroquine are contraindicated.

25.60 Commonly used small-molecule disease-modifying antirheumatic drugs in rheumatoid arthritis

Drug	Mechanism of action	Usual maintenance dose	Principal side-effects	Monitoring requirement	Monitoring frequency
Methotrexate	Inhibits DNA synthesis and cell division	5–25 mg/wk	GI upset, stomatitis, rash, alopecia, hepatotoxicity, acute pneumonitis	FBC, LFTs	Initially monthly, then every 3 mths
Sulfasalazine	Unknown	2–4 g/day	Nausea, GI upset, rash, hepatitis, neutropenia, pancytopenia (rare)	FBC, LFTs	Monthly for 3 mths, then 3-monthly
Hydroxychloroquine	Unknown	200–400 mg/day	Rash, nausea, diarrhoea, headache, corneal deposits, retinopathy (rare)	Visual acuity, fundoscopy	12-monthly
Leflunomide	Blocks T-cell division	10–20 mg/day	Nausea, GI upset, rash, alopecia, hepatitis, hypertension	FBC, LFTs, BP	2–4-weekly
D-Penicillamine	Unknown	250–750 mg/day	Rash, stomatitis, metallic taste, proteinuria, thrombocytopenia	FBC, urine (for protein)	Initially 1–2-weekly; 4–6-weekly for maintenance
Gold	Unknown	50 mg/mth by IM injection	Rash, stomatitis, alopecia, proteinuria, thrombocytopenia, myelosuppression	FBC, urine (protein)	Each injection
Ciclosporin	Blocks T-cell activation	150–300 mg/day	Nausea, GI upset, renal impairment, hypertension	FBC, LFTs, U&E, BP	2–4-weekly

(BP = blood pressure; FBC = full blood count; LFT = liver function tests; U&E = urea and electrolytes)

Disease-modifying antirheumatic drugs

Methotrexate

Methotrexate is the anchor DMARD in RA. It is usually given as a starting weekly oral dose of 7.5–10 mg and this is increased in 2.5 mg increments every 2–4 weeks until benefit occurs or toxicity is limiting. The maximum recommended dose is 25 mg. The benefits of methotrexate usually start to appear within 1–2 months but a 6-month course should be given before concluding that it has been ineffective. The most common adverse effects are nausea, vomiting and malaise within 24–48 hours of administration. Patients who experience these can sometimes be successfully treated with subcutaneous methotrexate. Folic acid (5 mg/week) reduces the incidence of adverse effects without reducing efficacy. Patients should be warned of drug interaction with sulphonamides and to avoid excess alcohol, which enhances methotrexate hepatotoxicity. Acute pulmonary toxicity (pneumonitis) is rare but can occur at any time during treatment. Patients should therefore be warned to seek early advice if they develop any new respiratory symptoms. Methotrexate should be stopped immediately if pneumonitis is suspected and high-dose steroids should be given.

Sulfasalazine

Sulfasalazine (SSZ) is widely used, both alone and in combination with methotrexate and other drugs. The mechanism of action is incompletely understood. Nausea and gastrointestinal intolerance are the main adverse effects. The usual starting dose is 500 mg daily, building up gradually to a maintenance dose of 2–4 g/day. The patient should be warned of possible orange staining of urine and contact lenses. Monitoring should be performed for liver and haematological toxicity.

Hydroxychloroquine

Hydroxycholoroquine is given in a dose of 400 mg daily, usually in combination with other DMARDs. Ocular toxicity can occur with long-term use due to retinal damage. It is usual to check visual acuity before starting treatment and to repeat this periodically whilst treatment is continued.

Leflunomide

Leflunomide can be used alone or in combination with other drugs. It works by inhibiting lymphocyte proliferation and activation. It is usually well tolerated and has low marrow toxicity, but may cause liver dysfunction. The usual maintenance dose is 10–20 mg/day. It is possible to give a loading dose of 100 mg on 3 consecutive days at the start of treatment, but this is seldom used in routine clinical practice. Monitoring should be performed for liver and haematological toxicity.

Gold, penicillamine and ciclosporin A

These are only occasionally used due to the availability of drugs with a better risk–benefit profile. Gold (sodium aurothiomalate) is given by deep intramuscular injection of 50 mg after an initial 10 mg test dose. Treatment is continued weekly for up to 6 months until benefit occurs, when the frequency is reduced to fortnightly and then monthly. Penicillamine is given in a starting dose of 125–250 mg daily on an empty stomach, and increased in 125-mg increments every 6 weeks until benefit occurs or adverse effects develop. Ciclosporin A inhibits lymphocyte division and activation. It is given in a dose of 150–300 mg/day with monitoring of blood pressure and renal function.

Corticosteroids

Systemic corticosteroids have disease-modifying activity, but their primary role is in the induction of remission in patients with early RA who are starting synthetic DMARD treatment. Various regimens have been used but there is little evidence to suggest that one is superior to another. One strategy is to give a high dose of oral prednisolone initially (60 mg daily) and to reduce and stop this gradually over a period of 3 months as the DMARD starts to take effect. Another is to employ low-dose prednisolone (5–10 mg daily for 6–24 months) or to give intramuscular injections of methylprednisolone or triamcinolone every 6–8 weeks. Intramuscular steroids are often used to treat flares of disease activity in patients who are established on DMARD therapy. Intra-articular corticosteroids are primarily indicated when there are one or two 'problem joints' with persistent synovitis despite good general control of the disease. Although corticosteroids are very useful, they also have significant adverse effects (p. 776). In the context of RA, osteoporosis is probably the most important since this is a known complication of RA, even in the absence of corticosteroid therapy. Accordingly DEXA scanning followed by bone protection should be considered in any patient with RA who is expected to be on more than 7.5 mg prednisolone daily for more than 3 months.

Biological therapies

The use of biological agents (often abbreviated to 'biologics') is reserved for the treatment of patients who have high disease activity despite having had an adequate trial of traditional DMARDs. These agents are targeted towards specific cytokines and other cell-surface molecules regulating the immune response. Although generally well tolerated, biological therapies increase the risk of serious infections due to suppression of the immune response. Although biological treatment is more effective than standard DMARD therapy, treatment costs are significantly greater. Because of this, many countries have set guidelines restricting their use. Current UK recommendations are that biological therapy should be initiated only in active RA (DAS28 > 5.1; p. 1100) when an adequate trial of at least two other DMARDs (including methotrexate) has failed. Details of the individual agents, their mechanisms of action and their toxicity are shown in Box 25.61.

Anti-TNF therapy

Anti-TNF therapy is the first-line biological drug in RA. Several agents are available, as summarised in Box 25.61. With the exception of infliximab, which must be prescribed with methotrexate to reduce the risk of neutralising antibodies developing, these agents can be used as monotherapy. In clinical practice, however, most are co-prescribed with methotrexate, as this is more efficacious. The main adverse effects are serious infections

25.61 Commonly used biological drugs in rheumatoid arthritis

Drug	Usual maintenance dose	Comment	NICE[1]
Anti-TNF-α			
Etanercept	50 mg every wk SC	Decoy receptor for TNF-α	Yes
Infliximab	3 mg/kg every 8 wks IV	Antibodies to TNF. Infliximab must be given in combination with methotrexate	Yes
Adalimumab	40 mg every 2 wks SC		Yes
Certolizumab	200 mg every 2 wks SC		Yes
Golimumab	50 mg every 4 wks SC		Yes
Anti-B-cell therapy			
Rituximab	1000 mg IV; repeat after 2 wks	Pre-medication with methylprednisolone 100 mg IV, chlorphenamine 10 mg IV and paracetamol given 30 min prior to each infusion	Yes[2]
Inhibitor of T-cell activation			
Abatacept	125 mg SC once a week	Favourable safety profile	Yes[2]
Anti-IL6			
Tocilizumab	8 mg/kg every 4 wks IV	More effective than anti-TNF in methotrexate-intolerant patients	Yes
Anti IL-1			
Anakinra	100 mg daily, SC	Less effective than other biological drugs	No

[1]Recommended for use by the National Institute of Clinical Excellence in the UK.
[2]Second-line, if patient has failed to respond to at least one TNF inhibitor.

and reactivation of latent tuberculosis. There is evidence that TNF blockade can increase the risk of some malignancies, particularly basal cell carcinoma of the skin, and that it can accelerate progression of cancer in patients with prior malignant disease. In contrast, the risk of vascular disease in RA patients seems to be reduced by anti-TNF therapy.

Rituximab

Rituximab is an antibody directed against the CD20 receptor, which is expressed on B lymphocytes and immature plasma cells. It is given by two intravenous infusions, 2 weeks apart, usually in combination with intravenous corticosteroid. It causes depletion of peripheral and synovial B cells, which is sustained for several months after administration. The treatment is repeated usually when signs of improvement are wearing off (anything from 6 months to 1 year). It is mostly used in the treatment of patients with resistant RA who have failed to respond to TNF blockade.

Abatacept

Abatacept is an agent in which the Fc domain of IgG is fused to the extracellular domain of CTLA4. It blocks the interaction between CD28 and CD80/86 that is required for full activation of T cells following antigen presentation by dendritic cells or macrophages. Abatacept has a good safety profile and is as efficacious as anti-TNF therapy in biological-naïve patients who fail to respond to conventional DMARD therapy.

Tocilizumab

This agent is an antibody directed against the IL-6 receptor, and is licensed for the treatment of rheumatoid arthritis. It prevents IL-6 activating its receptor within the synovial membrane and in other tissues such as liver and muscle. It has similar efficacy to anti-TNF therapy and is licensed for use as monotherapy or in combination with methotrexate. Adverse effects include leucopenia, hypercholesterolaemia and an increased risk of infections. It is generally used as second-line treatment in patients who have failed to respond to anti-TNF therapy, except in those who are intolerant of methotrexate, in which case it is used as a first-line treatment.

Anakinra

Anakinra is a decoy receptor for IL-1. It has some activity in RA but is seldom used since it appears to be less effective than other biological drugs.

Other treatments

Surgery

Synovectomy of the wrist or finger tendon sheaths of the hands may be required for pain relief or to prevent tendon rupture when medical interventions have failed. In later stages when joint damage has occurred, osteotomy, arthrodesis or arthroplasty may be required (see Box 25.35, p. 1080).

General measures

The general principles outlined on page 1077 should be followed. Physical rest, analgesics and NSAID may be required to control symptoms. Passive exercises and joint protection measures should be encouraged with the aim of conserving function in affected joints. During treatment, periodic assessment of disease activity, progression and disability is essential. In the vast majority, management is outpatient- or day patient-based, but hospital admission can be helpful in patients with very active disease for a period of bed rest, multiple joint injections, splinting, regular hydrotherapy, physiotherapy and education.

JUVENILE IDIOPATHIC ARTHRITIS

Inflammatory arthritis occurs rarely in children. Several distinct subtypes are recognised (Box 25.62). Systemic juvenile idiopathic arthritis (JIA; formerly known as

25.62 Clinical features of juvenile idiopathic arthritis

Subtype	Frequency	Clinical features	Immunology
Systemic JIA	5%	Fever, rash, arthralgia, hepatosplenomegaly	Autoantibody-negative
Oligoarthritis (≤ 4 joints)	60%	Large-joint arthritis, uveitis	ANA-positive
Polyarthritis (≥ 5 joints)	20%	Polyarthritis. May be extended form of oligoarthritis	ANA-positive
Enthesis-related	5%	Sacroiliitis, enthesopathy	HLA-B27-positive
Rheumatoid factor-positive	5%	Polyarthritis, similar to RA	RF-positive, ACPA-positive
Psoriatic arthritis	5%	Same as adult disease (p. 1108)	Autoantibody-negative

(ACPA = anti-citrullinated peptide antibodies; ANA = antinuclear antibody; HLA = human leucocyte antigen; RF = rheumatoid factor)

25.63 Juvenile idiopathic arthritis in adolescence

- **Uveitis**: may be clinically silent and persist into adulthood, necessitating routine screening for eye involvement.
- **Persistence into adulthood**: persists in 50% of cases, especially in systemic disease, necessitating long-term follow-up.
- **Reduced peak bone mass**: common in polyarthritis and systemic JIA but little data on fracture risk, and evidence base for treatment is poor
- **Biological drugs**: effective in JIA but long-term safety remains unclear.

Still's disease) is a systemic disorder characterised by fever, rash, arthritis, hepatosplenomegaly and serositis in association with a raised ESR and CRP. Autoantibody tests are negative.

Oligoarthritis is the most common form, accounting for about 60% of cases. Two subtypes are recognised, depending on the extent of involvement, but they probably form part of a single disease spectrum. Oligoarticular JIA is more common in females and tends to affect large joints in an asymmetrical pattern. There is an association with uveitis and many patients are ANA-positive. Rheumatoid factor-negative polyarthritis is a heterogeneous form. Some patients are ANA-positive and these probably represent a subtype of oligoarticular JIA with more extensive joint involvement. Other patients present with polyarticular disease that is similar to adult seronegative RA. Juvenile forms of ankylosing spondylitis and psoriatic arthritis also occur.

Patients with JIA should be referred to a paediatric rheumatologist. The principles of management are similar to those in adult inflammatory disease, and corticosteroids and methotrexate are required for systemic JIA. Recent trials indicate that TNF blockers, IL-1 inhibitors and tocilizumab may also be effective. Steroids and methotrexate are also indicated for oligoarticular and polyarticular JIA, with progression to anti-TNF therapy in poor responders.

The prognosis of oligoarthritis is good and in many patients the condition resolves at puberty. Polyarticular and systemic JIA have a poorer prognosis, however, and in about 50% of cases the disease remains active into adulthood, requiring extended follow-up by adult rheumatology services. Common issues encountered during transition of paediatric patients into adulthood are shown in Box 25.63.

Adult-onset Still's disease

This is a rare systemic inflammatory disorder of unknown cause, similar to juvenile idiopathic arthritis, which presents with intermittent fever, rash and arthralgia. Splenomegaly, hepatomegaly and lymphadenopathy may be present. Investigations typically show evidence of an acute phase response, with a markedly elevated serum ferritin. Tests for RF and ANA are negative. Most patients respond to corticosteroids but DMARDs may also be required as steroid-sparing agents. Anecdotal reports indicate that anakinra (p. 1103), anti-TNF therapy and tocilizumab may be helpful in patients with resistant disease, but none of these has been tested in a randomised trial.

SERONEGATIVE SPONDYLOARTHROPATHIES

These comprise a group of related inflammatory joint diseases, which show considerable overlap in their clinical features and a shared immunogenetic association with the HLA-B27 antigen (Box 25.64). They include:

- ankylosing spondylitis
- axial spondyloarthritis
- reactive arthritis, including Reiter's syndrome
- psoriatic arthritis
- arthropathy associated with inflammatory bowel disease.

The synovitis is non-specific and is often indistinguishable from RA. However, the distinctive feature of this group of diseases is the marked degree of extrasynovial inflammation, especially of the enthesis but also of the joint capsule, periosteum, cartilage and subchondral bone. There is a striking association with carriage of the HLA-B27 allele, particularly for ankylosing spondylitis (> 95%) and reactive arthritis (90%), and especially associated with sacroiliitis, uveitis or balanitis. Understanding of the cause is incomplete but an aberrant response to infection is thought to be involved in genetically predisposed individuals. In some situations, a triggering organism can be identified, as in reactive arthritis following bacterial dysentery or chlamydial urethritis, but in others the environmental trigger remains obscure. Familial clustering not only is common to the specific condition occurring in the proband, but also may extend to other diseases in the seronegative spondyloarthropathy group.

25.64 Clinical features common to seronegative spondyloarthritis

- Asymmetrical inflammatory oligoarthritis (lower > upper limb)
- Sacroiliitis and inflammatory spondylitis
- Inflammatory enthesitis
- Tendency for familial aggregation
- RF and ACPA negative
- Absence of nodules and other extra-articular features of RA
- Typical overlapping extra-articular features:
  - Mucosal inflammation: conjunctivitis, buccal ulceration, urethritis, prostatitis, bowel ulceration
  - Pustular skin lesions and nail dystrophy
  - Anterior uveitis
  - Aortic root fibrosis (aortic incompetence, conduction defects)
  - Erythema nodosum

Ankylosing spondylitis

Ankylosing spondylitis (AS) is characterised by a chronic inflammatory arthritis predominantly affecting the sacroiliac joints and spine, which can progress to bony fusion of the spine. The onset is typically between the ages of 20 and 30, with a male preponderance of about 3:1. In Europe, more than 90% of those affected are HLA-B27-positive. The overall prevalence is less than 0.5% in most populations. Over 75% of patients are able to remain in employment and enjoy a good quality of life. Even if severe ankylosis develops, functional limitation may not be marked as long as the spine is fused in an erect posture.

Pathophysiology

Ankylosing spondylitis is thought to arise from an as yet ill-defined interaction between environmental pathogens and the host immune system in genetically susceptible individuals. Increased faecal carriage of *Klebsiella aerogenes* occurs in patients with established AS and may relate to exacerbation of both joint and eye disease. Wider alterations in the human gut microbial environment are increasingly implicated, which could lead to increased levels of circulating cytokines such as IL-23 that can activate enthesial or synovial T cells. The HLA-B27 molecule itself is implicated through its antigen-presenting function (it is a class I MHC molecule) or because of its propensity to form homodimers that activate leucocytes. HLA-B27 molecules may also misfold, causing increased endoplasmic reticulum stress. This could lead to inflammatory cytokine release by macrophages and dendritic cells, thus triggering inflammatory disease.

Clinical features

The cardinal feature is low back pain and early morning stiffness with radiation to the buttocks or posterior thighs. Symptoms are exacerbated by inactivity and relieved by movement. The disease tends to ascend slowly, ultimately involving the whole spine, although some patients present with symptoms of the thoracic or cervical spine. As the disease progresses, the spine becomes increasingly rigid as ankylosis occurs. Secondary osteoporosis of the vertebral bodies frequently occurs, leading to an increased risk of vertebral fracture.

25.65 Extra-articular features of ankylosing spondylitis

- Anterior uveitis (25%) and conjunctivitis (20%)
- Prostatitis (80% men): usually asymptomatic
- Cardiovascular disease
  - Aortic incompetence
  - Mitral incompetence
  - Cardiac conduction defects
  - Pericarditis
- Amyloidosis
- Atypical upper lobe pulmonary fibrosis

Early physical signs include a reduced range of lumbar spine movements in all directions and pain on sacroiliac stressing. As the disease progresses, stiffness increases throughout the spine and chest expansion becomes restricted. Spinal fusion varies in its extent and in most cases does not cause a gross flexion deformity, but a few patients develop marked kyphosis of the dorsal and cervical spine that may interfere with forward vision. This may prove incapacitating, especially when associated with fixed flexion contractures of hips or knees. Pleuritic chest pain aggravated by breathing is common and results from costovertebral joint involvement. Plantar fasciitis, Achilles tendinitis and tenderness over bony prominences such as the iliac crest and greater trochanter may all occur, reflecting inflammation at the sites of tendon insertions (enthesitis).

Up to 40% of patients also have peripheral arthritis. This is usually asymmetrical, affecting large joints such as the hips, knees, ankles and shoulders. In about 10% of cases, involvement of a peripheral joint may antedate spinal symptoms, and in a further 10%, symptoms begin in childhood, as in the syndrome of oligoarticular juvenile idiopathic arthritis.

Fatigue is a major complaint and may result from both chronic interruption of sleep due to pain, and chronic systemic inflammation with direct effects of inflammatory cytokines on the brain. Acute anterior uveitis is the most common extra-articular feature, which occasionally precedes joint disease. Other extra-articular features are occasionally observed but are rare (Box 25.65). Disease activity in AS can be assessed by the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), a questionnaire in which patients and their physician rate severity of various symptoms (Box 25.66). This is important in assessing eligibility for biological treatment. The criteria for the diagnosis of classical AS and axial spondyloarthropathy (SpA) are shown in Box 25.67. The criteria for axial SpA were developed to take account of the fact that X-rays may be normal in patients with early AS.

Investigations

In established AS, radiographs of the sacroiliac joint show irregularity and loss of cortical margins, widening of the joint space and subsequently sclerosis, joint space narrowing and fusion. Lateral thoracolumbar spine X-rays may show anterior 'squaring' of vertebrae due to erosion and sclerosis of the anterior corners and periostitis of the waist. Bridging syndesmophytes may also be

seen. These are areas of calcification that follow the outermost fibres of the annulus (Fig. 25.36). In advanced disease, ossification of the anterior longitudinal ligament and facet joint fusion may also be visible. The combination of these features may result in the typical 'bamboo' spine (Fig. 25.37). Erosive changes may be seen in the symphysis pubis, the ischial tuberosities and peripheral joints. Osteoporosis and atlanto-axial dislocation can occur as late features. Patients with early disease can have normal X-rays, and if clinical suspicion is high, MRI should be performed. This is much more sensitive for detection of early sacroiliitis than X-ray (Fig. 25.38) and can also detect inflammatory changes in the lumbar spine.

25.66 Bath Ankylosing Spondylitis Disease Activity Index

Question	Score
1. How would you describe the overall level of fatigue or tiredness you have experienced?	1–10
2. How would you describe the overall level of neck, back or hip pain you have had?	1–10
3. How would you describe the overall level of pain and swelling you have had in joints other than the neck, back or hip?	1–10
4. How would you describe the overall level of discomfort you have had from any areas tender to touch or pressure?	1–10
5. How would you describe the overall level of discomfort you have had from the time you wake up?	1–10
6. How long does your morning stiffness last from the time you wake up?	0 hr to 2+ hrs

The patient is asked to complete each question. The score is calculated by taking the average of all 6 questions, where duration of morning stiffness in minutes is coded in 12-minute increments from none (1) to 120 (10). Online calculators are also available at http://basdai.com

25.67 Diagnostic criteria for ankylosing spondylitis and axial spondyloarthritis

Axial spondyloarthritis	Ankylosing spondylitis
Imaging	
Sacroiliitis on MRI only	Bilateral sacroiliitis on X-ray, even if changes are mild Unilateral sacroiliitis on X-ray if changes are definite
History	
Back pain > 3 mths which has four of the following characteristics: 1. improved by exercise 2. not relieved by rest 3. insidious onset 4. night pain 5. age at onset < 40 Good response of back pain to NSAID Family history of spondyloarthritis History of inflammatory bowel disease	Back pain > 3 mths improved by exercise and not relieved by rest
Clinical examination	
Arthritis Enthesitis Uveitis Dactylitis Psoriasis	Limitation of lumbar spine movement in sagittal and frontal planes Chest expansion reduced
Investigations	
HLA-B27-positive Elevated CRP	

Axial spondyloarthritis is diagnosed when there is sacroiliitis on MRI plus one other feature on history, clinical examination or investigation. The diagnosis can also be made in patients who are HLA-B27-positive with two or more clinical features in the absence of sacroiliitis

Ankylosing spondylitis can be diagnosed when X-ray evidence of sacroiliitis occurs with one other feature on history or clinical examination

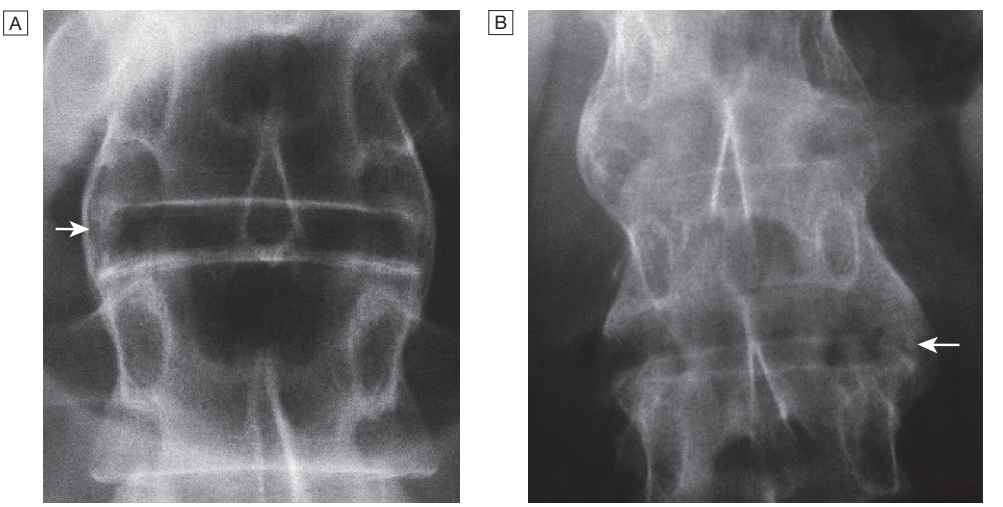

Fig. 25.36 X-ray changes in spondyloarthropathies. A Fine symmetrical marginal syndesmophytes typical of ankylosing spondylitis (arrow). B Coarse, asymmetrical non-marginal syndesmophytes typical of psoriatic/Reiter's spondylitis (arrow).

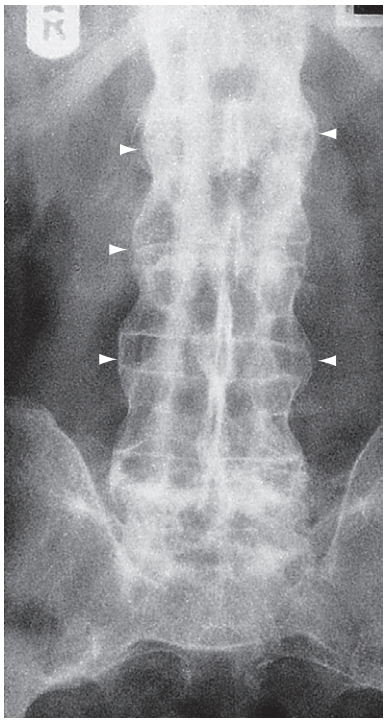

Fig. 25.37 'Bamboo' spine of severe late ankylosing spondylitis. Note the symmetrical marginal syndesmophytes (arrows), sacroiliac joint fusion and generalised osteopenia.

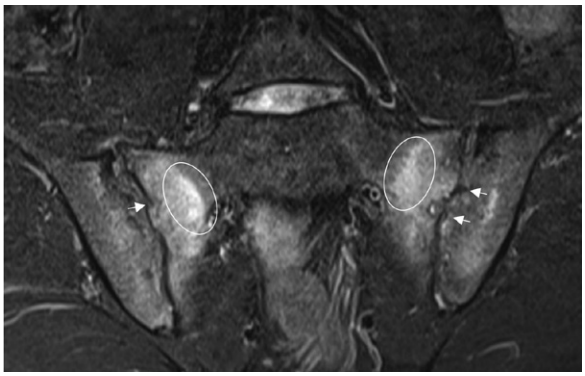

Fig. 25.38 MRI appearances in sacroiliitis. Coronal MRI short T1 inversion recovery (STIR) sequence showing bilateral sacroiliitis in early ankylosing spondylitis. Bone marrow oedema (circles) is present around both sacroiliac joints, which show irregularities due to erosions (arrows).

The ESR and CRP are usually raised in active disease but may be normal. Testing for HLA-B27 can be helpful, especially in patients with back pain suggestive of an inflammatory cause, when other investigations have yielded equivocal results. Autoantibodies such as RF, ACPA and ANA are negative.

Management

The aims of management are to relieve pain and stiffness, maintain a maximal range of skeletal mobility and avoid the development of deformities. Education and appropriate physical activity are the cornerstones of management. Early in the disease, patients should be taught to perform daily back extension exercises, including a morning 'warm-up' routine, and to punctuate prolonged periods of inactivity with regular breaks. Swimming is ideal exercise. Poor posture must be avoided. NSAIDs and analgesics are often effective in relieving symptoms and may alter the underlying course of the disease. A long-acting NSAID at night is helpful for alleviation of morning stiffness. Peripheral arthritis can be treated with methotrexate or sulfasalazine, but these drugs have no effect on axial disease. Anti-TNF therapy should be considered in patients who are inadequately controlled on standard therapy with a BASDAI score of ≥ 4.0 and a spinal pain score of ≥ 4.0. Anti-TNF therapy frequently improves symptoms but has not been shown to prevent ankylosis or alter natural history of the disease. Other biological interventions using agents developed for RA have been disappointing, suggesting fundamental differences in disease pathogenesis.

Local corticosteroid injections can be useful for persistent plantar fasciitis, other enthesopathies and peripheral arthritis. Oral corticosteroids may be required for acute uveitis but do not help spinal disease. Severe hip, knee or shoulder restriction may require surgery. Total hip arthroplasty has largely removed the need for difficult spinal surgery in those with advanced deformity.

Reactive arthritis

Reactive arthritis (previously known as Reiter's disease) is predominantly a disease of young men, with a male preponderance of 15:1. It is the most common cause of inflammatory arthritis in men aged 16–35 but may occur at any age. Between 1 and 2% of patients with non-specific urethritis seen at genitourinary medicine clinics have reactive arthritis (p. 415). Following an epidemic of *Shigella* dysentery, 20% of HLA-B27-positive men developed reactive arthritis. Reactive arthritis may present with the triad described in Box 25.68 but many patients present with arthritis only.

Clinical features

The onset is typically acute, with an inflammatory oligoarthritis that is asymmetrical and targets lower limb joints, such as the knees, ankles, midtarsal and MTP joints. It occasionally presents with single joint

25.68 Reiter's disease

Classic triad*

- Non-specific urethritis
- Conjunctivitis (~50%)
- Reactive arthritis

Additional extra-articular features

- Circinate balanitis (20–50%)
- Keratoderma blennorrhagica (15%)
- Nail dystrophy
- Buccal erosions (10%)

Precipitated by

- Bacterial dysentery, mainly *Salmonella*, *Shigella*, *Campylobacter* or *Yersinia*
- Sexually acquired infection with *Chlamydia*

*Incomplete forms with just one or two of the classic triad are more frequent than the full syndrome.

involvement and no clear history of an infectious trigger. There may be considerable systemic disturbance, with fever and weight loss. Achilles tendinitis or plantar fasciitis may also be present. The first attack of arthritis is usually self-limiting, but recurrent or chronic arthritis develops in more than 60% of patients, and about 10% still have active disease 20 years after the initial presentation. Low back pain and stiffness are common and 15–20% of patients develop sacroiliitis. Spondylitis, chronic erosive arthritis, recurrent acute arthritis and uveitis are the major causes of long-term morbidity.

Several extra-articular features may occur (see Box 25.68). Circinate balanitis starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give a circular pattern. Lesions are often painless and may escape notice. Keratoderma blennorrhagica begins as discrete waxy, yellow-brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques. The palms and soles are particularly affected but spread may occur to the scrotum, scalp and trunk. These lesions are indistinguishable from pustular psoriasis. Nail dystrophy with subungual hyperkeratosis is common and indistinguishable from psoriatic nail dystrophy. Mouth ulcers manifest as shallow red painless patches on tongue, palate, buccal mucosa and lips, lasting only a few days. Conjunctivitis may accompany the first acute episode. Uveitis is rare with the first attack but occurs in 30% of patients with recurring or chronic arthritis.

Other complications are rare but include aortic incompetence, conduction defects, pleuropericarditis, peripheral neuropathy, seizures and meningoencephalitis.

Investigations

The diagnosis is usually made clinically but joint aspiration may be required to exclude crystal arthritis and articular infection. Synovial fluid is leucocyte-rich and may contain multinucleated macrophages (Reiter's cells). ESR and CRP are raised during an acute attack. Urethritis may be confirmed in the 'two-glass test' by demonstration of mucoid threads in the first-void specimen that clear in the second. High vaginal swabs may reveal *Chlamydia* on culture. Except for post-*Salmonella* arthritis, stool cultures are usually negative by the time the arthritis presents, but serum agglutinin tests may help confirm previous dysentery. RF, ACPA and ANA are negative.

In chronic or recurrent disease, X-rays show periarticular osteoporosis, joint space narrowing and proliferative erosions. Another characteristic feature is periostitis, especially of metatarsals, phalanges and pelvis, and large, 'fluffy' calcaneal spurs. In contrast to AS, radiographic sacroiliitis is often asymmetrical and sometimes unilateral, and syndesmophytes are predominantly coarse and asymmetrical, often extending beyond the contours of the annulus ('non-marginal') (see Fig. 25.36B). X-ray changes in the peripheral joints and spine are identical to those in psoriasis.

Management

The acute attack should be treated with rest, oral NSAIDs and analgesics. Intra-articular steroids may be required in patients with severe synovitis. Non-specific chlamydial urethritis is usually treated with a short course of doxycycline or a single dose of azithromycin, and this may reduce the frequency of arthritis in sexually acquired cases. Treatment with DMARDs should be considered for patients with persistent marked symptoms, recurrent arthritis or severe keratoderma blennorrhagica. Anterior uveitis is a medical emergency requiring topical, subconjunctival or systemic corticosteroids.

Psoriatic arthritis

Psoriatic arthritis (PsA) occurs in 7–20% of patients with psoriasis and in up to 0.6% of the general population. The onset is usually between 25 and 40 years of age. Most patients (70%) have pre-existing psoriasis but in 20% the arthritis predates the occurrence of skin disease. Occasionally, the arthritis and psoriasis develop synchronously.

Clinical features

The presentation is with pain and swelling affecting the joints and entheses. Several patterns of joint involvement are recognised but the course is generally one of intermittent exacerbation followed by varying periods of complete or near-complete remission. Destructive arthritis and disability are uncommon, except in the case of arthritis mutilans.

- *Asymmetrical inflammatory oligoarthritis* affects about 40% of patients and often presents abruptly with a combination of synovitis and adjacent periarticular inflammation. This occurs most characteristically in the hands and feet, when synovitis of a finger or toe is coupled with tenosynovitis, enthesitis and inflammation of intervening tissue to give a 'sausage digit' or dactylitis (Fig. 25.39A). Large joints, such as the knee and ankle, may also be involved, sometimes with very large effusions.
- *Symmetrical polyarthritis* occurs in about 25% of cases. It predominates in women and may strongly resemble RA, with symmetrical involvement of small and large joints in both upper and lower limbs. Nodules and other extra-articular features of RA are absent and arthritis is generally less extensive and more benign. Much of the hand deformity often results from tenosynovitis and soft tissue contractures.
- *Distal IPJ arthritis* is an uncommon but characteristic pattern affecting men more often than women. It targets finger DIP joints and surrounding periarticular tissues, almost invariably with accompanying nail dystrophy (Fig. 25.39B).
- *Psoriatic spondylitis* presents a similar clinical picture to AS but with less severe involvement. It may occur alone or with any of the other clinical patterns described above and is typically unilateral or asymmetric in severity.
- *Arthritis mutilans* is a deforming erosive arthritis targeting the fingers and toes that occurs in 5% of cases of PsA. Prominent cartilage and bone destruction results in marked instability. The encasing skin appears invaginated and 'telescoped' ('main en lorgnette') and the finger can be pulled back to its original length.

Fig. 25.39 Psoriatic arthropathy. A 'Sausage' middle finger of a patient with psoriatic arthritis. B Typical distal interphalangeal joint pattern with accompanying nail dystrophy (pitting and onycholysis).

Nail changes include pitting, onycholysis, subungual hyperkeratosis and horizontal ridging. They are found in 85% of those with PsA and only 30% of those with uncomplicated psoriasis, and can occur in the absence of skin disease. The characteristic rash of psoriasis (p. 1286) may be widespread, or confined to the scalp, natal cleft and umbilicus, where it is easily overlooked. Conjunctivitis can occur, whereas uveitis is mainly confined to HLA-B27-positive individuals with sacroiliitis and spondylitis.

Investigations

The diagnosis is made on clinical grounds. Autoantibodies are generally negative and acute phase reactants, such as ESR and CRP, are raised in only a proportion of patients with active disease. X-rays may be normal or show erosive change with joint space narrowing. Features that favour PsA over RA include the characteristic distribution (see Fig 25.9, p. 1070) of proliferative erosions with marked new bone formation, absence of periarticular osteoporosis and osteosclerosis. Imaging of the axial skeleton often reveals features similar to those in chronic reactive arthritis, with coarse, asymmetrical, non-marginal syndesmophytes and asymmetrical sacroiliitis. MRI and ultrasound with power Doppler are increasingly employed to detect synovial inflammation and inflammation at the entheses.

Management

Therapy with NSAID and analgesics may be sufficient to control symptoms in mild disease. Intra-articular steroid injections can control synovitis in problem joints. Splints and prolonged rest should be avoided because of the tendency to fibrous and bony ankylosis. Patients with spondylitis should be prescribed the same exercise and posture regime as in AS.

Therapy with DMARDs should be considered for persistent synovitis unresponsive to conservative treatment. Methotrexate is the drug of first choice since it may also help skin psoriasis, but other DMARDs may also be effective, including sulfasalazine, ciclosporin and leflunomide. DMARD monitoring should take place with particular attention to liver function since abnormalities are common in PsA. Hydroxychloroquine is generally avoided, as it can cause exfoliative skin reactions. Anti-TNF treatment should be considered for patients with active synovitis who respond inadequately to standard DMARDs. This is effective for both PsA and psoriasis. Other biological treatments, such as ustekinumab, are emerging, which target the IL-12/23 receptor. Ustekinumab is highly effective in the treatment of psoriatic skin disease and is often effectve in PsA.

The retinoid acitretin (p. 1267) is effective for skin lesions and, anecdotally, may also help arthritis, but it is teratogenic so must be avoided in young women. It also causes mucocutaneous side-effects, hyperlipidaemia, myalgias and extraspinal calcification. Photochemotherapy with methoxypsoralen and long-wave ultraviolet light (psoralen + UVA, PUVA) is primarily used for skin disease, but can also help those with synchronous exacerbations of inflammatory arthritis.

Enteropathic arthritis

An acute inflammatory oligoarthritis occurs in around 10% of patients with ulcerative colitis and 20% of those with Crohn's disease. It predominantly affects the large lower limb joints (knees, ankles, hips) but wrists and small joints of the hands and feet can also be involved. The arthritis usually coincides with exacerbations of the underlying bowel disease, and sometimes is accompanied by aphthous mouth ulcers, iritis and erythema nodosum. It improves with effective treatment of the bowel disease, and can be cured by total colectomy in patients with ulcerative colitis. Patients with inflammatory bowel disease may also develop sacroiliitis (16%) and AS (6%), which are clinically and radiologically identical to classic AS. These can predate or follow the onset of bowel disease and there is no correlation between activity of the spondylitis and bowel disease. The arthritis often remits with treatment of the bowel disease but DMARD and biological treatment is occasionally required.

CONNECTIVE TISSUE DISEASES

These share overlapping clinical features, characterised by dysregulation of immune responses, autoantibody production often directed at components of the cell nucleus, and widespread tissue damage.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a rare disease with a prevalence that ranges from about 0.03% in

Caucasians to 0.2% in Afro-Caribbeans. Some 90% of affected patients are female and the peak age at onset is between 20 and 30 years. Lupus is associated with considerable morbidity and a five-fold increase in mortality compared to age- and gender-matched controls, mainly because of an increased risk of premature cardiovascular disease.

Pathophysiology

The cause of SLE is incompletely understood but genetic factors play an important role. There is a higher concordance in monozygotic twins and the disease is strongly associated with polymorphic variants at the HLA locus. In a few instances, SLE is associated with inherited mutations in complement components C1q, C2 and C4, in the immunoglobulin receptor FcγRIIIb or in the DNA exonuclease *TREX1*. Genome-wide association studies have identified common polymorphisms near several other genes that predispose to SLE, most of which are involved in regulating immune cell function. From an immunological standpoint, the characteristic feature of SLE is autoantibody production. These autoantibodies have specificity for a wide range of targets but many are directed against antigens present within the cell or within the nucleus. This has led to the hypothesis that SLE may occur because of defects in apoptosis or in the clearance of apoptotic cells, which causes inappropriate exposure of intracellular antigens on the cell surface, leading to polyclonal B- and T-cell activation and autoantibody production. This is supported by the fact that environmental factors that cause flares of lupus, such as UV light and infections, increase oxidative stress and cause cell damage. Whatever the underlying cause of the autoantibody production, immune complex formation is thought to be an important mechanism of tissue damage in active SLE, leading to vasculitis and organ damage.

Clinical features

Symptoms such as fever, weight loss and mild lymphadenopathy may occur during flares of disease activity, whereas others such as fatigue, malaise and fibromyalgia-like symptoms can be constant and not particularly associated with active inflammatory disease.

Arthritis

Arthralgia is a common symptom, occurring in 90% of patients, and is often associated with early morning stiffness. Tenosynovitis may also occur but clinically apparent synovitis with joint swelling is rare. Joint deformities may occur (Jaccoud's arthropathy) as the result of tendon damage, but joint erosions do not occur.

Raynaud's phenomenon

Raynaud's syndrome (p. 602) is common and may antedate other symptoms by months or years. A common presentation is Raynaud's in combination with arthralgia or arthritis (Fig. 25.40). Raynaud's associated with SLE and other connective tissue disease needs to be differentiated from primary Raynaud's, which is common in healthy young women. Features in favour of secondary Raynaud's include age at onset of over 25 years, absence of a family history of Raynaud's, and occurrence in a male. Examination of capillary nail-fold loops using an ophthalmoscope (and oil placed on the skin) may help distinguish primary from secondary Raynaud's.

Fig. 25.40 Severe secondary Raynaud's phenomenon leading to digital ulceration.

Fig. 25.41 Butterfly (malar) rash of systemic lupus erythematosus, sparing the nasolabial folds.

Loss of the normal loop pattern, with capillary 'fallout' and dilatation and branching of loops, supports connective tissue disease.

Skin

Rash is common in SLE and is classically precipitated by exposure to UV light. Three distinct types occur:

- The classic butterfly facial rash (up to 20% of patients). This is erythematous, raised and painful or itchy, and occurs over the cheeks with sparing of the nasolabial folds (Fig. 25.41).
- The subacute cutaneous lupus erythematosus (SCLE) rash, which is migratory, non-scarring and either annular or psoriaform.
- The discoid lupus rash characterised by hyperkeratosis and follicular plugging, with scarring alopecia if it occurs on the scalp.

Diffuse, usually non-scarring alopecia may also occur with active disease. Other skin manifestations include periungual erythema (reflecting dilated capillary loops), vasculitis and livedo reticularis (Fig. 25.42), which is also a common feature of the antiphospholipid syndrome (p. 1055).

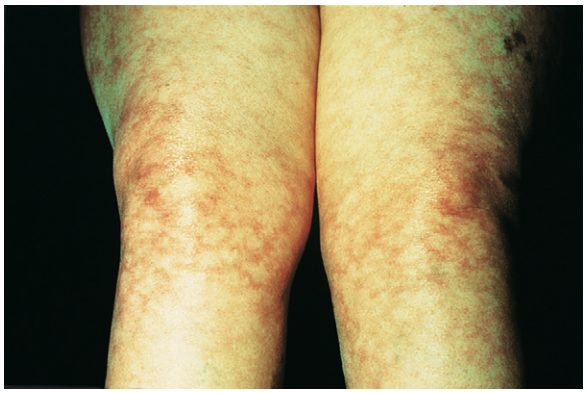

Fig. 25.42 Livedo reticularis in systemic lupus erythematosus.

Kidney

Renal involvement is one of the main determinants of prognosis, and regular monitoring of urinalysis and blood pressure is essential. The typical renal lesion is a proliferative glomerulonephritis (p. 498), characterised by heavy haematuria, proteinuria and casts on urine microscopy.

Cardiovascular

The most common manifestation is pericarditis. Myocarditis and Libman–Sacks endocarditis can also occur. The endocarditis is due to accumulation on the heart valves of sterile fibrin containing vegetations, which is thought to be a manifestation of hypercoagulability associated with antiphospholipid antibodies. The risk of atherosclerosis is greatly increased, as is the risk of stroke and myocardial infarction. This is thought to be multifactorial due to the adverse effects of inflammation on the endothelium, chronic steroid therapy and the procoagulant effects of antiphospholipid antibodies.

Lung

Lung involvement is common and most frequently manifests as pleurisy or pleural effusion. Other features include pneumonitis, atelectasis, reduced lung volume and pulmonary fibrosis that leads to breathlessness. The risk of thromboembolism is increased, especially in patients with antiphospholipid antibodies.

Neurological

Fatigue, headache and poor concentration are common, and often occur in the absence of laboratory evidence of active disease. More specific features of cerebral lupus include visual hallucinations, chorea, organic psychosis, transverse myelitis and lymphocytic meningitis.

Haematological

Neutropenia, lymphopenia, thrombocytopenia or haemolytic anaemia may occur, due to antibody-mediated destruction of peripheral blood cells. The degree of lymphopenia is a good guide to disease activity.

Gastrointestinal

Mouth ulcers may occur and may or may not be painful. Mesenteric vasculitis is a serious complication, which can present with abdominal pain, bowel infarction or perforation.

25.69 Revised American Rheumatism Association criteria for systemic lupus erythematosus

Features	Characteristics
Malar rash	Fixed erythema, flat or raised, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scarring and follicular plugging
Photosensitivity	Rash due to unusual reaction to sunlight
Oral ulcers	Oral or nasopharyngeal ulceration, which may be painless
Arthritis	Non-erosive, involving two or more peripheral joints
Serositis	Pleuritis (history of pleuritic pain or rub, or pleural effusion) *or* pericarditis (rub, ECG evidence or effusion)
Renal disorder	Persistent proteinuria > 0.5 g/day *or* cellular casts (red cell, granular or tubular)
Neurological disorder	Seizures or psychosis, in the absence of provoking drugs or metabolic derangement
Haematological disorder	Haemolytic anaemia *or* leucopenia* (< 4×10^9/L) *or* lymphopenia* (< 1×10^9/L) *or* thrombocytopenia* (< 100×10^9/L) in the absence of offending drugs
Immunological disorder	Anti-DNA antibodies in abnormal titre *or* presence of antibody to Sm antigen *or* positive antiphospholipid antibodies
ANA disorder	Abnormal titre of ANA by immunofluorescence

A person has SLE if any 4 out of these 11 features are present serially or simultaneously.

*On two separate occasions.

Investigations

The diagnosis is based on a combination of clinical features and laboratory abnormalities. To fulfil the classification criteria for SLE, at least 4 of the 11 factors shown in Box 25.69 must be present or have occurred in the past. Patients should be screened for ANA and antibodies to extractable nuclear antigens, and have complement levels checked along with routine haematology and biochemistry. Patients with active SLE almost always test positive for ANA, but ANA-negative SLE can very rarely occur in the presence of antibodies to the Ro antigen. Anti-dsDNA antibodies are characteristic of severe active SLE but only occur in around 30% of cases. Similarly, patients with active disease tend to have low levels of C3 and C4, but this may be the result of inherited complement deficiency that predisposes to SLE. Studies of other family members can help to differentiate inherited deficiency from complement consumption. A raised ESR, leucopenia and lymphopenia are typical of active SLE, along with anaemia, haemolytic anaemia and thrombocytopenia. CRP is often normal in active SLE, except in the presence of serositis, and an elevated CRP suggests coexisting infection.

Management

The therapeutic goals are to educate the patient about the nature of the illness, to control symptoms and to

prevent organ damage. Patients should be advised to avoid sun and UV light exposure and to employ sun blocks (factor 25–50).

Mild to moderate disease

Patients with mild disease restricted to skin and joints can sometimes be managed with analgesics, NSAID and hydroxychloroquine (200–400 mg daily). Frequently, however, corticosteroids are also necessary (prednisolone 5–20 mg/day), often in combination with immunosuppressants such as methotrexate, azathioprine or mycophenolate mofetil (MMF). Increased doses of steroids may be required for flares in activity or complications such as pleurisy or pericarditis. The monoclonal antibody belimumab, which targets the β-cell growth factor BLyS, has recently been shown to be effective in patients with active SLE who have responded inadequately to standard therapy.

Life-threatening disease

High-dose corticosteroids and immunosuppressants are required for the treatment of renal, CNS and cardiac involvement. A commonly used regimen is pulse methylprednisolone (10 mg/kg IV), coupled with cyclophosphamide (15 mg/kg IV), repeated at 2–3-weekly intervals for six cycles. Cyclophosphamide may cause haemorrhagic cystitis, but the risk can be minimised by good hydration and co-prescription of mesna, which binds its urotoxic metabolites. Because of the risk of azoospermia and anovulation (which may be permanent), pre-treatment sperm or ova collection and storage need to be considered prior to treatment with cyclophosphamide.

Mycophenolate mofetil has been used successfully in combination with high-dose steroids for renal involvement in SLE, with results equivalent to those of pulse cyclophosphamide but fewer adverse effects. The role of belimumab in life-threatening SLE remains to be established since clinical trials of this agent excluded patients with renal and cerebral lupus.

Maintenance therapy

Following control of the acute episode, the patient should be switched to oral immunosuppressive medication. A typical regimen is to start oral prednisolone in a dose of 40–60 mg daily on cessation of pulse therapy, gradually reducing to reach a target of 10–15 mg/day or less by 3 months. Azathioprine (2–2.5 mg/kg/day), methotrexate (10–25 mg/week) or MMF (2–3 g/day) should also be prescribed. The long-term aim is to continue the lowest dose of corticosteroids and immunosuppressant that will maintain remission. Cardiovascular risk factors, such as hypertension and hyperlipidaemia, should be controlled and patients advised to stop smoking.

Lupus patients with the antiphospholipid antibody syndrome (p. 1055) who have had previous thrombosis require life-long warfarin therapy.

Systemic sclerosis

Systemic sclerosis, or scleroderma, is a generalised disorder of connective tissue affecting the skin, internal organs and vasculature. It is characterised by sclerodactyly in combination with Raynaud's and digital ischaemia (Fig. 25.43). The peak age of onset is in the fourth and fifth decades, and overall prevalence is 10–20 per 100 000, with a 4:1 female preponderance. It is subdivided into diffuse cutaneous systemic sclerosis (DCSS: 30% of cases) and limited cutaneous systemic sclerosis (LCSS: 70% of cases). Many patients with LCSS have features that are phenotypically grouped into the 'CREST' syndrome (**C**alcinosis, **R**aynaud's, o**E**sophageal involvement, **S**clerodactyly and **T**elangiectasia). The prognosis in DCSS is poor, with a 5-year survival of approximately 70%. Features that associate with a poor prognosis include older age, diffuse skin disease, proteinuria, high ESR, a low TLCO (gas transfer factor for carbon monoxide) and pulmonary hypertension.

Fig. 25.43 Systemic sclerosis. Hands showing tight, shiny skin, sclerodactyly, flexion contractures of the fingers and thickening of the left middle finger extensor tendon sheath.

Pathophysiology

The cause of systemic sclerosis is poorly understood. There is evidence for a genetic component, and associations with alleles at the HLA locus have been found. The disease occurs in all ethnic groups, and race may influence severity, since DCSS is significantly more common in black women than white. Isolated cases have been reported in which a systemic sclerosis-like disease has been triggered by exposure to silica dust, vinyl chloride, hypoxyresins and trichloroethylene. There is clear evidence of immunological dysfunction: T lymphocytes, especially those of the Th17 subtype, infiltrate the skin and there is abnormal fibroblast activation, leading to increased production of extracellular matrix in the dermis, primarily type I collagen. This results in symmetrical thickening, tightening and induration of the skin (sclerodactyly). Arterial and arteriolar narrowing occurs due to intimal proliferation and vessel wall inflammation. Endothelial injury causes release of vasoconstrictors and platelet activation, resulting in further ischaemia, which is thought to exacerbate the fibrotic process.

Clinical features

Skin

Initially, there is non-pitting oedema of fingers and flexor tendon sheaths. Subsequently, the skin becomes shiny and taut, and distal skin creases disappear. This is accompanied by erythema and tortuous dilatation of capillary loops in the nail-fold bed, readily visible with

Fig. 25.44 Typical facial appearance in the CREST syndrome.

an ophthalmoscope or dissecting microscope (and oil placed on the skin). The face and neck are usually involved next, with thinning of the lips and radial furrowing. In some patients, skin thickening stops at this stage. Skin involvement restricted to sites distal to the elbow or knee (apart from the face) is classified as 'limited disease' or CREST syndrome (Fig. 25.44). Involvement proximal to the knee and elbow and on the trunk is classified as 'diffuse disease'.

Raynaud's phenomenon

This is a universal feature and can precede other features by many years. Involvement of small blood vessels in the extremities may cause critical tissue ischaemia, leading to skin ulceration over pressure areas, localised areas of infarction and pulp atrophy at the fingertips.

Musculoskeletal features

Arthralgia, morning stiffness and flexor tenosynovitis are common. Restricted hand function is due to skin rather than joint disease and erosive arthropathy is uncommon. Muscle weakness and wasting can occur due to myositis.

Gastrointestinal involvement

Smooth muscle atrophy and fibrosis in the lower two-thirds of the oesophagus lead to reflux with erosive oesophagitis. Dysphagia and odynophagia may also occur. Involvement of the stomach causes early satiety and occasionally outlet obstruction. Recurrent occult upper gastrointestinal bleeding may indicate a 'watermelon' stomach (antral vascular ectasia), which occurs in up to 20% of patients. Small intestine involvement may lead to malabsorption due to bacterial overgrowth and intermittent bloating, pain or constipation. Dilatation of large or small bowel due to autonomic neuropathy may cause pseudo-obstruction with nausea, vomiting, abdominal discomfort and distension, often worse after food.

Pulmonary involvement

This is a major cause of morbidity and mortality. Pulmonary hypertension complicates long-standing disease and is six times more prevalent in LCSS than in DCSS. It presents with rapidly progressive dyspnoea (more rapid than interstitial lung disease), right heart failure and angina, often in association with severe digital ischaemia. Fibrosing alveolitis mainly affects patients with DCSS who have topoisomerase 1 antibodies.

Renal involvement

One of the main causes of death is hypertensive renal crisis, characterised by rapidly developing malignant hypertension and renal failure. Hypertensive renal crisis is much more likely to occur in DCSS than in LCSS, and in patients with topoisomerase 1 antibodies.

Investigations

Scleroderma is primarily a clinical diagnosis but various laboratory abnormalities are characteristic. The ESR is usually elevated and raised levels of IgG are common, but CRP values tend to be normal unless there is severe organ involvement or coexisting infection. ANA is positive in about 70%, and approximately 30% of patients with DCSS have antibodies to topoisomerase 1 (Scl-70). About 60% of patients with CREST syndrome have anticentromere antibodies (p. 1068).

Management

No treatments are available that halt or reverse the fibrotic changes that underlie the disease. The focus of management, therefore, is to ameliorate the effects of the disease on target organs.

- *Raynaud's syndrome and digital ulcers*. Raynaud's should be treated by avoidance of cold exposure and use of mittens (heated mittens are available), supplemented if necessary with calcium antagonists. Intermittent infusions of prostacyclin may benefit severe digital ischaemia. The endothelin 1 antagonist bosentan can be of value in promoting healing of digital ulcers. If these become infected, antibiotics may be required, but as these penetrate tissues poorly in scleroderma, they need to be given at higher doses for a longer duration than usual.
- *Oesophageal reflux* should be treated with proton pump inhibitors and anti-reflux agents. Antibiotics may be required for bacterial overgrowth syndromes, and metoclopramide or domperidone may help patients with symptoms of pseudo-obstruction.
- *Hypertension* should be treated aggressively with ACE inhibitors, even if renal impairment is present.
- *Joint involvement* may be treated with analgesics and/or NSAID. If synovitis is present, immunosuppressants such as methotrexate can also be of value.
- *Pulmonary hypertension* may be treated with bosentan. In selected patients, heart–lung transplantation may be considered. Corticosteroids and cytotoxic drugs are indicated in patients who have coexisting myositis or fibrosing alveolitis.

Mixed connective tissue disease

Mixed connective tissue disease (MCTD) is a condition in which the clinical features of SLE, systemic sclerosis and myositis may all occur in the same patient. It most commonly presents with synovitis and oedema of the hands, in combination with Raynaud's phenomenon and muscle pain or weakness. Most patients have

anti-ribonucleoprotein (RNP) antibodies, but these can occur in SLE without overlap features. Management focuses on treating the individual components of the syndrome.

Sjögren's syndrome

This is an autoimmune disorder of unknown cause, characterised by lymphocytic infiltration of salivary and lachrymal glands, leading to glandular fibrosis and exocrine failure. The typical age of onset is between 40 and 50, with a 9:1 female preponderance. The disease may occur in isolation (primary Sjögren's syndrome) or in patients with other autoimmune diseases (secondary Sjögren's syndrome).

Clinical features

The eye symptoms, termed keratoconjunctivitis sicca, are due to a lack of lubricating tears, which, in turn, reflects inflammatory infiltration of the lacrimal glands. Conjunctivitis and blepharitis are frequent, and may lead to filamentary keratitis due to tenacious mucous filaments binding to the cornea and conjunctiva. Oral involvement manifests as a dry mouth and typically the patient needs to sip water to swallow food. There is a high incidence of dental caries. Other sites of extraglandular involvement are listed in Box 25.70. The disease is associated with a 40-fold increased lifetime risk of lymphoma.

Investigations

The diagnosis can be established by the Schirmer tear test, which measures tear flow over 5 minutes using absorbent paper strips placed on the lower eyelid; a normal result is more than 6 mm of wetting. Staining with rose Bengal may show punctate epithelial abnormalities over the area not covered by the open eyelid. If the diagnosis remains in doubt, it can be confirmed by lip biopsy, which shows focal lymphocytic infiltrate of the minor salivary glands. Most patients have an elevated ESR and hypergammaglobulinaemia, and one or more autoantibodies, including ANA and RF. Anti-Ro and anti-La antibodies are commonly present (see Box 25.11, p. 1068).

Management

No treatments that have disease-modifying effects have yet been identified and management is symptomatic. Lachrymal substitutes, such as hypromellose, should be used during the day in combination with more viscous lubricating ointment at night. Soft contact lenses can be useful for corneal protection in patients with filamentary keratitis, and occlusion of the lachrymal ducts is occasionally needed. Artificial saliva and oral gels can be tried for xerostomia but are often not effective. Stimulation of saliva flow by sugar-free chewing gum or lozenges may be helpful. Adequate post-prandial oral hygiene and prompt treatment of oral candidiasis are essential. Vaginal dryness is treated with lubricants such as K-Y jelly. Extraglandular and musculoskeletal manifestations may respond to steroids, and if so, immunosuppressive drugs can be added for their steroid-sparing effect. Fatigue is difficult to treat; this is usually due to non-restorative sleep (often because of xerostomia) and is unresponsive to steroids. Immunosuppression does not improve sicca symptoms. If lymphadenopathy or salivary gland enlargement develops, biopsy should be performed to exclude malignancy.

25.70 Features of Sjögren's syndrome

Risk factors	
• Age of onset 40–60 • Female > male	• HLA-B8/DR3
Common clinical features	
• Keratoconjunctivitis sicca • Xerostomia • Salivary gland enlargement	• Non-erosive arthritis • Raynaud's phenomenon • Fatigue
Less common features	
• Low-grade fever • Interstitial lung disease • Anaemia, leucopenia • Thrombocytopenia • Cryoglobulinaemia • Vasculitis	• Peripheral neuropathy • Lymphadenopathy • Lymphoreticular lymphoma • Glomerulonephritis • Renal tubular acidosis
Autoantibodies frequently detected	
• RF • ANA • SS-A (anti-Ro)	• SS-B (anti-La) • Gastric parietal cell • Thyroid
Associated autoimmune disorders	
• SLE • Progressive systemic sclerosis	• Primary biliary cirrhosis • Chronic active hepatitis • Myasthenia gravis

Polymyositis and dermatomyositis

Polymyositis and dermatomyositis are related disorders that are characterised by an inflammatory process affecting skeletal muscle. In dermatomyositis, characteristic skin changes also occur. Both diseases are rare, with an incidence of 2–10 cases per million/year. They can occur in isolation or in association with other autoimmune diseases, such as SLE, systemic sclerosis and Sjögren's syndrome. The cause is unknown, although there is evidence for a genetic contribution.

Clinical features

The typical presentation of polymyositis is with symmetrical proximal muscle weakness, usually affecting the lower limbs more than the upper. The onset is usually between 40 and 60 years of age and is typically gradual, over a few weeks. Myositis is usually widespread but focal disease can also occur. Affected patients report difficulty rising from a chair, climbing stairs and lifting, sometimes in combination with muscle pain. Systemic features of fever, weight loss and fatigue are common. Respiratory or pharyngeal muscle involvement can lead to ventilatory failure or aspiration that requires urgent treatment. Interstitial lung disease occurs in up to 30% of patients and is strongly associated with the presence of antisynthetase (Jo-1) antibodies.

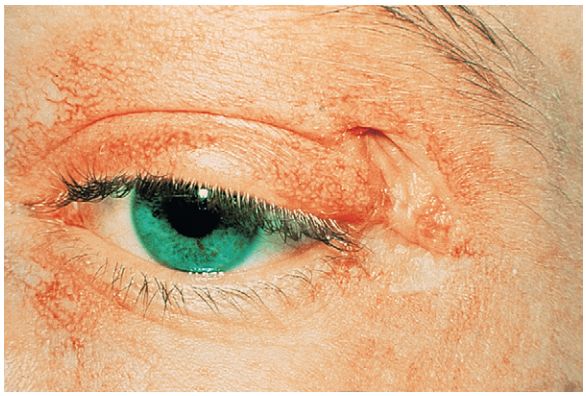

Fig. 25.45 Typical eyelid appearance in dermatomyositis. Note the oedema and telangiectasia.

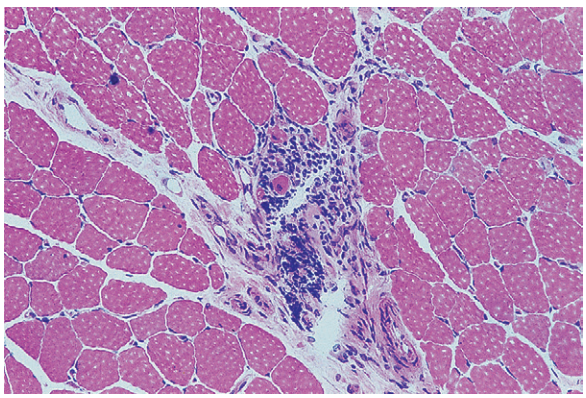

Fig. 25.46 Muscle biopsy from a patient with inflammatory myositis. The sample shows an intense inflammatory cell infiltrate in an area of degenerating and regenerating muscle fibres.

Dermatomyositis presents similarly but in combination with characteristic skin lesions. These include Gottron's papules, which are scaly, erythematous or violaceous, psoriaform plaques occurring over the extensor surfaces of PIP and DIP joints, and a heliotrope rash that is a violaceous discoloration of the eyelid in combination with periorbital oedema (Fig. 25.45). Similar rashes occur on the upper back, chest and shoulders ('shawl' distribution). Periungual nail-fold capillaries are often enlarged and tortuous. There is about a threefold increased risk of malignancy in patients with dermatomyositis and polymyositis. This may be apparent at the time of presentation, but the risk remains increased for at least 5 years following diagnosis.

Investigations

Muscle biopsy is the pivotal investigation and shows the typical features of fibre necrosis, regeneration and inflammatory cell infiltrate (Fig. 25.46). Occasionally, however, a biopsy may be normal, particularly if myositis is patchy. In such cases, MRI is used to identify areas of abnormal muscle for biopsy. Serum levels of CK are usually raised and are a useful measure of disease activity, although a normal CK does not exclude the diagnosis, particularly in juvenile myositis. EMG can confirm the presence of myopathy and exclude neuropathy. Screening for underlying malignancy should be undertaken routinely, and should include CT of chest/abdomen/pelvis, upper and lower gastrointestinal endoscopy, and mammography in women.

Management

Oral corticosteroids (prednisolone 1 mg/kg daily) are the mainstay of initial treatment, but high-dose intravenous methylprednisolone (1 g/day for 3 days) may be required in patients with respiratory or pharyngeal weakness. If there is a good response, steroids should be reduced by approximately 25% per month to a maintenance dose of 5–7.5 mg. Although most patients respond well to corticosteroids, many need additional immunosuppressive therapy. Azathioprine and methotrexate are the agents of first choice, but ciclosporin, cyclophosphamide, tacrolimus or MMF can be used as alternatives. Intravenous immunoglobulin may be effective in refractory cases. Relapses may occur in association with a rising CK, and indicate the need for additional therapy. If the patient relapses or fails to respond to treatment, this may be due to steroid-induced myopathy. A further biopsy should be performed and may show type 2 fibre atrophy in steroid-induced myopathy, as opposed to necrosis and regeneration in active myositis.

Inclusion body myositis

This is an inflammatory disease of muscle of unknown cause with a genetic component, which is associated with the accumulation of abnormal protein aggregates in affected tissue. It presents with muscle weakness in those over the age of 40 and is more common in men. Although proximal weakness does occur, distal involvement is more usual and may be asymmetrical. Investigation is the same as for polymyositis (p. 1115) and typically reveals a slightly elevated CK and both myopathic and neurogenic changes on EMG. Muscle biopsy shows abnormal fibres containing rimmed vacuoles and filamentous inclusions in the nucleus and cytoplasm. Treatment can be tried with high-dose corticosteroids, immunosuppressants and immunoglobulin, as described for polymyositis, but the therapeutic response is often poor.

VASCULITIS

These are a heterogeneous group of diseases characterised by inflammation and necrosis of blood-vessel walls, with associated damage to skin, kidney, lung, heart, brain and gastrointestinal tract. There is a wide spectrum of involvement and disease severity, ranging from mild and transient disease affecting only the skin, to life-threatening fulminant disease with multiple organ failure. Principal sites of involvement for the main types of vasculitis are summarised in Figure 25.47. The clinical features result from a combination of local tissue ischaemia (due to vessel inflammation and narrowing) and the systemic effects of widespread inflammation. Systemic vasculitis should be considered in any patient with fever, weight loss, fatigue, evidence of multisystem involvement, rashes, raised inflammatory markers and abnormal urinalysis (Box 25.71).

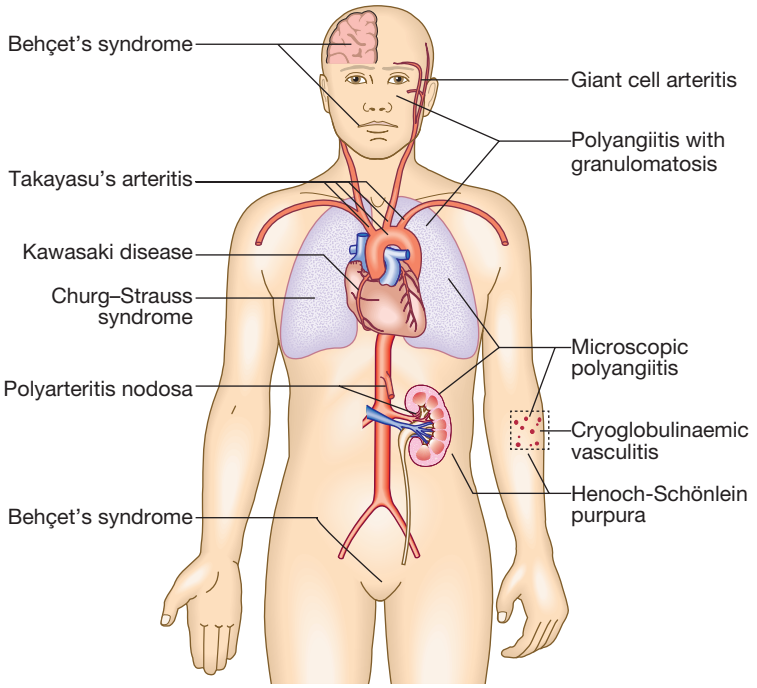

Fig. 25.47 Types of vasculitis. The anatomical targets of different forms of vasculitis are shown.

25.71 Clinical features of systemic vasculitis

Systemic	
• Malaise • Fever • Night sweats	• Weight loss with arthralgia and myalgia
Rashes	
• Palpable purpura • Pulp infarcts	• Ulceration • Livedo reticularis
Ear, nose and throat	
• Epistaxis • Recurrent sinusitis	• Deafness
Respiratory	
• Haemoptysis • Cough	• Poorly controlled asthma
Gastrointestinal	
• Abdominal pain (due to mucosal inflammation or enteric ischaemia)	• Mouth ulcers • Diarrhoea
Neurological	
• Sensory or motor neuropathy	

Takayasu's disease

Takayasu's disease predominantly affects the aorta, its major branches and occasionally the pulmonary arteries. The typical age at onset is between 25 and 30 years, with an 8:1 female preponderance. It has a worldwide distribution but is most common in Asia. Takayasu's is characterised by granulomatous inflammation of the vessel wall, leading to vessel occlusion or weakening of the vessel wall. It presents with claudication, fever, arthralgia and weight loss. The vessels most commonly affected are the aorta and carotid, ulnar, brachial, radial and axillary arteries. Clinical examination may reveal loss of pulses, bruits, hypertension and aortic incompetence. Investigation will identify an acute phase response and normocytic, normochromic anaemia, but the diagnosis is based on angiography, which reveals coarctation, occlusion and aneurysmal dilatation. The distribution of involvement is classified into four types:

- type 1: localised to the aorta and its branches
- type 2: localised to the descending thoracic and abdominal aorta
- type 3: combines features of 1 and 2
- type 4: involves the pulmonary artery.

Treatment is with high-dose steroids and immunosuppressants, as described for SLE. With appropriate treatment, the 5-year survival is 83%.

Kawasaki disease

Kawasaki disease is a vasculitis that mostly affects the coronary vessels. It presents as an acute systemic disorder, usually affecting children under 5 years. It occurs mainly in Japan and other Asian countries, such as China and Korea, but other ethnic groups may also be affected. Presentation is with fever, generalised rash, including palms and soles, inflamed oral mucosa and conjunctival injection resembling a viral exanthem. The cause is unknown but is thought to be the result of an abnormal immune response to an infectious trigger. Cardiovascular complications include coronary arteritis, leading to myocardial infarction, transient coronary dilatation, myocarditis, pericarditis, peripheral vascular insufficiency and gangrene. Treatment is with aspirin (5 mg/kg daily for 14 days) and intravenous gamma-globulin (400 mg/kg daily for 4 days).

Fig. 25.48 Rash of systemic vasculitis (palpable purpura).

Polyarteritis nodosa

Polyarteritis nodosa has a peak incidence between the ages of 40 and 50, with a male preponderance of 2:1. The annual incidence is around 2/1 000 000. Hepatitis B is an important risk factor, and the incidence is 10 times higher in the Inuit of Alaska, in whom hepatitis B infection is endemic. Presentation is with fever, myalgia, arthralgia and weight loss, in combination with manifestations of multisystem disease. The most common skin lesions are palpable purpura (Fig. 25.48), ulceration, infarction and livedo reticularis (see Fig. 25.42, p. 1111). Pathological changes comprise necrotising inflammation and vessel occlusion, and in 70% of patients, arteritis of the vasa nervorum leads to neuropathy, which is typically symmetrical and affects both sensory and motor function. Severe hypertension and/or renal impairment may occur due to multiple renal infarctions, but glomerulonephritis is rare (in contrast to microscopic polyangiitis). The diagnosis is confirmed by angiography, which shows multiple aneurysms and smooth narrowing of mesenteric, hepatic or renal systems, or by muscle or sural nerve biopsy, which reveals the histological changes above. Treatment is with high-dose steroids and immunosuppressants, as described for SLE.

Giant cell arteritis and polymyalgia rheumatica

Giant cell arteritis (GCA) is a granulomatous arteritis that predominantly affects medium-sized arteries in the head and neck. It is commonly associated with polymyalgia rheumatica (PMR), which presents with symmetrical muscle pain and stiffness affecting the shoulder and pelvic girdles. Since many patients with GCA have symptoms of PMR, and many patients with PMR go on to develop GCA if untreated, many rheumatologists consider them to be different manifestations of the same underlying disorder. Both diseases are rare under the age of 60 years. The average age at onset is 70, with a female preponderance of about 3:1. The overall prevalence is about 20 per 100 000 in those over the age of 50 years.

25.72 Conditions that can mimic polymyalgia rheumatica

- Fibromyalgia
- Hypothyroidism
- Cervical spondylosis
- RA
- Systemic vasculitis
- Inflammatory myopathy (particularly inclusion body myositis, p. 1115)
- Malignancy

Clinical features

The cardinal symptom of GCA is headache, which is often localised to the temporal or occipital region and may be accompanied by scalp tenderness. Jaw pain develops in some patients, brought on by chewing or talking, due to ischaemia of the masseter muscles. Visual disturbance can occur and a catastrophic presentation is with blindness in one eye due to occlusion of the posterior ciliary artery. On fundoscopy, the optic disc may appear pale and swollen with haemorrhages, but these changes may take 24–36 hours to develop and the fundi may initially appear normal. Other visual symptoms include loss of visual acuity, reduced colour perception and papillary defects. Rarely, neurological involvement may occur, with transient ischaemic attacks, brainstem infarcts and hemiparesis.

The cardinal features of PMR are symmetrical muscle pain and stiffness affecting the shoulder and pelvic girdles. Constitutional symptoms, such as weight loss, fatigue, malaise and night sweats, are common. The onset of symptoms is usually fairly sudden over a few days, but may be more insidious. On examination, there may be stiffness and painful restriction of active shoulder movement but passive movements are preserved. Muscles may be tender to palpation but weakness and muscle-wasting are absent. Other conditions that mimic PMR are shown in Box 25.72.

Investigations

The typical laboratory abnormality is an elevated ESR, often with a normochromic, normocytic anaemia. CRP may also be elevated and in some cases this precedes elevation of the ESR. Rarely, PMR and GCA can present with a normal ESR. The diagnosis is usually based on a combination of the typical clinical features, raised ESR and prompt response to steroid. However, if there is doubt concerning the diagnosis of GCA, a temporal artery biopsy may be undertaken. Characteristic biopsy findings are fragmentation of the internal elastic lamina with necrosis of the media in combination with a mixed inflammatory cell infiltrate. Whilst a positive biopsy is helpful, a negative biopsy does not exclude the diagnosis because the lesions are focal. Ultrasound or arteriography may be used to help guide the biopsy.

Management

Corticosteroids are the treatment of choice and should be commenced urgently in suspected GCA because of the risk of visual loss (Box 25.73). Response to treatment

25.73 Emergency management of giant cell arteritis

- Take blood for ESR and CRP
- Commence prednisolone 40–60 mg daily
- Review patient in 3–4 days
- Continue steroids in patients whose symptoms have resolved, with gradual reduction in dose
- Organise temporal artery biopsy in patients with poor or equivocal response

is dramatic, such that symptoms will have completely resolved within 48–72 hours of starting corticosteroid therapy in virtually all patients. It is customary to use higher doses in GCA (60–80 mg prednisolone) than in PMR (15–30 mg), although the evidence base for this is weak. In both conditions the steroid dose should be progressively reduced, guided by symptoms and ESR, with the aim of reaching a dose of 10–15 mg by about 8 weeks. Thereafter, the rate of reduction should be slower – by 1 mg per month – until an acceptable dose is achieved (5–7.5 mg daily). If symptoms recur, the dose should be increased to that which previously controlled the symptoms, and reduction attempted again in another few weeks. Most patients need steroids for an average of 12–24 months. Some patients also require steroid-sparing agents, such as methotrexate or azathioprine, if they require a maintenance dose of prednisolone of more than 7.5 mg daily. Prophylaxis against osteoporosis should be given in patients with low BMD.

Antineutrophil cytoplasmic antibody-associated vasculitis

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis is a life-threatening disorder characterised by inflammatory infiltration of small blood vessels, fibrinoid necrosis and the presence of circulating antibodies to ANCA. The combined incidence is about 10–15/1 000 000. Two subtypes are recognised. Microscopic polyangiitis (MPA) is a necrotising small-vessel vasculitis found with rapidly progressive glomerulonephritis, often in association with alveolar haemorrhage. Cutaneous and gastrointestinal involvement is common and other features include neuropathy (15%) and pleural effusions (15%). Patients are usually myeloperoxidase (MPO) antibody-positive. In granulomatosis with polyangiitis (also known as Wegener's granulomatosis (WG)), the vasculitis is characterised by granuloma formation, mainly affecting the nasal passages, airways and kidney. A minority of patients present with glomerulonephritis. The most common presentation of WG is with epistaxis, nasal crusting and sinusitis, but haemoptysis and mucosal ulceration may also occur. Deafness may be a feature due to inner ear involvement, and proptosis may occur because of inflammation of the retro-orbital tissue (Fig. 25.49). This causes diplopia due to entrapment of the extra-ocular muscles, or loss of vision due to optic nerve compression. Disturbance of colour vision is an early feature of optic nerve compression. Untreated nasal disease ultimately leads to destruction of bone and cartilage. Migratory pulmonary infiltrates and nodules occur in 50% of patients. Patients with WG are usually proteinase-3 (PR3) antibody-positive.

Fig. 25.49 Eye involvement in granulomatosis with polyangiitis.

Patients with active disease usually have a leucocytosis with an elevated CRP and ESR, in association with raised ANCA levels. Complement levels are usually normal or slightly elevated. Imaging of the upper airways or chest with MRI can be useful in localising abnormalities but, where possible, the diagnosis should be confirmed by biopsy of the kidney or lesions in the sinuses and upper airways.

Management is with high-dose steroids and cyclophosphamide, as described for SLE, followed by maintenance therapy with lower-dose steroids and azathioprine, methotrexate or mycophenolate mofetil (MMF). Rituximab in combination with high-dose steroids is equally effective as oral cyclophosphamide at inducing remission in ANCA-associated vasculitis. Both MPA and WG have a tendency to relapse, and patients must be followed on a regular and long-term basis to check for clinical signs of recurrence. Measurements of ESR, CRP and levels of ANCA antibodies are useful in monitoring disease activity.

Churg–Strauss syndrome

Churg–Strauss syndrome (CSS) is a small-vessel vasculitis with an incidence of about 1–3 per 1 000 000; it is associated with eosinophilia. Some patients have a prodromal period for many years, characterised by allergic rhinitis, nasal polyposis and late-onset asthma that is often difficult to control. The typical acute presentation is with a triad of skin lesions (purpura or nodules), asymmetric mononeuritis multiplex and eosinophilia. Pulmonary infiltrates and pleural or pericardial effusions due to serositis may be present. Up to 50% of patients have abdominal symptoms provoked by mesenteric vasculitis. Patients with active disease have raised levels of ESR and CRP and an eosinophilia. Although antibodies to MPO or PR3 can be detected in up to 60% of cases, CSS is considered to be a distinct disorder from the other ANCA-associated vasculitides. Biopsy of an affected site reveals a small-vessel vasculitis with eosinophilic infiltration of the vessel wall. Management is with high-dose steroids and cyclophosphamide, followed by maintenance therapy with low-dose steroids and azathioprine, methotrexate or MMF.

Henoch–Schönlein purpura

Henoch–Schönlein purpura (HSP) is a small-vessel vasculitis caused by immune complex deposition following an infectious trigger. It is predominantly a disease of children and young adults. The usual presentation is with purpura over the buttocks and lower legs, accompanied by abdominal pain, gastrointestinal bleeding and arthralgia. Nephritis can also occur and may present up to 4 weeks after the onset of other symptoms. Biopsy of affected tissue shows a vasculitis with IgA deposits in the vessel wall. HSP is usually a self-limiting disorder that settles spontaneously without specific treatment. Corticosteroids and immunosuppressive therapy may be required in patients with more severe disease, particularly in the presence of nephritis.

Cryoglobulinaemic vasculitis

This is a small-vessel vasculitis that can develop in some patients with circulating cryoglobulins, which are immunoglobulins that precipitate out in the cold. Cryoglobulins are classified into three types (see Box 4.14, p. 88), and types II and III are associated with vasculitis. The typical presentation is with a vasculitic rash over the lower limbs, arthralgia, Raynaud's phenomenon and neuropathy. Some cases are secondary to hepatitis infection and others are secondary to other autoimmune diseases. Affected patients should be screened for evidence of hepatitis B and C infection, and if the results are positive, these should be treated appropriately (pp. 952 and 955). There is no consensus as to how best to treat cryoglobulinaemic vasculitis in the absence of an obvious trigger. Corticosteroids and immunosuppressive therapy are often used empirically but their efficacy is uncertain.

Behçet's syndrome

This is a vasculitis of unknown aetiology that characteristically targets small arteries and venules. It is rare in Western Europe but more common in 'Silk Route' countries around the Mediterranean and Japan, where there is a strong association with HLA-B51.

Oral ulcers are universal (Fig. 25.50). Unlike aphthous ulcers, they are usually deep and multiple, and last for 10–30 days. Genital ulcers are also a common problem, occurring in 60–80% of cases. The usual skin lesions are erythema nodosum or acneiform lesions, but migratory thrombophlebitis and vasculitis also occur. Ocular involvement is common and may include anterior or posterior uveitis or retinal vasculitis. Neurological involvement occurs in 5% and mainly involves the brainstem, although the meninges, hemispheres and cord can also be affected, causing pyramidal signs, cranial nerve lesions, brainstem symptoms or hemiparesis. Recurrent thromboses also occur. Renal involvement is extremely rare.

The diagnosis is primarily made on clinical grounds (Box 25.74) but one characteristic feature that can be of diagnostic value is the pathergy test, which involves pricking the skin with a needle and looking for evidence of pustule development within 48 hours.

Fig. 25.50 Oral ulceration in Behçet's syndrome.

25.74 Criteria for the diagnosis of Behçet's syndrome

- Recurrent oral ulceration: minor aphthous, major aphthous or herpetiform ulceration at least three times in 12 mths

Plus two of the following:

- Recurrent genital ulceration
- Eye lesions: anterior uveitis, posterior uveitis, cells in vitreous on slit-lamp examination, retinal vasculitis
- Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, acneiform nodules
- Positive pathergy test

Oral ulceration can be managed with topical steroid preparations (soluble prednisolone mouthwashes, steroid pastes). Colchicine can be effective for erythema nodosum and arthralgia. Thalidomide (100–300 mg per day for 28 days initially) is very effective for resistant oral and genital ulceration but is teratogenic and neurotoxic. Steroids and immunosuppressants are indicated for uveitis and neurological disease.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory disease of cartilage that classically presents with acute pain and swelling of one or both ear pinnae, sparing the lower, non-cartilaginous portion. Around 30% of patients have coexisting autoimmune or connective tissue disease. Involvement of tracheobronchial cartilage leads to hoarse voice, cough, stridor or expiratory wheeze. Other manifestations include collapse of the bridge of the nose, scleritis, hearing loss and cardiac valve dysfunction. Cartilage biopsy shows an inflammatory infiltrate in the perichondrium. Both ESR and CRP are raised in active disease. Pulmonary function tests, including flow volume loops, should be performed to assess the degree of laryngotracheal disease, since this is an important cause of mortality. Mild disease usually responds to low-dose steroids or NSAID, whereas major tracheobronchial involvement requires high-dose steroids and immunosuppressants, as described for SLE.

DISEASES OF BONE

Osteoporosis

Osteoporosis is the most common bone disease and affects millions of people worldwide. Fractures related to osteoporosis are estimated to affect around 30% of women and 12% of men in developed countries, and are a major public health problem. In the UK alone, fractures are sustained by over 250 000 individuals annually, with treatment costs of about £1.75 billion. Osteoporotic fractures can affect any bone, but the most common sites are the forearm (Colles fracture), spine (vertebral fracture) and hip (Fig. 25.51). Of these, hip fractures are the most serious. Their immediate mortality is about 12% and there is a continued increase in mortality of about 20% when compared with age-matched controls. Treatment of hip fracture accounts for the majority of the healthcare costs associated with osteoporosis.

The defining feature of osteoporosis is reduced bone density, which causes a micro-architectural deterioration of bone tissue and leads to an increased risk of fracture. The prevalence of osteoporosis increases with age, reflecting the fact that bone density declines with age, especially in women (Fig. 25.52). The age-related decline in bone mass is accompanied by an increased risk of fractures (Fig. 25.53). This is due in part to the fall in bone density, but more importantly, to the increased risk of falling, which increases with age (p. 172).

Pathophysiology

Osteoporosis occurs because of a defect in attaining peak bone mass and/or because of accelerated bone loss. In normal individuals, bone mass increases during skeletal growth to reach a peak between the ages of 20 and 40 years but falls thereafter (see Fig. 25.52). In women there is an accelerated phase of bone loss after the menopause due to oestrogen deficiency, which causes uncoupling of bone resorption and bone formation, such that the amount of bone removed by osteoclasts exceeds the rate of new bone formation by osteoblasts. Age-related bone loss is a distinct process that accounts for the gradual bone loss that occurs with advancing age in both genders. Bone resorption is not particularly increased but bone formation is reduced and fails to keep pace with bone resorption. Accumulation of fat in the bone marrow space also occurs because of an age-related decline in the ability of bone marrow stem cells to differentiate into osteoblasts and an increase in their ability to differentiate into adipocytes.

Peak bone mass and bone loss are regulated by both genetic and environmental factors. Genetic factors account for up to 80% of the population variance in peak bone mass and other determinants of fracture risk, such as bone turnover and bone size. Polymorphisms have been identified in several genes that contribute to the pathogenesis of osteoporosis and many of these are in the RANK and Wnt signalling pathways, which play a critical role in regulating bone turnover (see Fig. 25.2, p. 1061). However, these account for only a small proportion of the genetic contribution to osteoporosis and many additional genetic variants remain to be discovered.

Environmental factors, such as exercise and calcium intake during growth and adolescence, are important in maximising peak bone mass and in regulating rates of post-menopausal bone loss. Smoking has a detrimental effect on bone mineral density (BMD) and is associated with an increased fracture risk, partly because female smokers have an earlier menopause than non-smokers. Heavy alcohol intake is a recognised cause of osteoporosis and fractures, but moderate intake does not substantially alter risk.

Post-menopausal osteoporosis

This is the most common cause of osteoporosis because of the effects of oestrogen deficiency, as described above. Early menopause (below the age of 45 years) is a particularly important risk factor.

Male osteoporosis

Osteoporosis is less common in men and a secondary cause can be identified in about 50% of cases. The most common are hypogonadism, corticosteroid use (see below) and alcoholism. In hypogonadism, the pathogenesis is as described for post-menopausal osteoporosis, as testosterone deficiency results in an increase in bone turnover and uncoupling of bone resorption from bone formation. Genetic factors are probably important in the 50% of cases with no identifiable cause.

Corticosteroid-induced osteoporosis

This is an important cause of osteoporosis that relates to dose and duration of corticosteroid therapy. Although there is no 'safe' dose of corticosteroid, the risk increases when the dose of prednisolone exceeds 7.5 mg daily and is continued for more than 3 months. Corticosteroids have adverse effects on calcium metabolism and bone cell function. A key abnormality is reduced bone

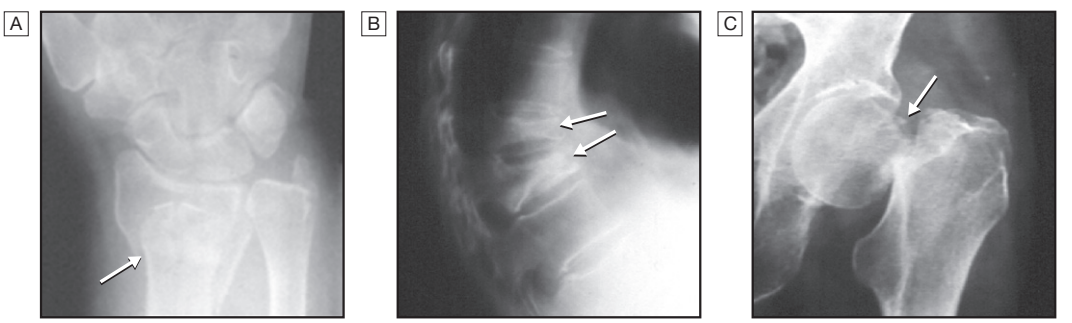

Fig. 25.51 Osteoporotic fractures: X-rays. A Wrist (Colles fracture). B Spine. C Hip.

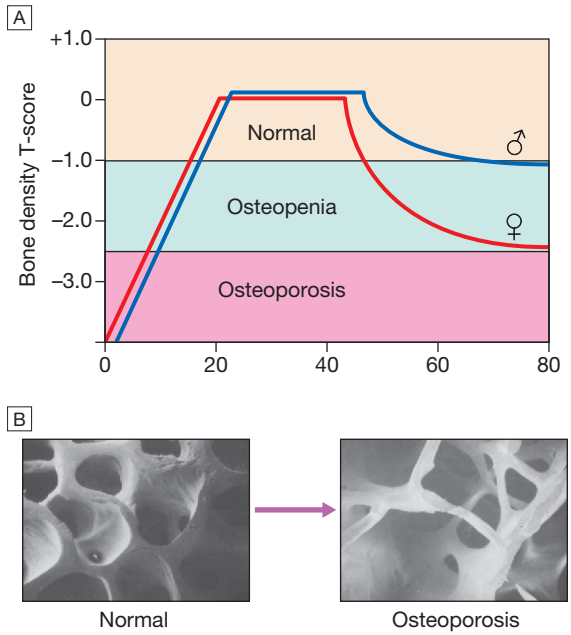

Fig. 25.52 Changes in bone mass and microstructure with age. A Changes in bone mass with age in men (blue line) and women (red line). B Scanning electron micrographs of normal bone (left) and osteoporotic bone (right).

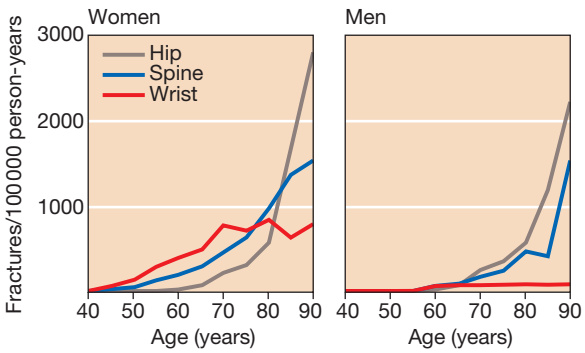

Fig. 25.53 Relationship between age and the incidence of osteoporotic fractures. Changes in the incidence of wrist fractures, vertebral fractures and hip fractures with age.

formation due to a direct inhibitory effect on osteoblast function and steroid-induced osteoblast and osteocyte apoptosis. Corticosteroids also inhibit intestinal calcium absorption and cause a renal leak of calcium, and this tends to reduce serum calcium, leading to secondary hyperparathyroidism with increased osteoclastic bone resorption. Hypogonadism may also occur with high-dose steroids.

Pregnancy-associated osteoporosis

This is a rare condition that typically presents with back pain and multiple vertebral fractures during the second or third trimester. The cause is unknown but may relate to an exaggeration of the bone loss that normally occurs during pregnancy, in patients with pre-existing low bone mass.

Other causes

Osteoporosis can occur as a complication of many diseases and drug treatments (Box 25.75). Primary

25.75 Secondary causes of osteoporosis and osteoporotic fractures

Endocrine disease	
• Hypogonadism	• Hyperparathyroidism
• Hyperthyroidism	• Cushing's syndrome
Inflammatory disease	
• Inflammatory bowel disease	• RA
• Ankylosing spondylitis	
Drugs	
• Corticosteroids	• Thiazolidinediones
• Gonadotrophin-releasing hormone (GnRH) agonists	• Sedatives
	• Anticonvulsants
• Aromatase inhibitors	• Alcohol intake > 3 U/day
• Thyroxine over-replacement	• Heparin
Gastrointestinal disease	
• Malabsorption	• Chronic liver disease
Lung disease	
• Chronic obstructive pulmonary disease	• Cystic fibrosis
Miscellaneous	
• Myeloma	• Systemic mastocytosis
• Homocystinuria	• Immobilisation
• Anorexia nervosa*	• Body mass index < 18
• Highly trained athletes*	• Heavy smokers
• HIV infection	• Autoantibodies to osteoprotegerin (OPG)
• Gaucher's disease	

*Hypogonadism also plays a role in osteoporosis associated with these conditions.

hyperparathyroidism causes bone loss because sustained elevation in PTH increases bone turnover, and bone formation cannot keep pace with resorption. A similar mechanism operates in thyrotoxicosis, driven by raised levels of thyroid hormones. Cushing's disease is a rare cause, identical in mechanism to corticosteroid-induced osteoporosis. Anorexia nervosa causes osteoporosis through calcium deficiency, low body weight and hypogonadism, whereas malabsorption predisposes to it through malnutrition, calcium and vitamin D deficiency and consequent secondary hyperparathyroidism. Chronic HIV infection predisposes to osteoporosis because of low body weight, chronic immune activation and antiretroviral therapy. Inflammatory diseases increase bone resorption and suppress bone formation through release of pro-inflammatory cytokines such as IL-1 and TNF, and increased expression of RANK by lymphocytes. Similar mechanisms operate in certain cancers, which release a variety of bone-resorbing factors, including TNF, lymphotoxin and parathyroid hormone-related protein (PTHrP). Gaucher's disease (p. 451) and systemic mastocytosis also cause release of bone resorbing factors. Thiazolidinediones such as rosiglitazone inhibit osteoblast differentiation and promote adipocyte differentiation in the bone marrow, leading to reduced bone formation and bone loss. Aromatase inhibitors cause osteoporosis by reducing peripheral conversion of adrenal androgens to oestrogen, whereas gonadotrophin-releasing hormone agonists do so by causing hypogonadism.

Clinical features

Patients with osteoporosis are asymptomatic until a fracture occurs. Osteoporotic spinal fracture may present with acute back pain or gradual onset of height loss and kyphosis with chronic pain. The pain of acute vertebral fracture can occasionally radiate to the anterior chest or abdominal wall and be mistaken for a myocardial infarction or intra-abdominal pathology, but worsening of pain by movement and local tenderness both suggest vertebral fracture. Peripheral osteoporotic fractures present with local pain, tenderness and deformity, often after an episode of minimal trauma. In patients with hip fracture, the affected leg is shortened and externally rotated. Many patients present with incidental osteopenia on an X-ray performed for other reasons.

Investigations

The pivotal investigation is dual energy X-ray absorptiometry (DEXA) at the lumbar spine and hip (see Fig. 25.8, p. 1066). This should be considered in patients with clinical risk factors for osteoporosis (Box 25.76), and those with an elevated 10-year fracture risk as defined by a fracture risk assessment tool (websites listed on p. 1135). Figure 25.54 provides an algorithm for the investigation of patients with suspected osteoporosis based on clinical risk factors, fracture risk assessment and DEXA.

A history should be taken to identify any predisposing causes, such as early menopause, excessive alcohol intake, smoking and corticosteroid therapy. Signs of endocrine disease, neoplasia and inflammatory disease should be sought on clinical examination. A falls history should be taken and a 'get up and go' test performed, especially in older patients (p. 167). Renal function, liver function, thyroid function, immunoglobulins and ESR, with screening for coeliac disease (anti-tissue transglutaminase (tTG) antibodies), should be performed. Serum 25(OH) vitamin D and PTH measurements are useful to exclude vitamin D deficiency and secondary hyperparathyroidism. Primary hyperparathyroidism should be suspected if hypercalcaemia is present (p. 769). Levels of sex hormones and gonadotrophins should be measured in men with osteoporosis and women under the age of 50. Transiliac bone biopsy is sometimes required in early-onset osteoporosis of unknown cause or when coexisting osteomalacia is suspected.

25.76 Indications for bone densitometry

- Low trauma fracture age > 50 years*
- Clinical features of osteoporosis (height loss, kyphosis)
- Osteopenia on plain X-ray
- Corticosteroid therapy (> 7.5 mg prednisolone daily for > 3 mths)
- Family history of hip fracture
- Low body weight (BMI < 18)
- Early menopause (< 45 yrs)
- Diseases associated with osteoporosis
- Increased fracture risk on risk factor analysis (FRAX or QFracture)
- Assessing response of osteoporosis to treatment

*Defined as a fracture that occurs as the result of a fall from standing height or less.

Management

The aim of treatment is to reduce the risk of fracture and this can be achieved by a combination of non-pharmacological and pharmacological approaches.

Non-pharmacological interventions

Advice on smoking cessation, moderation of alcohol intake, adequate dietary calcium intake and exercise should be given. Those with recurrent falls or unsteadiness on a 'get up and go' test should be referred to a multidisciplinary falls prevention team (p. 172). Hip protectors can reduce the risk of hip fracture in selected patients but adherence is often poor.

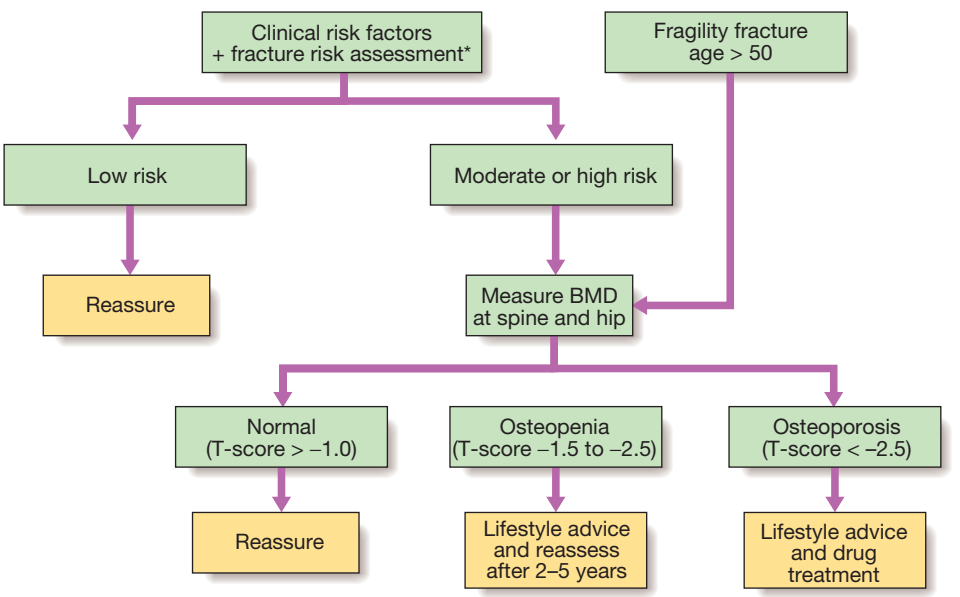

Fig. 25.54 Algorithm for the investigation of patients with suspected osteoporosis. *Using FRAX® or QFracture (see Further information, p. 1135). (BMD = bone mineral density)

Drug treatment

Several drugs have been shown to reduce the risk of osteoporotic fractures in randomised controlled trials. Their effects on vertebral and non-vertebral fracture are also summarised in Box 25.77.

Drug treatment should be considered in patients with BMD T-score values below –2.5 or below –1.5 in corticosteroid-induced osteoporosis, because there is evidence that fractures occur at a higher BMD value in steroid users and that drugs prevent fracture in patients with T-scores at this level. Treatment should also be considered in patients with vertebral fractures, irrespective of BMD, unless they resulted from significant trauma.

Bisphosphonates

Bisphosphonates inhibit bone resorption by binding to hydroxyapatite crystals on the bone surface. When osteoclasts attempt to resorb bone that contains bisphosphonate, the drug is released within the cell, where it inhibits key signalling pathways that are essential for osteoclast function. Although bisphosphonates primarily target the osteoclast, bone formation is also suppressed because of coupling between bone formation and bone resorption and an inhibitory effect on osteoblasts. However, the balance of effect on bone turnover is favourable, resulting in a gain in bone density due partly to increased mineralisation of bone. Bisphosphonate treatment typically leads to an increase in spine BMD of about 5–8% and in hip BMD of 2–4% during the first 3 years of treatment and plateaus thereafter.

Alendronic acid is the bisphosphonate used most frequently. It reduces risk of vertebral fractures by 40% and non-vertebral fractures by about 25% in postmenopausal women with osteoporosis. Risedronate is an alternative with similar efficacy, but may be better tolerated in patients with a history of gastrointestinal upset. Both drugs are effective in the treatment of corticosteroid-induced osteoporosis. They can also be used to treat male osteoporosis but neither has been shown to prevent non-vertebral fractures in men. Ibandronate is sometimes used but the evidence for prevention of non-vertebral fractures is less robust. Zoledronic acid is effective in the treatment of post-menopausal osteoporosis, corticosteroid-induced osteoporosis and osteoporosis in men. It reduces the risk of vertebral fracture by about 75% with similar effects to alendronic acid on non-vertebral fractures. It is especially useful for secondary prevention of fractures in elderly patients with hip fracture and reduces mortality in this group, being the only treatment that has been shown to modify this. Etidronate reduces the risk of vertebral fracture but the effects on non-vertebral fracture are less robust than those of other bisphosphonates. It is now seldom used.

Oral bisphosphonates are poorly absorbed from the gastrointestinal tract and should be taken on an empty stomach with plain water; no food should be eaten for 30–45 minutes after administration. Upper gastrointestinal upset occurs in about 5% so oral bisphosphonates should be used with caution in patients with existing gastro-oesophageal reflux disease. They should be avoided in patients with oesophageal stricture or achalasia, since tablets may stick in the oesophagus, causing ulceration and perforation. The most common adverse effect with intravenous bisphosphonates is a transient influenza-like illness characterised by fever, malaise, anorexia and generalised aches, which occurs 24–48 hours after administration. This is self-limiting but can be treated with paracetamol or NSAID if necessary. It predominantly occurs after the first exposure and tolerance develops thereafter. Other adverse effects are shown in Box 25.78. Osteonecrosis of the jaw (ONJ) is characterised by the presence of necrotic bone in the mandible or maxilla, typically occurring after tooth extraction when the socket fails to heal. Most ONJ cases have occurred in cancer patients with coexisting morbidity, such as infection and diabetes, who have received high doses of intravenous bisphosphonates; this complication is very rare in patients who are treated with the

25.77 Effects of drugs on the risk of osteoporotic fractures

Drug	Regimen	Vertebral fracture	Non-vertebral fracture	Hip fracture
Alendronic acid	70 mg/wk orally	+	+	+
Risedronate	35 mg/wk orally	+	+	+
Ibandronate	150 mg/mth orally 3 mg 3-monthly IV	+	+/–	–

(+ effective, – not effective; +/– equivocal results, or efficacy based on post-hoc subgroup analysis of clinical trials.)

25.78 Adverse effects of bisphosphonates

Common

- Upper gastrointestinal intolerance (oral)
- Acute phase response (intravenous)

Less common

- Atrial fibrillation (intravenous zoledronic acid)
- Renal impairment (intravenous zoledronic acid)
- Atypical subtrochanteric fractures

Rare

- Uveitis
- Osteonecrosis of the jaw

dose regimes used in osteoporosis. None the less, all patients receiving bisphosphonates for any reason should be advised to pay attention to good oral hygiene. There is no evidence that temporarily stopping medication in patients undergoing tooth extraction is necessary or alters the occurrence of ONJ. Atypical subtrochanteric fractures have been described in patients who have received long-term bisphosphonates, and may be the result of over-suppression of normal bone remodelling. In the vast majority, the benefits of bisphosphonate therapy far outweigh the risks, but it is important that treatment is targeted to patients with low BMD who are most likely to benefit.

Denosumab

Denosumab is a monoclonal antibody that neutralises the effects of RANKL (see Figure 25.2, p. 1061); it is administered by subcutaneous injection every 6 months in the treatment of osteoporosis. It is a powerful inhibitor of bone resorption and reduces the risk of hip fractures by 40%, vertebral fractures by 70% and other non-vertebral fractures by 20%. It has few adverse effects but there are isolated reports of ONJ with long-term use. Unlike bisphosphonates, its duration of action is short and it must be administered on a long-term basis to maintain its effect on bone mass and bone turnover.

Calcium and vitamin D

Calcium and vitamin D have limited efficacy in the prevention of osteoporotic fractures when given in isolation but are widely used as an adjunct to other treatments, most often as combination preparations containing 500 mg calcium and 800 U vitamin D. They are of greatest value in preventing fragility fractures in elderly or institutionalised patients who are at high risk of calcium and vitamin D deficiency (Box 25.79).

Strontium ranelate

Strontium ranelate reduces vertebral fracture risk by about 50% after 3 years and non-vertebral fracture risk by 12%. The mechanism of action is poorly understood. It has a weak inhibitory effect on bone resorption, stimulates biochemical markers of bone formation and is incorporated within hydroxyapatite crystals in place of calcium. Large changes in BMD (12%) occur, although this is partly an artefact due to substitution of strontium for calcium in bone mineral. The most common adverse effect is diarrhoea. Strontium is contraindicated in patients with cardiovascular disease due to an increased risk of myocardial infarction. There is also an increased risk of venous thrombosis. Rarely, a severe rash occurs, and this is an indication to stop treatment.

25.79 Osteoporosis in old age

- **Bone loss**: due to increased bone turnover, with an age-related defect switch in differentiation of bone marrow stromal cells to form adipocytes as opposed to osteoblasts.
- **Fractures due to osteoporosis**: common cause of morbidity and mortality, although fracture healing is not delayed by age.
- **Recurrent fractures**: those who suffer a fragility fracture are at increased risk of further fracture, so should be investigated for osteoporosis and treated if this is confirmed.
- **Falls**: risk factors for falls (such as visual and neuromuscular impairments) are independent risk factors for hip fracture in elderly women, so intervention to prevent falls is as important as treatment of osteoporosis (p. 172).
- **Intravenous zoledronic acid**: reduces mortality and subsequent fracture in elderly patients with hip fractures.
- **Calcium and vitamin D**: reduce the risk of fractures in those who are housebound or living in care homes.

Parathyroid hormone

PTH is an anabolic agent that works by stimulating new bone formation. The most widely used preparation is the 1-34 fragment of PTH (teriparatide) given by single daily subcutaneous injection of 20 µg. Teriparatide increases BMD by 10% or more in osteoporotic subjects and reduces risk of vertebral fractures by about 65% and non-vertebral fractures by 50%. It is also effective in corticosteroid-induced osteoporosis and appears superior to alendronate in terms of BMD gain and vertebral fracture reduction. It is also effective in male osteoporosis. PTH is expensive and is usually reserved for patients with severe osteoporosis (BMD T-score of –3.5 to –4.0 or below) and those who have failed to respond adequately to other treatments. The recommended duration of treatment is 24 months, after which patients should receive an antiresorptive drug, such as a bisphosphonate, to maintain the increase in BMD. Teriparatide should not be administered at the same time as bisphosphonates, as this blunts the anabolic effect. In patients who are being treated with teriparatide because of failure to respond, existing treatments should be stopped. The 1-84 fragment of PTH acts in a similar way to teriparatide but the evidence for prevention of non-vertebral fracture is less robust.

Hormone replacement therapy, raloxifene and tibolone

Cyclical HRT with oestrogen and progestogen prevents post-menopausal bone loss and reduces the risk of vertebral and non-vertebral fractures in post-menopausal women. It is primarily indicated for the prevention of osteoporosis in women with an early menopause (p. 760) and for treatment of women with osteoporosis in their early fifties who have troublesome menopausal symptoms. HRT should be avoided in older women with established osteoporosis because it significantly increases the risk of breast cancer and cardiovascular disease. Raloxifene acts as a partial agonist at oestrogen receptors in bone and liver but as an antagonist in breast and endometrium, and is classified as a selective oestrogen receptor modulator (SERM). It results in a

modest increase in BMD (2%) and a 40% reduction in vertebral fractures, but does not influence the risk of non-vertebral fracture and can provoke muscle cramps and worsen hot flushes. It increases the risk of VTE to a similar extent as HRT but reduces the risk of breast cancer; it does not influence the risk of cardiovascular disease. Bazedoxifene is a related SERM that has similar effects to raloxifene. Tibolone is a steroid that has partial agonist activity at oestrogen, progestogen and androgen receptors. It has similar effects on BMD to raloxifene and has been found to prevent vertebral and non-vertebral fractures in post-menopausal osteoporosis. Treatment is associated with a slightly increased risk of stroke but a reduced risk of breast cancer.

Other drugs

Calcitonin is an osteoclast inhibitor that has weak anti-fracture efficacy but is no longer used in the treatment of osteoporosis because of concerns about an increased risk of cancer with long-term use. It is occasionally used (unlicensed) in the short-term treatment of patients with acute vertebral fracture, when it is given by subcutaneous or intramuscular injection (100–200 U daily). Calcitriol ($1,25(OH)_2D_3$), the active metabolite of vitamin D, is licensed for treatment of osteoporosis, but it is seldom used since the data on fracture prevention are less robust than for other agents.

Duration of therapy and monitoring response

Oral bisphosphonates are usually given on a long-term basis for osteoporosis with periodic review of the continued need for therapy at 5-yearly intervals. The evidence base on duration of treatment is limited. Alendronate and risedronate appear to be safe and effective for up to 10 years in most patients, although one randomised trial with alendronate showed that overall fracture rates were similar in those given 5 years' therapy as opposed to 10. Studies with intravenous zoledronic acid have shown that 3 years' treatment give equal protection from fractures as 6 years' treatment. Other drug treatments, such as HRT, raloxifene and denosumab, need to be given continuously for a beneficial effect. The optimal duration of treatment for strontium has not been established. For anabolic drugs such as PTH, a 2-year course of treatment is given and followed by long-term anti-resorptive therapy.

The response to drug treatment can be assessed by repeating BMD measurements after 2–3 years. However, changes in BMD do not predict anti-fracture efficacy well and there is little evidence that monitoring by BMD or markers improves adherence. It may, however, reassure the patient that the treatment is working. Since the precision of spine BMD (approximately 1%) is better than hip (approximately 2.5%), spine BMD is best for monitoring. To be sure that a change has occurred, about twice the precision (about 2% for spine, 5% for hip) is required. This means that, under normal circumstances, at least 2 years should have elapsed before a repeat scan is performed. Biochemical markers of bone turnover, such as N-telopeptide (NTX), respond more quickly than BMD and can be used to assess adherence, but the correlation with anti-fracture efficacy is modest. Treatment response can also be established by measuring change in patient height (to assess progression of vertebral osteoporosis) and documenting the occurrence of clinical fractures.

Surgery

Orthopaedic surgery is frequently required to reduce and stabilise osteoporotic fractures. Patients with intracapsular fracture of the femoral neck generally require hemi-arthroplasty or total hip replacement in view of the high risk of avascular necrosis.

Vertebroplasty and kyphoplasty

Vertebroplasty (VP) is sometimes used in the treatment of painful vertebral compression fractures. It involves injecting methyl methacrylate (MMA) into the affected vertebral body. Although VP has been found to give better pain relief than medical therapy in the short term, recent randomised controlled trials that compared VP with a sham procedure showed no benefit (Box 25.80), indicating that the reduction in pain may be a placebo response. Kyphoplasty (KP) is used under similar circumstances but in this case a needle is introduced into the affected vertebral body and a balloon is inflated, which is then filled with MMA. This procedure is more effective than medical treatment at relieving pain in the short term, with results similar to VP. The effects of KP have not so far been compared with a sham procedure. Both procedures are generally safe but serious adverse effects include spinal cord compression, and fat embolus may occur.

EBM 25.80 Vertebroplasty in painful vertebral fractures

'Meta-analysis of individual patient data from two placebo controlled trials of vertebroplasty showed no advantage of active treatment over a sham procedure.'

- Staples MP, et al BMJ 2011; 343:d3952.

Management of recurrent fracture

Since the treatments for osteoporosis are incompletely effective at preventing fracture, it is not uncommon to encounter patients who suffer recurrent fractures whilst on treatment. In these circumstances it is useful to perform DEXA to determine whether BMD has increased, provided that sufficient time has elapsed to assess this (see above). If BMD has increased, then treatment should be continued. If there has been no BMD response or significant bone loss has occurred, the patient should be questioned about adherence and asked if the treatment is being taken correctly. This is particularly important with oral bisphosphonates, where absorption is poor and is inhibited by food. If the patient appears to be taking the medication correctly and significant bone loss has occurred, then a different treatment should be considered.

Osteomalacia and rickets

These conditions are characterised by defective mineralisation of bone due to vitamin D deficiency, resistance to the effects of vitamin D or hypophosphataemia. Osteomalacia describes a syndrome in adults of defective bone mineralisation, bone pain, increased bone

25.81 Causes of osteomalacia and rickets

Cause	Predisposing factor	Mechanism
Vitamin D deficiency		
Classical	Lack of sunlight exposure and poor diet	Reduced cholecalciferol synthesis in the skin/low levels of vitamin D in diet
Gastrointestinal disease	Malabsorption	Malabsorption of dietary vitamin D and calcium
Failure of 1,25 vitamin D synthesis		
Chronic renal failure	Hyperphosphataemia and kidney damage	Impaired conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$
Vitamin D-resistant rickets type I (autosomal recessive)	Loss-of-function mutations in renal 25(OH)D 1α-hydroxylase enzyme	Impaired conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$
Vitamin D receptor defects		
Vitamin D-resistant rickets type II (autosomal recessive)	Loss-of-function mutations in vitamin D receptor	Impaired response to $1,25(OH)_2D_3$
Defects in phosphate and pyrophosphate metabolism		
Hypophosphataemic rickets (X-linked dominant)	Mutations in *PHEX*	Increased FGF23 production (mechanism unclear)
Autosomal dominant hypophosphataemic rickets	Mutation in *FGF23*	Mutant FGF23 is resistant to degradation
Autosomal recessive hypophosphataemic rickets	*DMP1* mutation	Increased production of FGF23 Local deficiency of DMP1 inhibits mineralisation
Tumour-induced hypophosphataemic osteomalacia	Ectopic production of FGF23 by tumour	Over-production of FGF23
Hypophosphatasia	Mutations in bone-specific alkaline phosphatase	Inhibition of bone mineralisation due to accumulation of pyrophosphate in bone
Iatrogenic and other		
Bisphosphonate therapy	High-dose etidronate/pamidronate	Drug-induced impairment of mineralisation
Aluminium	Use of aluminium-containing phosphate binders or aluminium in dialysis fluid	Aluminium-induced impairment of mineralisation
Fluoride	High fluoride in water	Fluoride inhibits mineralisation

fragility and fractures. Rickets is the equivalent syndrome in children and is characterised by enlargement of the growth plate and bone deformity. The disease remains prevalent in frail older people who have a poor diet and limited sunlight exposure, and in some Muslim women who live in northern latitudes. There are four main causes of osteomalacia and rickets (Box 25.81).

Vitamin D deficiency

The most common cause of osteomalacia and rickets is vitamin D deficiency, which can result from either lack of sunlight exposure, from which the majority of vitamin D is derived; dietary deficiency (Fig. 25.55); or malabsorption of vitamin D in patients with gastrointestinal disease.

Pathophysiology

The source of vitamin D and pathways involved in regulating its metabolism are shown in Figure 25.55. In normal individuals, vitamin D (also known as cholecalciferol) comes from two sources: about 70% is made in the skin from 7-dehydrocholesterol under the influence of ultraviolet light, whereas the remaining 30% is derived from the diet. On entering the circulation, vitamin D is hydroxylated in the liver to form 25(OH) vitamin D and this is further hydroxylated in the kidney to form $1,25(OH)_2D$, the biologically active metabolite. The $1,25(OH)_2D$ primarily acts on the gut to increase intestinal calcium absorption but also acts on the skeleton to stimulate bone remodelling. Synthesis of $1,25(OH)_2D$ is regulated by a negative feedback loop orchestrated by the parathyroid glands. When vitamin D levels fall – for example, as the result of reduced sunlight exposure or dietary lack – 25(OH)D and $1,25(OH)_2D$ levels also fall, resulting in a reduction in calcium absorption from the gut. This causes serum calcium levels to fall, and this is detected by calcium-sensing receptors on the parathyroid chief cells, which respond by secreting parathyroid hormone (PTH). The raised levels of PTH restore calcium levels to normal by stimulating production of $1,25(OH)_2D$, reducing renal calcium excretion and increasing bone resorption. Renal phosphate excretion also increases, lowering serum phosphate levels. Initially, these changes are effective in maintaining normal levels of serum calcium but, with prolonged vitamin D deficiency, reserves of 25(OH)D become progressively depleted (through increased conversion of 25(OH)D to $1,25(OH)_2D$), leading to hypocalcaemia and hypocalcaemia with progressive demineralisation of the skeleton and the clinical syndromes of osteomalacia and rickets.

Clinical features

Vitamin D deficiency in children causes delayed development, muscle hypotonia, craniotabes (small unossified areas in membranous bones of the skull that yield to finger pressure with a cracking feeling), bossing of the frontal and parietal bones and delayed anterior fontanelle closure, enlargement of epiphyses at the lower end of the radius, and swelling of the rib costochondral junctions ('rickety rosary'). Osteomalacia in adults presents insidiously. Mild osteomalacia can be asymptomatic or

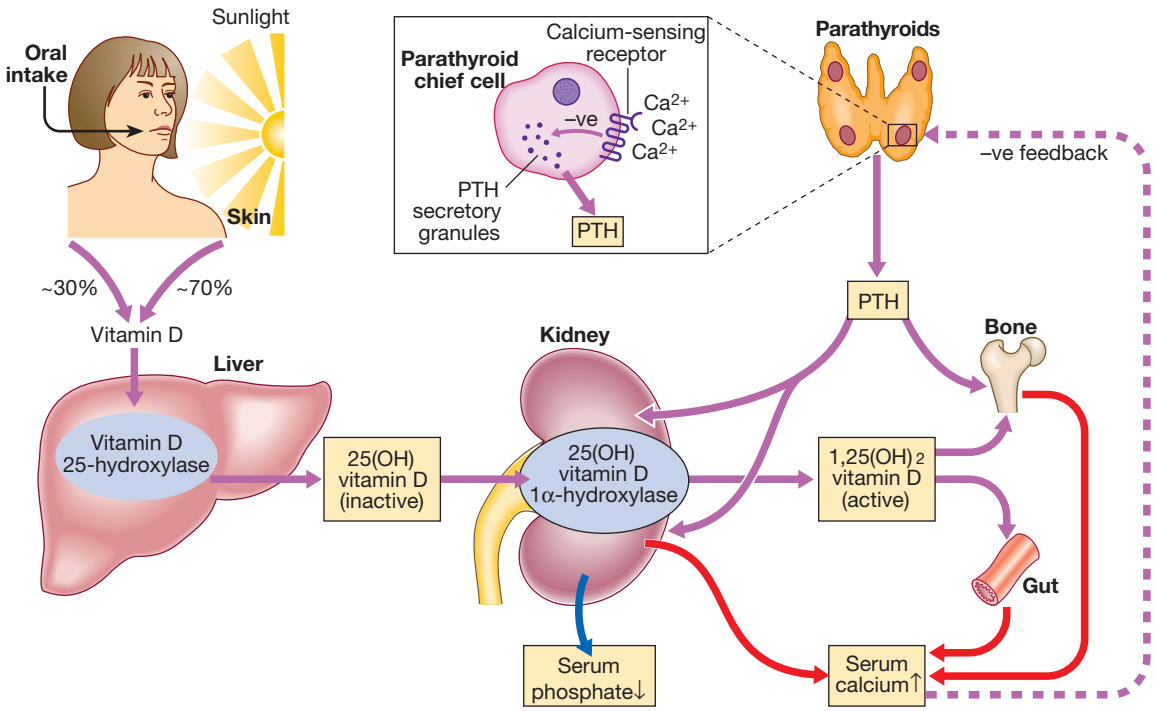

Fig. 25.55 Vitamin D metabolism. There is close interaction between vitamin D, serum calcium and parathyroid hormone (PTH). See text for details.

present with fractures and mimic osteoporosis. More severe osteomalacia presents with muscle and bone pain, general malaise and fragility fractures. Proximal muscle weakness is prominent and the patient may walk with a waddling gait and struggle to climb stairs or get out of a chair. There may be bone and muscle tenderness on pressure and focal bone pain can occur due to fissure fractures of the ribs and pelvis.

Investigations

The diagnosis can usually be made on a biochemical screen with measurement of serum 25(OH)D and PTH. Typically, serum ALP levels are raised, 25(OH)D levels are low or undetectable, and PTH is elevated. Serum calcium and phosphate levels may also be low but normal values do not exclude the diagnosis. X-rays are normal until advanced disease, when focal radiolucent areas (pseudofractures or Looser's zones) may be seen in ribs, pelvis and long bones (Fig. 25.56A). Radiographic osteopenia is common and the presence of vertebral crush fractures may cause confusion with osteoporosis. In children, there is thickening and widening of the epiphyseal plate. Radionuclide bone scan can show multiple hot spots in the ribs and pelvis at the site of fractures and the appearance may be mistaken for metastases. Where there is doubt, the diagnosis can be confirmed by bone biopsy, which shows the pathognomonic features of increased thickness and extent of osteoid seams (Fig. 25.56B).

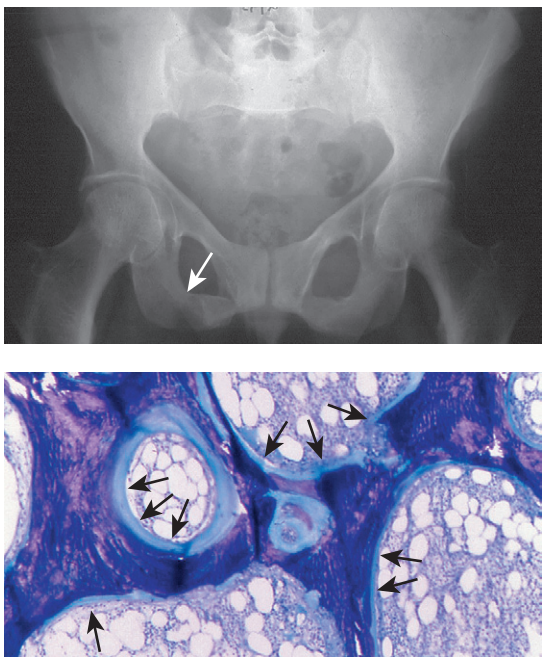

Fig. 25.56 Osteomalacia. A X-ray of the pelvis showing Looser's zones (arrow). B Photomicrograph of bone biopsy from osteomalacic patient showing thick osteoid seams (stained light blue) that cover almost all of the bone surface. Calcified bone is stained dark blue.

Management

Osteomalacia and rickets respond promptly to treatment with vitamin D (250–1000 µg daily), with rapid clinical improvement, an elevation in serum 25(OH)D and a reduction in PTH. Serum ALP levels sometimes rise initially as mineralisation of bone increases, but eventually fall to within the reference range as the bone disease heals. After 3–4 months, treatment can generally be stopped or the dose of vitamin D reduced to a maintenance level of 10–20 µg of cholecalciferol daily, except in patients with underlying disease such as malabsorption, in whom higher doses may be required.

Vitamin D-resistant rickets

The term vitamin D-resistant rickets (VDRR) describes osteomalacia and rickets caused by:

- inactivating mutations in the 25-hydroxyvitamin D 1α-hydroxylase (CYP27B1) enzyme, which converts 25(OH)D to the active metabolite $1,25(OH)_2D_3$ (type I VDRR)
- inactivating mutations in the vitamin D receptor, which impair its ability to activate transcription (type II VDRR).

Clinical features are similar to those of infantile rickets and the diagnosis is usually first suspected when the patient fails to respond to vitamin D supplementation. Since both are recessive disorders, consanguinity is common but there may or may not be a positive family history. Biochemical features of type I disease are similar to vitamin D deficiency, except that levels of 25(OH)D are normal. In type II disease, 25(OH)D is normal but PTH and $1,25(OH)_2D_3$ values are raised. Type I can be treated with the active vitamin D metabolites, 1α-hydroxyvitamin D (1–2 µg daily, orally) or 1,25 dihydroxyvitamin D (0.25–1.5 µg daily, orally), with or without calcium supplements, depending upon the patient's diet. Type II VDRR is extremely difficult to treat but sometimes responds partially to very high doses of active vitamin D metabolites and calcium and phosphate supplements.

Renal rickets and osteomalacia

Osteomalacia and rickets occur in patients with chronic renal failure due to defects in synthesis of renal $1,25(OH)_2D_3$ or due to over-aggressive treatment with oral phosphate binders. Pathogenesis and management are discussed on page 486.

Hypophosphataemic rickets and osteomalacia

Rickets and osteomalacia can occur as the result of inherited or acquired defects in renal tubular phosphate reabsorption, and rarely in patients with tumours that secrete phosphaturic substances (see Box 25.81).

Pathophysiology

Circulating levels of FGF23 play a critical role in regulating serum phosphate by modulating expression of sodium-dependent phosphate transporters in the kidney, which are responsible for renal tubular phosphate reabsorption. Osteocytes are the main source of FGF23 and levels of expression are regulated by the proteins DMP1 and PHEX, which are also produced by osteocytes (see Fig. 25.2, p. 1061). Inherited mutations affecting these proteins are summarised in Box 25.81 and account for most cases of hypophosphataemic rickets. Acquired hypophosphataemic rickets is mostly caused by over-production of FGF23 by tumours.

Clinical features and diagnosis

The hereditary disorders usually present in childhood with rickets. The diagnosis is made on the basis of the early age at onset and the presence of hypophosphataemia with renal phosphate wasting, in the absence of vitamin D deficiency. Molecular diagnosis can define the causal mutation. Tumour-induced hypophosphataemic osteomalacia presents with severe, rapidly progressive symptoms in patients with no obvious predisposing factor for osteomalacia. Strenuous efforts should be made to identify the underlying, usually occult tumour with whole-body MRI or CT.

Management

Treatment is with phosphate supplements (1–4 g daily) and active metabolites of vitamin D (1α-hydroxyvitamin D, 1–2 µg daily, or 1,25 dihydroxyvitamin D, 0.25–1.5 µg daily) to promote intestinal calcium and phosphate absorption. The aim is to ameliorate symptoms, restore normal growth, maintain serum phosphate levels within the reference range and normalise ALP levels. Levels of calcium, phosphate, ALP and renal function should be monitored. Tumour-induced osteomalacia can be managed in the same way but ideally should be treated with surgical excision of the tumour since this is curative.

Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder caused by inactivating mutations in the *TNALP* gene that impair ALP function, resulting in accumulation of pyrophosphate and inhibition of bone mineralisation. Chondrocalcinosis may also occur. The diagnosis should be suspected in osteomalacic patients with low or undetectable levels of serum ALP but normal levels of calcium, phosphate, PTH and vitamin D metabolites. Medical treatment with injections of recombinant ALP has recently been introduced with promising results.

Other causes of osteomalacia

These are summarised in Box 25.81. Aluminium intoxication is now rare due to reduced use of aluminium-containing phosphate binders and removal of aluminium from the water supplies used in dialysis. If aluminium intoxication is suspected, the diagnosis can be confirmed by demonstration of aluminium at the calcification front in a bone biopsy. Osteomalacia due to bisphosphonates has mostly been described in patients with Paget's disease receiving etidronate and high-dose pamidronate. It is usually asymptomatic and healing occurs when treatment is stopped. Excessive fluoride intake causes osteomalacia due to direct inhibition of mineralisation and is common in parts of the world where there is a high fluoride content in drinking water. The condition reverses when fluoride intake is reduced.

Paget's disease of bone

Paget's disease of bone (PDB) is a common condition characterised by focal areas of increased and disorganised bone remodelling. It mostly affects the axial skeleton, and bones that are commonly involved include the pelvis, femur, tibia, lumbar spine, skull and scapula. It is seldom diagnosed before the age of 40, but gradually increases in incidence thereafter to affect up to 8% of the UK population by the age of 85. The disease is common in Caucasians from north-west and southern Europe but is rare in Scandinavians, Asians, Chinese and Japanese. These ethnic differences persist after migration, supporting the importance of genetic factors in the aetiology, but the incidence of PDB has fallen in some countries over the past 25 years, suggesting that environmental triggers also play a role.

Pathophysiology

The primary abnormality is increased osteoclastic bone resorption, accompanied by marrow fibrosis, increased vascularity of bone and increased osteoblast activity. Bone in PDB is architecturally abnormal and has reduced mechanical strength. Osteoclasts in PDB are increased in number, are unusually large and contain characteristic nuclear inclusion bodies. Genetic factors are important and mutations in the *SQSTM1* gene are a common cause of classical PDB. The presence of nuclear inclusion bodies in osteoclasts has fuelled speculation that PDB might be caused by a slow virus infection with measles or distemper but the evidence is conflicting. Biomechanical factors may help determine the pattern of involvement, since PDB often starts at sites of muscle insertions into bone and, in some cases, localises to bones or limbs that have been subjected to repetitive trauma or overuse. Involvement of subchondral bone can compromise the joint and predispose to OA ('Pagetic arthropathy').

Clinical features

The classic presentation is with bone pain, deformity, deafness and pathological fractures, but many patients are asymptomatic and diagnosed from an abnormal X-ray or blood test performed for another reason. Clinical signs include bone deformity and expansion, increased warmth over affected bones, and pathological fracture. Bone deformity is most evident in weight-bearing bones such as the femur and tibia, but when the skull is affected the patient may complain that hats no longer fit due to cranial enlargement. Neurological problems, such as deafness, cranial nerve defects, nerve root pain, spinal cord compression and spinal stenosis, are recognised complications due to enlargement of affected bones and encroachment upon the spinal cord and nerve foraminae. Surprisingly, deafness seldom results from compression of the auditory nerve, but is conductive due to osteosclerosis of the temporal bone. The increased vascularity of Pagetic bone makes operative procedures difficult and, in extreme cases, can precipitate high-output cardiac failure in elderly patients with limited cardiac reserve. Osteosarcoma is a rare but serious complication that presents with subacute onset of increasing pain and swelling of an affected site.

Investigations

The characteristic features are an elevated serum ALP and bone expansion on X-ray, with alternating areas of radiolucency and osteosclerosis (Fig. 25.57B). ALP is normal in about 5% of cases, usually because of monostotic involvement. Radionuclide bone scanning is useful to define the presence and extent of disease (Fig. 25.57A). If the bone scan is positive, X-rays should be taken of an affected bone to confirm the diagnosis. Bone biopsy is not usually required but may help to exclude osteosclerotic metastases in cases of diagnostic uncertainty.

Management

The main indication for treatment with inhibitors of bone resorption is bone pain thought to be due to increased metabolic activity (Box 25.82). It is often difficult to differentiate this from pain due to complications such as bone deformity, nerve compression symptoms and OA. If there is doubt, it can be worthwhile giving a therapeutic trial of antiresorptive therapy to determine whether the symptoms improve. A positive response indicates that the pain was due to increased metabolic activity. The aminobisphosphonates pamidronate, zoledronate and risedronate are more effective than simple bisphosphonates such as etidronate and tiludronate at suppressing bone turnover in PDB, but their effects on pain are similar. Although bisphosphonates suppress bone turnover in PDB, there is no evidence to show that they alter the natural history or prevent complications. Calcitonin can be used as an alternative but is less convenient to administer and more expensive. Repeated courses of bisphosphonates or calcitonin can be given if symptoms recur. If symptoms do not respond to antiresorptive therapy, it is likely that the pain is due to a complication of the disease and this should be managed according to the principles described on page 1085.

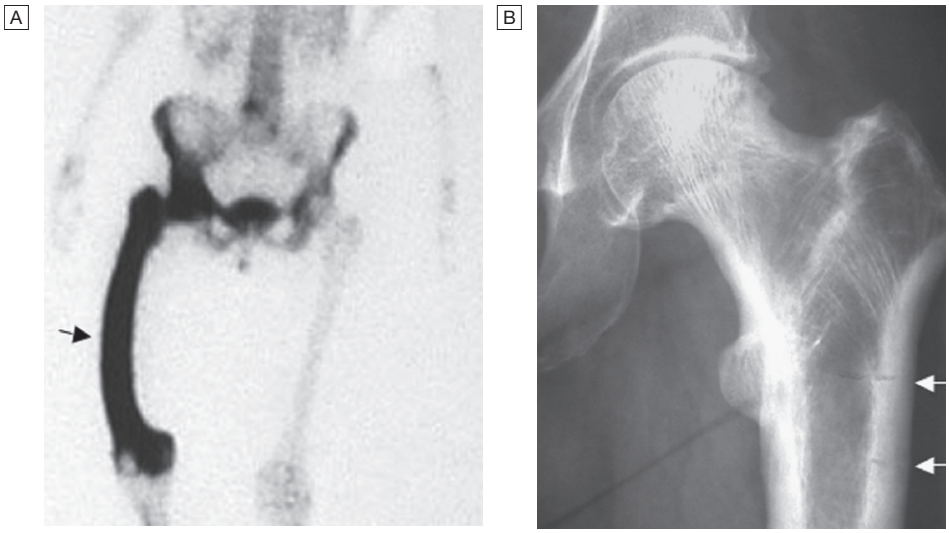

Fig. 25.57 Paget's disease. A Isotope bone scan from a patient with Paget's disease, illustrating the intense tracer uptake and deformity of the affected femur. B The typical radiographic features with expansion of the femur, alternating areas of osteosclerosis and radiolucency of the trochanter, and pseudofractures breaching the bone cortex (arrows).

25.82 Medical management of Paget's disease

Drug	Route of administration	Dose	Inhibitory effect on bone turnover
Etidronate	Oral	400 mg daily for 3–6 mths	+
Tiludronate	Oral	400 mg daily for 3–6 mths	+
Risedronate	Oral	30 mg daily for 2 mths	++
Pamidronate	IV	1–3 × 60 mg	++
Zoledronic acid	IV	1 × 5 mg	+++
Calcitonin	SC	100–200 U 3 times weekly for 2–3 mths	+

+ moderately effective; ++ effective; +++ highly effective.

Fig. 25.58 Reflex sympathetic dystrophy. Isotope bone scan showing increased uptake in femoral condyle.

Other bone diseases

Reflex sympathetic dystrophy syndrome

Reflex sympathetic dystrophy syndrome (RSDS), or algodystrophy, presents with gradual onset of severe pain, swelling and local tenderness, usually affecting a limb extremity. It is characterised by localised osteoporosis of the affected limb and evidence of regional autonomic dysfunction, such as abnormal sweating, colour and temperature change. It is commonly triggered by fracture, occurring in up to 25% of patients with Colles fracture. It can also associate with soft tissue injury, pregnancy and intercurrent illness, or can develop spontaneously. The cause is unknown but overactivity of the sympathetic nervous system is thought to be responsible for many of its features.

The diagnosis is clinical but supported by patchy osteoporosis of the affected bone on X-ray, by a local increase in isotope uptake on bone scanning (Fig. 25.58), or by marrow oedema on MRI. The differential diagnosis includes infection and malignancy. Usually, the diagnosis of RSD is clear on clinical grounds and by the absence of an acute phase response or other systemic features of malignancy, but a biopsy of the affected site can be undertaken if necessary and typically shows local osteopenia only.

The aims of treatment are to control pain and encourage mobilisation. Analgesics, NSAID, antineuropathic agents, calcitonin, corticosteroids, β-adrenoceptor antagonists (β-blockers), sympathectomy and bisphosphonates have all been tried, but none is particularly effective. Although some cases resolve with time, many have persistent symptoms and fail to regain normal function.

Osteonecrosis

Osteonecrosis describes death of bone due to impairment of its blood supply. The most commonly affected sites are the femoral head, humeral head and femoral condyles. In some cases, the condition occurs as the result of direct trauma that interrupts the blood supply to the affected bone. This is the reason for osteonecrosis of the femoral head in patients with subtrochanteric fractures of the femoral neck, and patients with thrombophilia and haemoglobinopathies such as sickle cell disease. Other important predisposing factors include high-dose corticosteroid treatment, alcohol excess, SLE and radiotherapy, but in many of these conditions, the pathophysiology is poorly understood. The presentation is with pain localised to the affected site, which is exacerbated by weight-bearing. The diagnosis can be confirmed by MRI, which shows evidence of subchondral necrotic bone and bone marrow oedema. X-rays are normal in the early stages but later may show evidence of osteosclerosis and deformity of the affected bone. There is no specific treatment. Management should focus on controlling pain and encouraging mobilisation (p. 1085). Symptoms often improve spontaneously with time but joint replacement may be required in patients who have persisting pain in association with significant structural damage to the affected joint.

Scheuermann's osteochondritis

This disorder predominantly affects adolescent boys, who develop a dorsal kyphosis in association with irregular radiographic ossification of the vertebral end plates. It has a strong genetic component and may be inherited in an autosomal dominant manner. Most patients are asymptomatic but back pain, aggravated by exercise and relieved by rest, may occur. Excessive exercise and heavy manual labour before epiphyseal fusion has occurred may aggravate symptoms. Management consists of advice to avoid excessive activity, and protective postural exercises. Rarely, corrective surgery may be required if there is severe deformity. During adulthood, Scheuermann's osteochondritis can sometimes be complicated by the development of

secondary OA, which may cause back pain. Occasionally, the vertebral deformity and kyphosis can be mistaken for osteoporotic vertebral fractures during adult life, but this can be excluded by DEXA examination, which typically shows normal or raised BMD values in Scheuermann's disease.

Polyostotic fibrous dysplasia

This is an acquired disorder caused by mutations in the *GNAS1* gene, characterised by focal or multifocal bone pain, bone deformity and expansion, and pathological fractures. Associated features include endocrine dysfunction, especially precocious puberty, and café-au-lait skin pigmentation (McCune–Albright syndrome). The diagnosis is made by imaging, which shows focal, predominantly osteolytic lesions and bone expansion on X-ray, and focal increased uptake on bone scan. The condition can resemble Paget's disease of bone but the earlier age of onset and pattern of involvement are usually distinctive. Management is symptomatic. Surgery is sometimes required for treatment of fracture and deformity. Very rarely, malignant change can occur and should be suspected if there is a sudden increase in pain and swelling. There is limited evidence that intravenous pamidronate may help bone pain and promote healing of lytic lesions.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is the name given to a group of disorders characterised by severe osteoporosis and multiple fractures in infancy and childhood. Most cases are caused by mutations in the *COL1A1* and *COL1A2* genes, which encode the proteins that make up type I collagen. This results either in reduced collagen production (in mild OI) or in formation of abnormal collagen chains that are rapidly degraded (in severe OI). Most patients have dominant inheritance but recessive forms have been described, caused by mutations in the *CRTAP* and *LEPRE* genes, which are involved in post-translational modification of collagen. Many patients have no family history and are presumed to have new mutations. Severity varies from neonatal lethal (type II), through very severe with multiple fractures in infancy and childhood (types III and IV), to mild (type I), in which affected patients typically have blue sclerae. The diagnosis of OI is usually obvious clinically. In childhood, the disease can be mistaken for non-accidental injury and in adulthood for osteoporosis. In such cases, genetic testing can be of diagnostic value. Treatment is multidisciplinary, involving surgical reduction and fixation of fractures and correction of limb deformities, and physiotherapy and occupational therapy for rehabilitation of patients with bone deformity. Bisphosphonates are widely used in the treatment of OI, especially intravenous pamidronate in children, but there is limited evidence that this prevents fractures or deformity.

Osteopetrosis

Osteopetrosis is a rare group of inherited diseases caused by failure of osteoclast function. Presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers–Schönberg disease) shows autosomal dominant inheritance and presents with bone pain, cranial nerve palsies, osteomyelitis, OA or fracture, or is sometimes detected as an incidental radiographic finding. The responsible mutations either affect the genes that regulate osteoclast differentiation (*RANK, RANKL*), causing 'osteoclast-poor' osteopetrosis, or affect the genes involved in bone resorption, causing 'osteoclast-rich' osteopetrosis. These include mutations in the *TCIRG1* gene, which encodes a component of the osteoclast proton pump, and mutations in the *CLCN7* gene, which encodes the osteoclast chloride pump. Management is difficult. IFN-γ treatment can improve blood counts and reduce frequency of infections, but in severe cases haematopoietic stem cell transplantation is required to provide a source of osteoclasts that resorb bone normally.

Sclerosing bone dysplasias

These are rare diseases characterised by osteosclerosis and increased bone formation. Van Buchem's disease and sclerosteosis are recessive disorders caused by loss-of-function mutations in the *SOST* gene (see Fig. 25.2, p. 1061). The resulting lack of sclerostin causes increased bone formation and bone overgrowth, leading to enlargement of the cranium and jaw, tall stature and cranial nerve palsies. There is no effective treatment. High bone mass syndrome is a benign disorder characterised by unusually high bone density. Most patients are asymptomatic but bone overgrowth in the palate can occur. Treatment is not usually required. Camurati–Engelmann disease is an autosomal dominant condition caused by gain of function in the *TGFB1* gene. It presents with bone pain, muscle weakness and osteosclerosis mainly affecting the diaphysis of long bones. Corticosteroids can help the bone pain, although analgesics are also usually required.

BONE AND JOINT TUMOURS

Primary tumours of bones and joints are rare, have a peak incidence in childhood and adolescence, and can be benign or malignant (Box 25.83). Paget's disease of

25.83 Primary tumours of the musculoskeletal system

Cell type	Benign	Malignant
Osteoblast	Osteoid osteoma	Osteosarcoma
Chondrocyte	Chondroma Osteochondroma	Chondrosarcoma
Fibroblast	Fibroma	Fibrosarcoma
Bone marrow cell	Eosinophilic granuloma	Ewing's sarcoma
Endothelial cell	Haemangioma	Angiosarcoma
Osteoclast precursor	Giant cell tumour	Malignant giant cell tumour

bone (p. 1128) accounts for most cases of osteosarcoma occurring above the age of 40.

Osteosarcoma

Osteosarcoma presents with local pain, swelling and tenderness. X-rays may show expansion of the bone with a surrounding soft tissue mass, often containing islands of calcification, but further evaluation by MRI or CT is necessary to determine the extent of tumour. The diagnosis can be confirmed by biopsy but this should be done after referral to a specialist team. Treatment depends on histological type but generally involves surgical removal of the tumour, followed by chemotherapy and radiotherapy. The prognosis is excellent with benign tumours and also generally good in cases that present in childhood and adolescence. The prognosis is poor in elderly patients with osteosarcoma related to Paget's disease of bone.

Metastatic bone disease

Metastatic bone disease may present in a variety of ways: with localised or generalised progressive bone pain, generalised regional pain, symptoms of spinal cord compression, or acute pain due to pathological fracture. Systemic features, such as weight loss and anorexia, and symptoms referable to the primary tumour are often present. The tumours that most commonly metastasise to bone are myeloma and those of bronchus, breast, prostate, kidney and thyroid. Management is discussed in Chapter 11.

RHEUMATOLOGICAL INVOLVEMENT IN OTHER DISEASES

Many systemic diseases can affect the locomotor system, and many drugs may cause adverse locomotor effects (Box 25.84). The most common examples are described here. Bone disease in sarcoidosis is described on page 710, haemophilia on page 1051 and sickle cell anaemia on page 1032.

Malignant disease

Malignant disease can cause a variety of non-metastatic musculoskeletal problems (Box 25.85). One of the most striking is hypertrophic pulmonary osteoarthropathy, characterised by clubbing and painful swelling of the limbs, periosteal new bone formation and arthralgia/arthritis. The most common causes are bronchial carcinoma and mesothelioma (pp. 699 and 719), but the condition can be inherited when it is caused by inactivating mutations in the *HPGD* gene, which is responsible for degradation of PGE_2, suggesting that over-production of prostaglandins may generally play a causal role in clubbing. Bone scans show increased periosteal uptake before new bone is apparent on X-ray. The course follows that of the underlying malignancy and resolves if this is cured.

25.85 Rheumatological manifestations of malignancy

- Polyarthritis
- Dermatomyositis and polymyositis
- Hypophosphataemic osteomalacia
- Hypertrophic osteoarthropathy
- Vasculitis, connective tissue disease
- Raynaud's syndrome
- Polymyalgia rheumatica-like syndrome

Endocrine disease

Hypothyroidism (p. 743) may present with carpal tunnel syndrome, or rarely with very painful, symmetrical proximal myopathy with muscle hypertrophy. Both resolve with thyroxine replacement. Hyperparathyroidism (p. 769) predisposes to calcium pyrophosphate dihydrate deposition disease and to calcific periarthritis, especially in patients with renal disease.

25.84 Drug-induced effects on the musculoskeletal system

Musculoskeletal problem	Principal drug
Secondary gout	Thiazides, furosemide, alcohol
Osteoporosis	Corticosteroids, heparin, glitazones, aromatase inhibitors, GnRH agonists
Osteomalacia	Anticonvulsants, etidronate and pamidronate (high-dose)
Osteonecrosis	Corticosteroids, alcohol
Drug-induced lupus syndrome	Procainamide, hydralazine, isoniazid, chlorpromazine
Arthralgias or arthritis	Corticosteroid withdrawal, glibenclamide, methyldopa, ciclosporin, isoniazid, barbiturates
Myalgia	Corticosteroid withdrawal, L-tryptophan, fibrates, statins
Myopathy	Corticosteroids, chloroquine
Myositis, myasthenia	Penicillamine, statins
Cramps	Corticosteroids, ACTH, diuretics, carbenoxolone
Vasculitis	Amphetamines, thiazides

(ACTH = adrenocorticotrophic hormone; GnRH = gonadotrophin-releasing hormone)

Diabetes mellitus (Ch. 21) commonly causes diabetic cheiroarthropathy characterised by tightening of skin and periarticular structures, causing flexion deformities of the fingers that may be painful. Diabetic osteopathy presents as forefoot pain with radiographic progression from osteopenia to complete osteolysis of the phalanges and metatarsals. Diabetes also predisposes to adhesive capsulitis, Dupuytren's contracture, septic arthritis and Charcot's joints.

Acromegaly (p. 792) can be associated with mechanical back pain, with normal or excessive (not restricted) movement; carpal tunnel syndrome; Raynaud's syndrome; and an arthropathy (50%). The arthropathy mainly affects the large joints and has clinical similarities to OA but with normal or an increased range of movement. X-rays may show widening of joint spaces, squaring of bone ends, generalised osteopenia and tufting of terminal phalanges. It does not improve with treatment of the acromegaly.

Haematological disease

Haemochromatosis (p. 972) is complicated by an arthropathy in about 50% of cases. It typically presents between the ages of 40 and 50, and may predate other features of the disease. The small joints of the hands and wrists are typically affected but the hips, shoulders and knees may also be involved. The X-ray changes resemble OA but cysts are often multiple and prominent, with little osteophyte formation. Involvement of the radiocarpal and MCP joints may occur, which is unusual in primary OA, and about 30% have calcium pyrophosphate dihydrate deposition disease and/or pseudogout. Treatment of the haemochromatosis does not influence the arthropathy, and management of the arthropathy is as described for OA. Haemophilia (p. 1051) can be complicated by haemarthrosis, which, if recurrent, can result in the development of secondary osteoarthritis. Sickle-cell disease (p. 1032) may be complicated by bone pain, osteonecrosis and osteomyelitis. Thalassaemia (p. 1033) may be complicated by bone deformity, especially affecting the craniofacial bones, and by osteoporosis.

Neurological disease

Neurological disease may result in rapidly destructive arthritis of joints, first described by Charcot in association with syphilis. The cause is incompletely understood but may involve repetitive trauma as the result of sensory loss and altered blood flow secondary to impaired sympathetic nervous system control. The main predisposing diseases and sites of involvement are:

- diabetic neuropathy (hindfoot)
- syringomyelia (shoulder, elbow, wrist)
- leprosy (hands, feet)
- tabes dorsalis (knees, spine).

The presentation is with subacute or chronic monoarthritis. Pain can occur, especially at the onset, but once the joint is severely deranged, pain is often minimal and signs become disproportionately greater than symptoms. The joint is often grossly swollen, with effusion, crepitus, marked instability and deformity, but usually no increased warmth. X-rays show disorganisation of normal joint architecture and often multiple loose bodies (Fig. 25.59), and either no (atrophic) or gross (hypertrophic) new bone formation. Management principally involves orthoses and occasionally arthrodesis.

Fig. 25.59 Wrist X-ray showing a neuropathic (Charcot) joint in a patient with syringomyelia. Note the disorganised architecture with complete loss of the proximal carpal row, bony fragments and soft tissue swelling.

MISCELLANEOUS CONDITIONS

Spondylolysis and spondylolisthesis

Spondylolysis describes a break in the integrity of the neural arch. The principal cause is an acquired defect in pars interarticularis due to a fracture, mainly seen in gymnasts, dancers and runners, in whom it is an important cause of back pain. Spondylolisthesis describes the condition where a defect causes slippage of a vertebra on the one below. This may be congenital, post-traumatic or degenerative. Rarely, it can result from metastatic destruction of the posterior elements. Uncomplicated spondylolysis does not cause symptoms but spondylolisthesis can cause low back pain aggravated by standing and walking. Occasionally, symptoms of nerve root or spinal compression may occur. The diagnosis can be made on lateral X-rays of the lumbar spine but MRI may be required if there is neurological involvement. Advice on posture and muscle-strengthening exercises is required in mild cases. Surgical fusion is indicated for severe and recurrent low back pain. Surgical decompression is mandatory prior to fusion in patients with significant lumbar stenosis or symptoms of cauda equina compression.

Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a common disorder, affecting 10% of men and 8% of women over the age of 65, and associated with obesity,

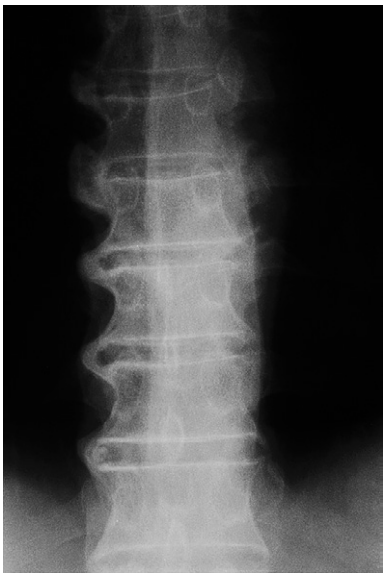

Fig. 25.60 Diffuse idiopathic skeletal hyperostosis (DISH). Antero-posterior X-ray of thoracic spine showing right-sided, flowing new bone joining more than four contiguous vertebrae. The disc spaces are preserved.

hypertension and type 2 diabetes mellitus. It is characterised by florid new bone formation along the anterolateral aspect of at least four contiguous vertebral bodies (Fig. 25.60). DISH is distinguished from lumbar spondylosis by the absence of disc space narrowing and marginal vertebral body sclerosis, and from ankylosing spondylitis by the absence of sacroiliitis or apophyseal joint fusion. It is usually an asymptomatic radiographic finding but can cause back pain or pain at peripheral sites, such as the heel in association with calcaneal spur formation.

Pigmented villonodular synovitis

Pigmented villonodular synovitis is an uncommon proliferative disorder of synovium, which typically affects young adults. It is caused by a somatic chromosomal translocation in synovial cells that places the *CSF1* gene downstream of the *COL6A3* gene promoter. The result is local over-production of macrophage colony-stimulating factor (M-CSF), which causes accumulation of macrophages in the joint. The presentation is with joint swelling, limitation of movement and local discomfort. The diagnosis can be confirmed by MRI or synovial biopsy. Treatment is by surgical or radiation synovectomy.

Joint hypermobility

Hypermobility is a relatively uncommon disorder associated with joint laxity. It may be primary or secondary to inherited diseases, such as Marfan's syndrome (p. 603), Ehlers–Danlos syndrome (p. 1050) and osteogenesis imperfecta (p. 1131). Benign joint hypermobility syndrome is diagnosed clinically when the modified Beighton score is 4 or above in the presence of arthralgia in four or more joints (Box 25.86). There is no specific treatment, apart from the general principles listed on page 1077.

25.86 Modified Beighton score for joint hypermobility

Clinical test	Score
Extend little finger > 90°	(1 point each side)
Bring thumb back parallel to/touching forearm	(1 point each side)
Extend elbow > 10°	(1 point each side)
Extend knee > 10°	(1 point each side)
Touch floor with flat of hands, legs straight	(1 point)

Hypermobile = a score of 6 or more points out of a possible 9 for epidemiological studies, or 4 or more points (with arthralgia in four or more joints) for a clinical diagnosis of the benign joint hypermobility syndrome.

Dupuytren's contracture

Dupuytren's contracture results from fibrosis and contracture of the superficial palmar fascia of the hands. The patient is unable to extend the fingers fully and there is puckering of the skin with palpable nodules. The ring and little fingers are usually the first and worst affected. It is usually painless, but causes problems due to limitation of hand function and snagging of the curled fingers in pockets. It is age-related, usually bilateral and more common in men. There is a strong genetic component and sometimes may be familial, with dominant inheritance. It can be associated with plantar fibromatosis, Peyronie's disease, alcohol misuse and chronic vibration injury. It is very slowly progressive. Often no treatment is required, but it can be treated medically by local injections of collagenase or surgically by fasciotomy if symptoms are troublesome.

Carpal tunnel syndrome

This is a common nerve entrapment syndrome caused by compression of the median nerve at the wrist. It presents with numbness, tingling and pain in a median nerve distribution (p. 1224). The most common causes are hypothyroidism, diabetes mellitus, RA, obesity and pregnancy, especially in the third trimester. In some patients no underlying cause may be identified. Carpal tunnel syndrome often responds to treatment of the underlying condition, but other options include local steroid injections and surgical decompression.

Trigger finger

This occurs as the result of stenosing tenosynovitis in the flexor tendon sheath, with intermittent locking of the finger in flexion. It can arise spontaneously or in association with inflammatory diseases like RA. Symptoms usually respond to local steroid injections but surgical decompression is occasionally required.

Periodic fever syndromes

These are a group of rare inherited disorders that present with intermittent attacks of fever, rash, arthralgia and myalgia. They usually occur in childhood but may present for the first time in adulthood. They are discussed in more detail on page 85.

Anterior tibial compartment syndrome

This is characterised by severe pain in the front of the lower leg, aggravated by exercise and relieved by rest. Symptoms result from fascial compression of the muscles in the anterior tibial compartment and may be associated with foot drop. Treatment is by surgical decompression.

Synovitis–acne–pustulosis–hyperostosis–osteitis syndrome

The synovitis–acne–pustulosis–hyperostosis–osteitis (SAPHO) syndrome is an uncommon disorder characterised by bone pain and swelling due to a sterile osteomyelitis and hyperostosis predominantly targeting the clavicles and bones of the anterior chest wall. Other features include a pustulotic rash affecting the palms and soles of the feet, sacroiliitis and synovitis of peripheral joints. It most commonly presents in children and young or middle-aged adults. Various treatments have been used, including corticosteroids, DMARDs, bisphosphonates and TNF blockers, with varying degrees of success. The cause is unknown but has been suggested to be an autoimmune process triggered by a bacterial or viral pathogen.

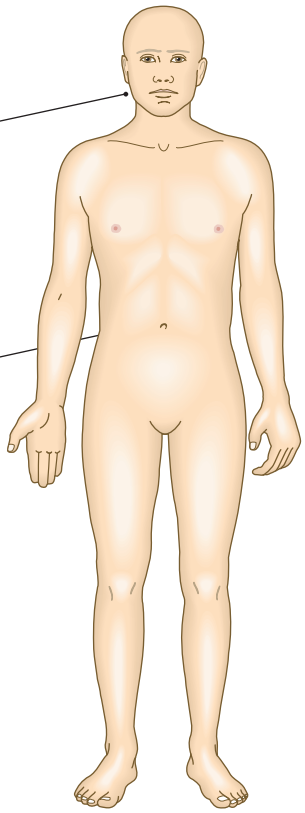
Diseases of muscle 1228

CLINICAL EXAMINATION OF THE NERVOUS SYSTEM

4 Cranial nerves

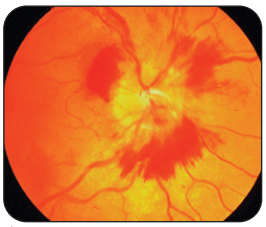
Right 12th nerve palsy: wasting of right side of tongue



3 Neck and skull
Skull size and shape
Neck stiffness and Kernig's test
Carotid bruit

2 Back
Scoliosis
Operative scars
Evidence of spina bifida occulta
Winging of scapula

Winging of right scapula (muscular dystrophy)



1 Stance and gait
Posture
Romberg's test
Arm swing
Pattern of gait
Tandem (heel-toe) gait

Observation

- General appearance
- Mood (e.g. anxious, depressed)
- Facial expression (or lack thereof)
- Handedness
- Nutritional status
- Blood pressure

5 Optic fundi
Papilloedema
Optic atrophy
Cupping of disc (glaucoma)
Hypertensive changes
Signs of diabetes

Haemorrhagic papilloedema

6 Motor
Wasting, fasciculation
Abnormal posture
Abnormal movements
Tone (including clonus)
Strength
Coordination
Tendon reflexes
Abdominal reflexes
Plantar reflexes

Wasting of right thenar eminence due to cervical rib

7 Sensory
Pin-prick, temperature
Joint position, vibration
Two-point discrimination

8 Higher cerebral function
Orientation
Memory
Speech and language
Localised cortical functions

1 Examination of gait and posture

	Procedure	Abnormality	Disease
1	Responds to call	No response	Deafness Delirium
2	Rising from chair	Difficulty rising	Proximal muscle weakness Joint stiffness
3	Examine posture	Stooped	Parkinsonism
	Retropulsion/anteropulsion	Postural instability	Parkinsonism
4	Examine arms during walking	Reduced arm swing	Parkinsonism, upper motor neuron lesion
5	Examine routine walking	Circumduction (stiff leg moves outwards in 'circular' manner)	Upper motor neuron lesion
		'Slapping' due to foot drop	Lower motor neuron lesion L5 root or common peroneal nerve
		Narrow-based, short strides	Parkinsonism
		Wide-based, short strides (marche à petits pas, magnetic gait)	Frontal lobe lesion
		Wide-based, irregular strides	Cerebellar lesion
		High-stepping gait	Dorsal column lesion/sensory neuropathy

4 Examination of cranial nerves

Nerve	Name	Tests
I	Olfactory	Ask patient about sense of smell (only examine if reported change)
II	Optic	Visual acuity Visual fields 'Swinging' torch test for relative afferent pupillary defect Ophthalmoscopy
III	Oculomotor	Eye movements (nystagmus) Eyelid movement Pupil size, symmetry, reactions
IV	Trochlear	Eye movements
V	Trigeminal	Facial sensation Corneal reflex Ask patient about taste
VI	Abducens	Eye movements
VII	Facial	Facial symmetry and movements Ask patient about taste
VIII	Vestibulocochlear	Hearing (rub fingertips next to each ear) Tuning fork tests (Rinne and Weber) Hallpike test for benign positional vertigo
IX	Glossopharyngeal	Gag reflex (sensory)
X	Vagus	Palatal elevation (uvula deviates to side opposite lesion) Gag reflex (motor) Cough (bovine)
XI	Accessory	Look for wasting of trapezius/sternocleidomastoid Elevation of shoulders Turning head to right and left
XII	Hypoglossal	Look for wasting/fasciculation Tongue protrusion (deviates to side of lesion)

6 Root values of tendon reflexes

Reflex	Root value
Upper limb	
Biceps jerk	C5/C6
Supinator jerk	C5/C6
Triceps jerk	C7
Finger jerk	C8
Lower limb	
Knee jerk	L3/L4
Ankle jerk	S1

Neurological examination in old age

- **Pupils**: tend to be smaller, which makes fundoscopy more difficult.
- **Limb tone**: difficult to assess because of poor relaxation and concomitant joint disease.
- **Ankle reflexes**: may be bilaterally absent.
- **Gait assessment**: more difficult because of concurrent musculoskeletal disease and pre-existing neurological deficits.
- **Sensory testing**: especially difficult when there is cognitive impairment.
- **Vibration sense**: may be reduced in the lower legs.

Neurology has long been misperceived as a specialty in which intricate clinical examination and numerous investigations are required to diagnose obscure and untreatable conditions. In fact, it requires careful history-taking with a lesser contribution from targeted examination and considered investigation. The development of specific, effective treatments has made accurate diagnosis essential.

The brain, spinal cord and peripheral nerves combine to allow us to perceive and react to the external world, while maintaining a stable internal environment. The brain provides a platform for processing information and forming a response and, in doing so, both forms and is affected by our personality and mental state. Nervous system disorders are common, accounting for around 10% of the UK's general practice consultations, 20% of acute medical admissions, and most chronic physical disability. While pathological and anatomical localisation is important, skill is required to identify those neurological symptoms *not* associated with neurological disease, to differentiate patients requiring investigation and treatment from those who need reassurance.

Initially, it is important to exclude conditions that constitute neurological emergencies (Box 26.1). If the presentation is not an emergency, more time can be taken to reach a diagnosis. The history should provide a hypothesis for the site and nature of the potential pathology, which a focused examination may refine and inform what further investigation would be useful. A discussion with the patient about possible interventions and rehabilitation may then take place.

As Stroke has become a specific subspecialty in many centres, it is described in a separate chapter, although it is clearly a neurological condition. This chapter should be read with it, to help clarify how the presentation, diagnosis and management of stroke differ from other conditions.

26.1 Neurological emergencies

- Status epilepticus (p. 1159)
- Stroke (if thrombolysis available) (p. 1237)
- Guillain–Barré syndrome (p. 1224)
- Myasthenia gravis (if bulbar and/or respiratory) (p. 1226)
- Spinal cord compression (p. 1220)
- Subarachnoid haemorrhage (p. 1246)
- Neuroleptic malignant syndrome (p. 249)

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Cells of the nervous system

The nervous system comprises billions of connections between billions of specialised cells, supplied by a complex network of specialised blood vessels. In addition to neurons, there are three types of glial cells. Astrocytes

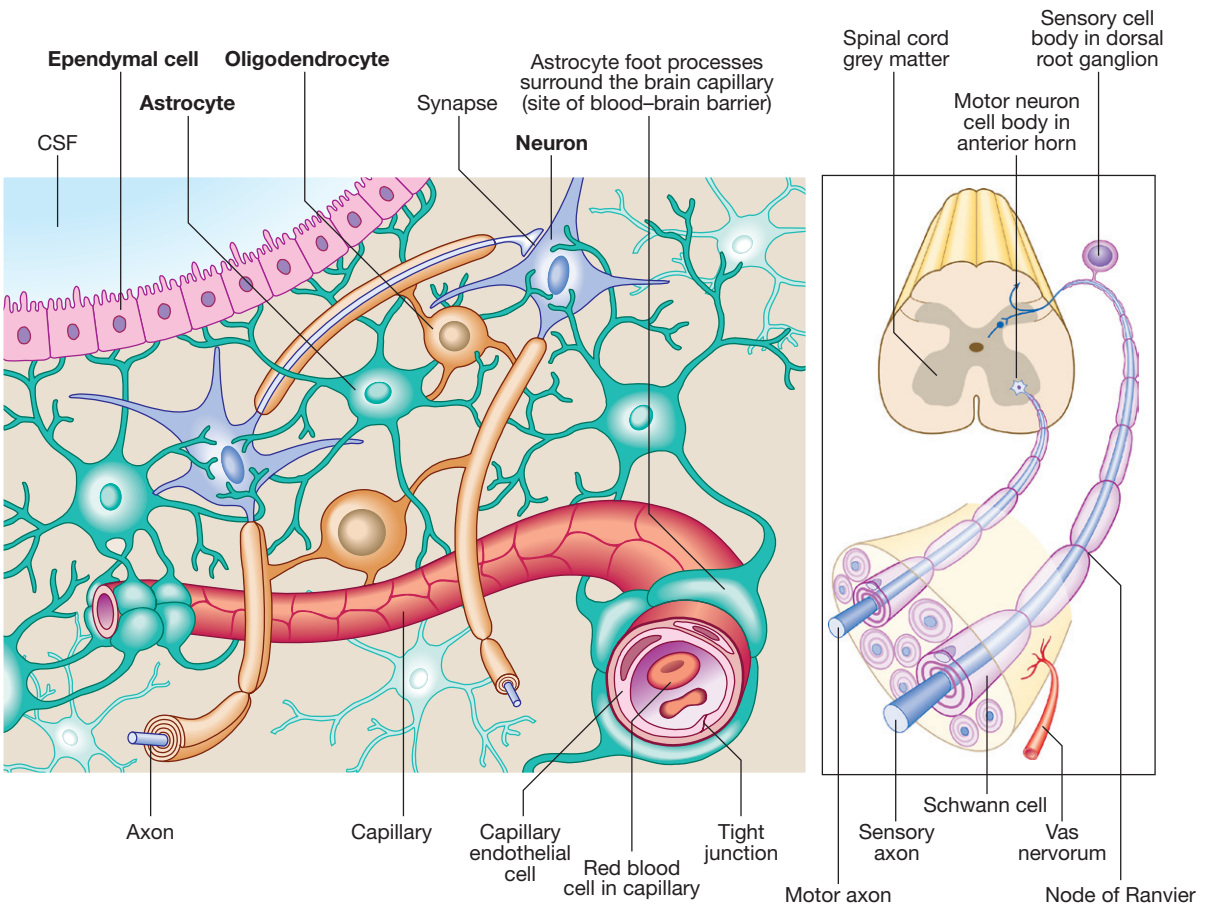


Fig. 26.1 Cells of the nervous system. (CSF = cerebrospinal fluid)

form the structural framework for neurons and control their biochemical environment. Astrocyte foot processes are intimately associated with blood vessels, forming the blood–brain barrier (Fig. 26.1). Oligodendrocytes are responsible for the formation and maintenance of the myelin sheath, which surrounds axons and is essential for the rapid transmission of action potentials by saltatory conduction. Microglial cells derive from monocytes/macrophages and play a role in fighting infection and removing damaged cells. Peripheral neurons have axons invested in myelin made by Schwann cells. Ependymal cells line the cerebral ventricles.

Generation and transmission of the nervous impulse

The role of the central nervous system (CNS) is to generate outputs in response to external stimuli and changes in internal conditions. Each neuron receives input by synaptic transmission from dendrites (branched projections of other neurons), which may sum to produce output in the form of an action potential. This is conducted down axons, with synaptic transmission to other neurons or, in the motor system, to muscle cells. These processes require the maintenance of an electrochemical gradient across neuron cell membranes by specialised membrane ion channels. Synaptic transmission involves the release of neurotransmitters that modulate the function of the target cell by interacting with structures on the cell surface, including ion channels and other cell surface receptors (Fig. 26.2). At least 20 different neurotransmitters are known to act at different sites in the nervous system, and all are potentially amenable to pharmacological manipulation.

The neuronal cell bodies may receive synaptic input from thousands of other neurons. The synapsing neuron terminals are also subject to feedback regulation via receptor sites on the pre-synaptic membrane, modifying the release of transmitter across the synaptic cleft. In addition to such acute effects, some neurotransmitters produce long-term modulation of metabolic function or gene expression. This effect probably underlies more complex processes in, for example, long-term memory.

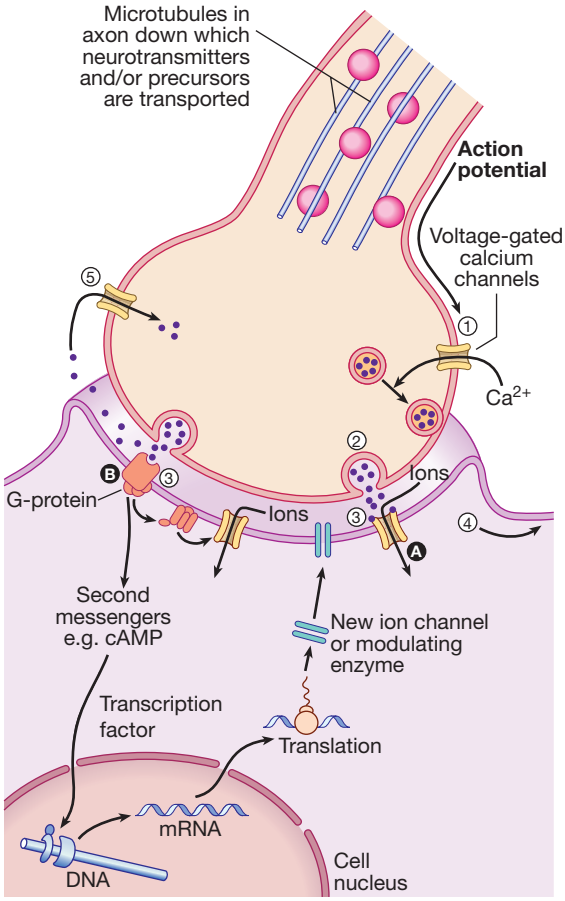

Fig. 26.2 Neurotransmission and neurotransmitters. (1) An action potential arriving at the nerve terminal depolarises the membrane and this opens voltage-gated calcium channels. (2) Entry of calcium causes the fusion of synaptic vesicles containing neurotransmitters with the pre-synaptic membrane and release of the neurotransmitter across the synaptic cleft. (3) The neurotransmitter binds to receptors on the post-synaptic membrane either (A) to open ligand-gated ion channels which, by allowing ion entry, depolarise the membrane and initiate an action potential (4), or (B) to bind to metabotrophic receptors that activate an effector enzyme (e.g. adenylyl cyclase) and thus modulate gene transcription via the intracellular second messenger system, leading to changes in synthesis of ion channels or modulating enzymes. (5) Neurotransmitters are taken up at the pre-synaptic membrane and/or metabolised. (cAMP = cyclic adenosine monophosphate; DNA = deoxyribonucleic acid; mRNA = messenger ribonucleic acid)

Functional anatomy of the nervous system

Major components of the nervous system and their interrelationships are depicted in Figure 26.3.

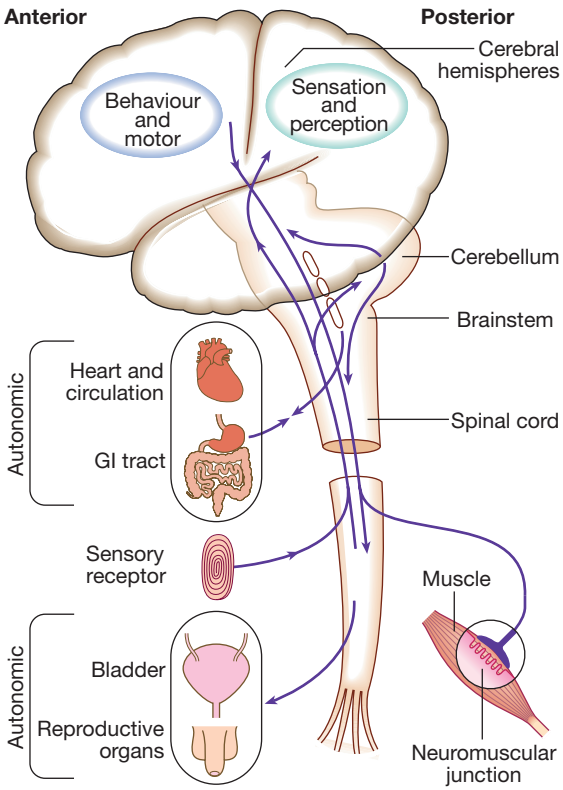

Fig. 26.3 The major anatomical components of the nervous system.

Cerebral hemispheres

The cerebral hemispheres coordinate the highest level of nervous function, the anterior half dealing with executive ('doing') functions and the posterior half constructing a perception of the environment. Each cerebral hemisphere has four functionally specialised lobes (Fig. 26.4 and Box 26.2), but some functions are lateralised, and this depends on cerebral dominance (i.e. the hemisphere in which language is represented). Cerebral dominance aligns limb dominance with language function: in right-handed individuals the left hemisphere is almost always dominant, while around half of left-handers have a dominant right hemisphere.

The frontal lobes are concerned with executive function, movement, behaviour and planning. In addition to the primary and supplementary motor cortex, there are specialised areas for the control of eye movements, speech (Broca's area) and micturition.

The parietal lobes integrate sensory perception. The primary sensory cortex lies in the post-central gyrus of the parietal lobe. Much of the remainder is devoted to 'association' cortex, which processes and interprets input from the various sensory modalities. The supramarginal and angular gyri of the dominant parietal lobe form part of the language area (p. 1169). Close to these are regions dealing with numerical function. The non-dominant parietal lobe is concerned with spatial awareness and orientation.

The temporal lobes contain the primary auditory cortex and primary vestibular cortex. On the inner medial sides lie the olfactory cortex and the parahippocampal cortex, which is involved in memory function. The temporal lobes also contain much of the limbic system, including the hippocampus and the amygdala, which are involved in memory and emotional processing. The dominant temporal lobe also participates in language functions, particularly verbal

26.2 Cortical lobar functions

		Effects of damage		
Lobe	**Function**	**Cognitive/behavioural**	**Associated physical signs**	**Positive phenomena**
Frontal	Personality Emotional control Social behaviour Contralateral motor control Language Micturition	Disinhibition Lack of initiation Antisocial behaviour Impaired memory Expressive dysphasia Incontinence	Impaired smell Contralateral hemiparesis Frontal release signs[1]	Seizures – often nocturnal with motor activity Versive head movements
Parietal: dominant	Language Calculation	Dysphasia Acalculia Dyslexia Apraxia[3] Agnosia[5]	Contralateral hemisensory loss Astereognosis[2] Agraphaesthesia[4] Contralateral homonymous lower quadrantanopia Asymmetry of optokinetic nystagmus (OKN)	Focal sensory seizures
Parietal: non-dominant	Spatial orientation Constructional skills	Neglect of contralateral side Spatial disorientation Constructional apraxia Dressing apraxia	Contralateral hemisensory loss Astereognosis[2] Agraphaesthesia[4] Contralateral homonymous lower quadrantanopia Asymmetry of OKN	Focal sensory seizures
Temporal: dominant	Auditory perception Language Verbal memory Smell Balance	Receptive aphasia Dyslexia Impaired verbal memory	Contralateral homonymous lower quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Temporal: non-dominant	Auditory perception Melody/pitch perception Non-verbal memory Smell Balance	Impaired non-verbal memory Impaired musical skills (tonal perception)	Contralateral homonymous upper quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Occipital	Visual processing	Visual inattention Visual loss Visual agnosia	Homonymous hemianopia (macular sparing)	Simple visual hallucinations (e.g. phosphenes, zigzag lines)

[1]Grasp reflex, palmomental response, pout response.
[2]Inability to determine three-dimensional shape by touch.
[3]Inability to perform complex movements in the presence of normal motor, sensory and cerebellar function.
[4]Inability to 'read' numbers or letters drawn on hand, with the eyes shut.
[5]Inability to recognise familiar objects, e.g. faces.

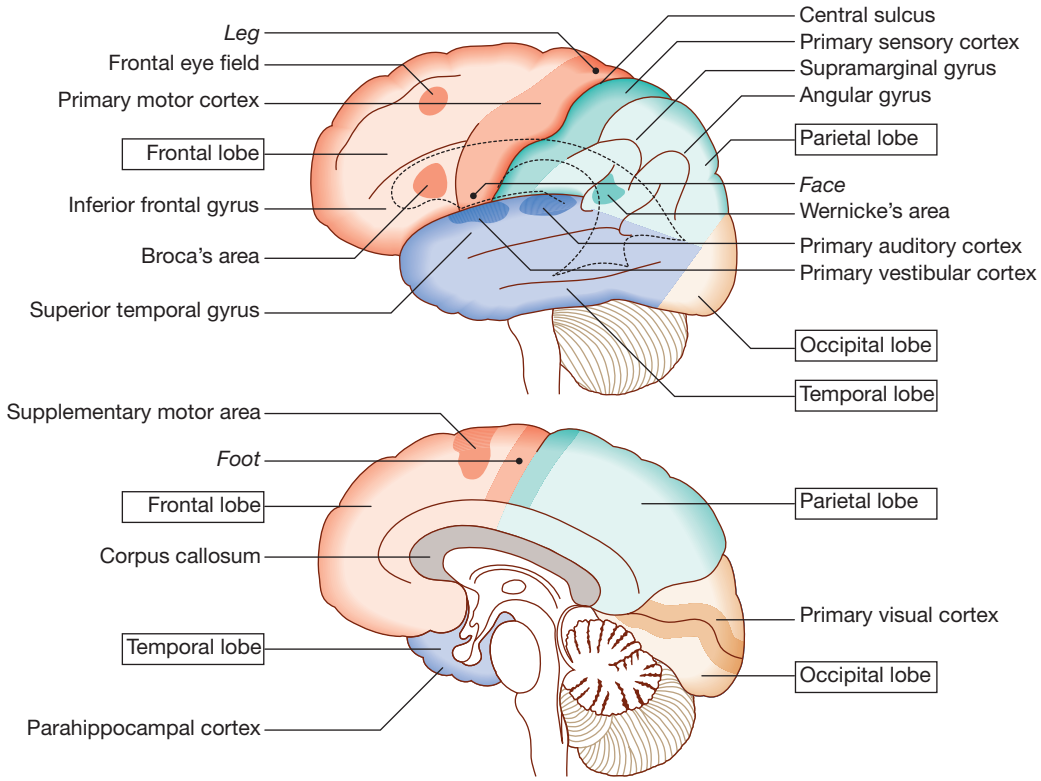

Fig. 26.4 The anatomy of the cerebral cortex.

comprehension (Wernicke's area). Musical processing occurs across both temporal lobes, rhythm on the dominant side and melody/pitch on the non-dominant.

The occipital lobes are responsible for visual interpretation. The contralateral visual hemifield is represented in each primary visual cortex, with surrounding areas processing specific visual submodalities such as colour, movement or depth, and the analysis of more complex visual patterns such as faces.

Deep to the grey matter in the cortices, and the white matter (composed of neuronal axons), are collections of cells known as the basal ganglia that are concerned with motor control; the thalamus, which is responsible for the level of attention to sensory perception; the limbic system, concerned with emotion and memory; and the hypothalamus, responsible for homeostasis, such as temperature and appetite control. The cerebral ventricles contain cerebrospinal fluid (CSF), which cushions the brain during cranial movement.

CSF is formed in the lateral ventricles and protects and nourishes the CNS. The CSF flows from third to fourth ventricles and through foramina in the brainstem to dissipate over the surface of the CNS, eventually being reabsorbed into the cerebral venous system (see Fig. 26.41, p. 1217).

The brainstem

In addition to containing all the sensory and motor pathways entering and leaving the hemispheres, the brainstem houses the nuclei and projections of the cranial nerves, as well as other important collections of neurons in the reticular formation (Fig. 26.5). Cranial nerve nuclei provide motor control to muscles of the head (including the face and eyes) and coordinate sensory input from the special sense organs and the face, nose, mouth, larynx and pharynx. They also relay autonomic messages, including pupillary, salivary and lacrimal functions. The

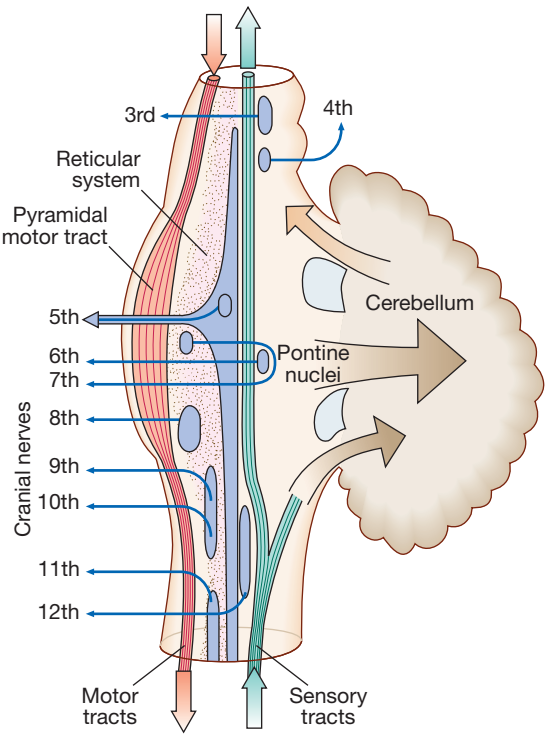

Fig. 26.5 Anatomy of the brainstem.

reticular formation is predominantly involved in the control of conjugate eye movements, the maintenance of balance, cardiorespiratory control and the maintenance of arousal.

The spinal cord

The spinal cord is the route for virtually all communication between the extracranial structures and the CNS. Afferent and efferent fibres are grouped in discrete bundles but collections of cells in the grey matter are responsible for lower-order motor reflexes and the primary processing of sensory information, including pain.

Sensory peripheral nervous system

The sensory cell bodies of peripheral nerves are situated just outside the spinal cord, in the dorsal root ganglia in the spinal exit foramina, whilst the distal ends of their neurons utilise various specialised endings for the conversion of external stimuli into action potentials. Sensory nerves consist of a combination of large, fast, myelinated axons (which carry information about joint position sense and commands to muscles) and smaller, slower, unmyelinated axons (which carry information about pain and temperature, as well as autonomic function).

Motor peripheral nervous system

The anterior horns of the spinal cord comprise lower motor cell bodies. To increase conduction speed, peripheral motor nerve axons are wrapped in myelin produced by Schwann cells. Motor neurons release acetylcholine across the neuromuscular junction, which changes the muscle end-plate potential and initiates muscle contraction.

The autonomic system

The autonomic system regulates the cardiovascular and respiratory systems, the smooth muscle of the gastrointestinal tract, and many exocrine and endocrine glands throughout the body. The autonomic system is controlled centrally by diffuse modulatory systems in the brainstem, limbic system, hypothalamus and frontal lobes, which are concerned with arousal and background behavioural responses to threat. Autonomic output divides functionally and pharmacologically into two divisions: the parasympathetic and sympathetic systems.

The motor system

A programme of movement formulated by the premotor cortex is converted into a series of signals in the motor cortex that are transmitted to the spinal cord in the pyramidal tract (Fig. 26.6). This passes through the internal capsule and the ventral brainstem before decussating in the medulla to enter the lateral columns of the spinal cord. The pyramidal tract 'upper motor neurons' synapse with the anterior horn cells of the spinal cord grey matter, which form the lower motor neurons.

Any movement necessitates changes in posture and muscle tone, sometimes in quite separate muscle groups to those involved in the actual movement. The motor system consists of a hierarchy of controls that maintain body posture and muscle tone, on which any movement

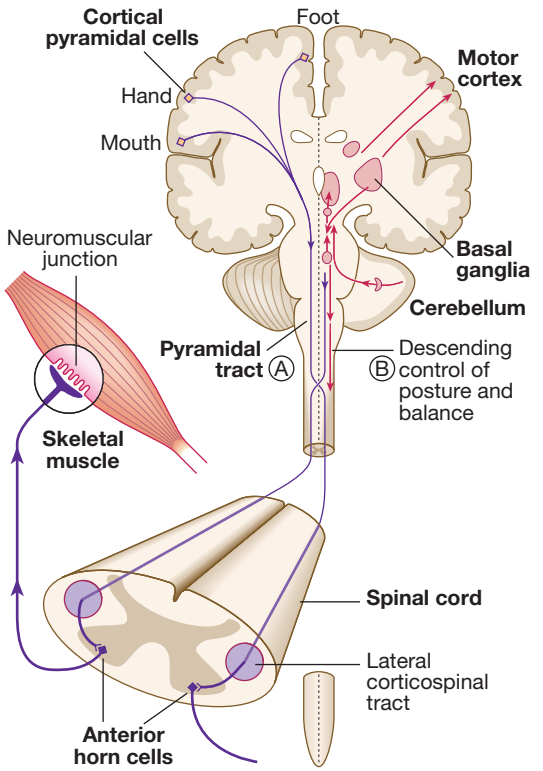

Fig. 26.6 The motor system. Neurons from the motor cortex descend as the pyramidal tract in the internal capsule and cerebral peduncle to the ventral brainstem, where most cross low in the medulla (A). In the spinal cord the upper motor neurons form the corticospinal tract in the lateral column before synapsing with the lower motor neurons in the anterior horns. The activity in the motor cortex is modulated by influences from the basal ganglia and cerebellum. Pathways descending from these structures control posture and balance (B).

is superimposed. In the grey matter of the spinal cord, the lowest order of the motor hierarchy controls reflex responses to stretch. Muscle spindles sense lengthening of the muscle; they provide the afferent side of the stretch reflex and initiate a monosynaptic reflex leading to protective or reactive muscle contraction. Inputs from the brainstem are largely inhibitory. Polysynaptic connections in the spinal cord grey matter control more complex reflex actions of flexion and extension of the limbs that form the basic building blocks of coordinated actions, but complete control requires input from the extrapyramidal system and the cerebellum.

Lower motor neurons

Lower motor neurons in the anterior horn of the spinal cord innervate a group of muscle fibres termed a 'motor unit'. Loss of lower motor neurons causes loss of contraction within this unit, resulting in weakness and reduced muscle tone. Subsequently, denervated muscle fibres atrophy, causing muscle wasting, and depolarise spontaneously, causing 'fibrillations'. Except in the tongue, these are usually only perceptible on electromyelography (EMG; p. 1152). With the passage of time, neighbouring intact neurons sprout to provide re-innervation, but the neuromuscular junctions of the enlarged motor units are unstable and depolarise spontaneously, causing fasciculations (which are large enough to be visible to the naked eye). Fasciculations

therefore imply chronic partial denervation with re-innervation.

Upper motor neurons

Upper motor neurons have both inhibitory and excitatory influence on the function of anterior horn motor neurons. Lesions affecting the upper motor neuron result in increased tone, most evident in the strongest muscle groups (i.e. the extensors of the lower limbs and the flexors of the upper limbs). The weakness of upper motor neuron lesions is conversely more pronounced in the opposing muscle groups. Loss of inhibition will also lead to brisk reflexes and enhanced reflex patterns of movement, such as flexion withdrawal to noxious stimuli and spasms of extension. The increased tone is more apparent during rapid stretching ('spastic catch'), but may suddenly give way with sustained tension (the 'clasp-knife' phenomenon). More primitive reflexes are also released, manifest as extensor plantar responses. Spasticity may not be present until some weeks after the onset of an upper motor neuron lesion. Chronic spasticity in a patient with a spinal cord lesion may also be exacerbated by increased sensory input – for example, from a pressure sore or urinary tract infection.

The extrapyramidal system

Circuits between the basal ganglia and the motor cortex constitute the extrapyramidal system, which controls muscle tone, body posture and the initiation of movement (see Fig. 26.6). Lesions of the extrapyramidal system produce an increase in tone that, unlike spasticity, is continuous throughout the range of movement at any speed of stretch ('lead pipe' rigidity). Involuntary movements are also a feature of extrapyramidal lesions (p. 1165), and tremor in combination with rigidity produces typical 'cogwheel' rigidity. Extrapyramidal lesions also cause slowed and clumsy movements (bradykinesia), which characteristically reduce in size with repetition, as well as postural instability, which can precipitate falls.

The cerebellum

The cerebellum fine-tunes and coordinates movements initiated by the motor cortex. It also participates in the planning and learning of skilled movements through reciprocal connections with the thalamus and cortex, and in articulation of speech. A lesion in a cerebellar hemisphere causes lack of coordination on the same side of the body. Cerebellar dysfunction impairs the smoothness of eye movements, causing nystagmus and renders speech dysarthric. In the limbs, the initial movement is normal, but as the target is approached, the accuracy of the movement deteriorates, producing an 'intention tremor'. The distances of targets are misjudged (dysmetria), resulting in 'past-pointing'. The ability to produce rapid, accurate, regularly alternating movements is also impaired (dysdiadochokinesis). The central vermis of the cerebellum is concerned with the coordination of gait and posture. Disorders of this therefore produce a characteristic ataxic gait (see below).

Vision

The neurological organisation of visual pathways is shown in Figure 26.7. Fibres from ganglion cells in the retina pass to the optic disc and then backwards through the lamina cribrosa to the optic nerve. Nasal optic nerve fibres (subserving the temporal visual field) cross at the chiasm, but temporal fibres do not. Hence, fibres in each optic tract and further posteriorly carry representation of contralateral visual space. From the lateral geniculate nucleus, lower fibres pass through the temporal lobes on their way to the primary visual area in the occipital cortex, while the upper fibres pass through the parietal lobe.

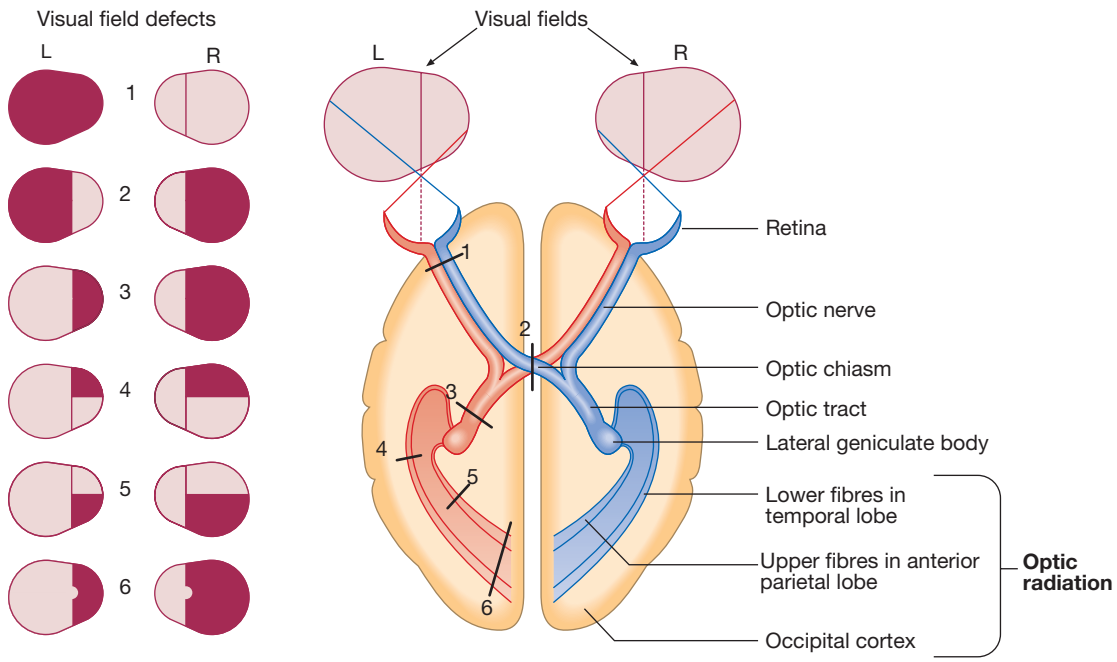

Fig. 26.7 Visual pathways and visual field defects. Schematic representation of eyes and brain in transverse section.

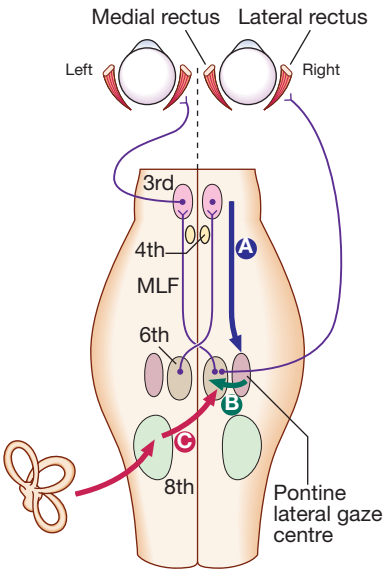

Fig. 26.8 Control of conjugate eye movements. Downward projections pass from the cortex to the pontine lateral gaze centre (A). The pontine gaze centre projects to the 6th cranial nerve nucleus (B), which innervates the ipsilateral lateral rectus and projects to the contralateral 3rd nerve nucleus (and hence medial rectus) via the medial longitudinal fasciculus (MLF). Tonic inputs from the vestibular apparatus (C) project to the contralateral 6th nerve nucleus via the vestibular nuclei.

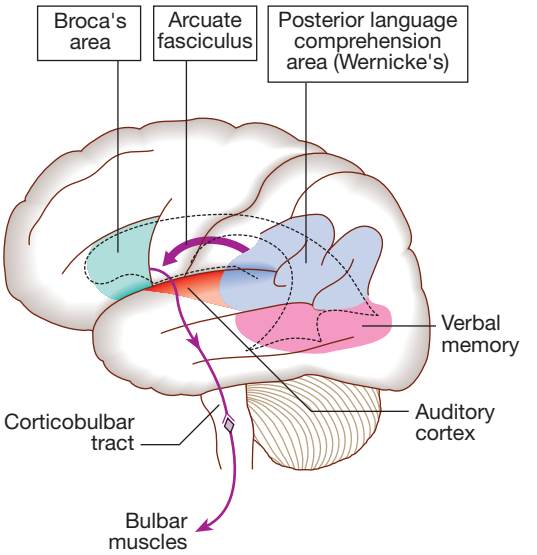

Fig. 26.9 Areas of the cerebral cortex involved in the generation of spoken language.

Normally, the eyes move conjugately (in unison), though horizontal convergence allows visual fusion of objects at different distances. The control of eye movements begins in the cerebral hemispheres, particularly within the frontal eye fields, and the pathway then descends to the brainstem with input from the visual cortex, superior colliculus and cerebellum. Horizontal and vertical gaze centres in the pons and mid-brain, respectively, coordinate output to the ocular motor nerve nuclei (3, 4 and 6), which are connected to each other by the medial longitudinal fasciculus (MLF) (Fig. 26.8). The MLF is particularly important in coordinating horizontal movements of the eyes. The extraocular muscles are then supplied by the oculomotor (3rd), trochlear (4th) and abducens (6th) cranial nerves.

The pupillary response to light is due to a combination of parasympathetic and sympathetic activity. Parasympathetic fibres originate in the Edinger–Westphal subnucleus of the 3rd nerve, and pass with the 3rd nerve to synapse in the ciliary ganglion before supplying the constrictor pupillae of the iris. Sympathetic fibres originate in the hypothalamus, pass down the brainstem and cervical spinal cord to emerge at T1, return up to the eye in association with the internal carotid artery, and supply the dilator pupillae.

Speech

Much of the cerebral cortex is involved in the process of forming and interpreting communicating sounds, especially in the dominant hemisphere (see Box 26.2, p. 1142). Decoding of speech sounds (phonemes) is carried out in the upper part of the posterior temporal lobe. The attribution of meaning, as well as the formulation of the language required for the expression of ideas and concepts, occurs predominantly in the lower parts of the anterior parietal lobe (the angular and supramarginal gyri). The temporal speech comprehension region is referred to as Wernicke's area (Fig. 26.9). Other parts of the temporal lobe contribute to verbal memory, where lexicons of meaningful words are 'stored'. Parts of the non-dominant parietal lobe appear to contribute to non-verbal aspects of language in recognising meaningful intonation patterns (prosody).

The frontal language area is in the posterior end of the dominant inferior frontal gyrus known as Broca's area. This receives input from the temporal and parietal lobes via the arcuate fasciculus. The motor commands generated in Broca's area pass to the cranial nerve nuclei in the pons and medulla, as well as to the anterior horn cells in the spinal cord. Nerve impulses to the lips, tongue, palate, pharynx, larynx and respiratory muscles result in the series of ordered sounds recognised as speech. The cerebellum also plays an important role in coordinating speech, and lesions of the cerebellum lead to dysarthria, where the problem lies in motor articulation of speech.

The somatosensory system

Sensory information from the limbs ascends the nervous system in two anatomically discrete systems (Fig. 26.10). Fibres from proprioceptive organs and those mediating well-localised touch (including vibration) enter the spinal cord at the posterior horn and pass without synapsing into the ipsilateral posterior columns. Neural fibres conveying pain and temperature sensory information (nociceptive neurons) synapse with second-order neurons that cross the midline in the spinal cord before ascending in the contralateral anterolateral spinothalamic tract to the brainstem.

The second-order neurons of the dorsal column sensory system cross the midline in the upper medulla to ascend through the brainstem. Here they lie just medial to the (already crossed) spinothalamic pathway.

Brainstem lesions can therefore cause sensory loss affecting all modalities of the contralateral side of the body. Sensory loss on the face due to brainstem lesions is dependent on the anatomy of the trigeminal fibres within the brainstem. Fibres from the back of the face (near the ears) descend within the brainstem to the upper part of the spinal cord before synapsing, the second-order neurons crossing the midline and then ascending with the spinothalamic fibres. Fibres conveying sensation from progressively more forward areas of the face descend a shorter distance in the brainstem. Thus, sensory loss in the face from low brainstem lesions is in a 'balaclava helmet' distribution, as the longer descending trigeminal fibres are affected. Both the dorsal column and spinothalamic tracts end in the thalamus, relaying from there to the parietal cortex.

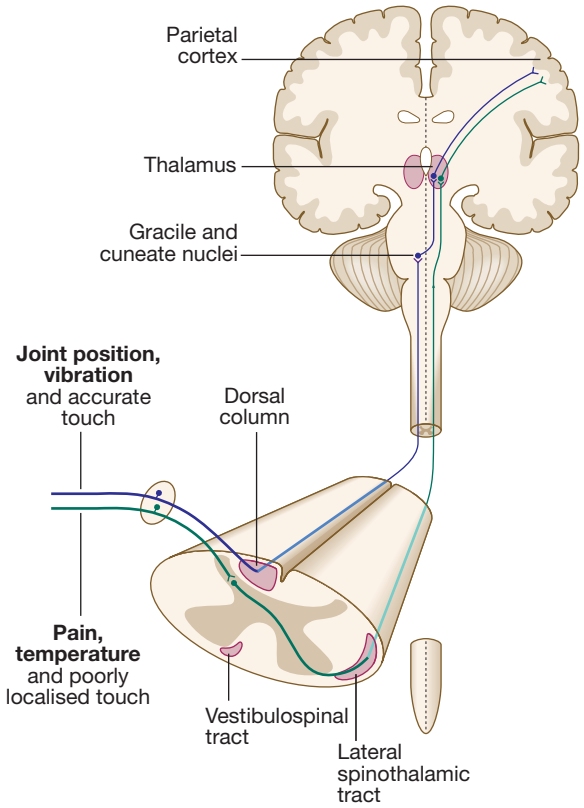

Fig. 26.10 The main somatic sensory pathways.

Pain

Pain is a complex percept that is only partly related to activity in nociceptor neurons (Fig. 26.11). In the posterior horn of the spinal cord, the second-order neuron of the spinothalamic tract is affected by a number of influences in addition to its synapse with the fibres from nociceptors. Branches from the larger mechanoceptor fibres destined for the posterior column also synapse with the second-order spinothalamic neurons and with interneurons of the grey matter of the posterior horn. The nociceptor neurons release neurotransmitters (such as substance P), in addition to excitatory transmitters, which influence the excitability of the spinothalamic neurons. Activity in the posterior horn neurons is modulated by fibres descending from the peri-aqueductal grey matter of the mid-brain and raphe nuclei of the medulla. Neurons of this 'descending analgesia system' are activated by endogenous opiate (endorphin) peptides. The spinal cord's posterior horn is therefore much more than a relay station in pain transmission; its complexity allows it to 'gate' and modulate painful sensation before it ascends in the spinothalamic tract. In the diencephalon, the perception of pain is further influenced by the rich interconnections of the thalamus with the limbic system.

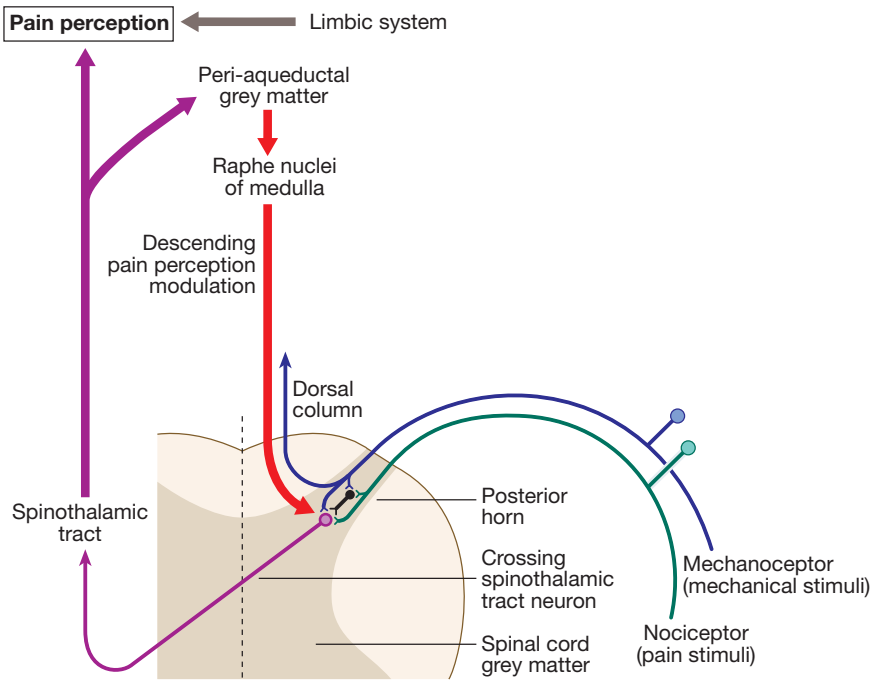

Fig. 26.11 The pain perception system.

Sphincter control

The sympathetic supply to the bladder leaves from T11–L2 to synapse in the inferior hypogastric plexus, while the parasympathetic supply leaves from S2–4. In addition, a somatic supply to the external (voluntary) sphincter arises from S2–4, travelling via the pudendal nerves.

Storage of urine is maintained by inhibiting parasympathetic activity and thus relaxing the detrusor muscle of the bladder wall. Continence is maintained by simultaneous sympathetic and somatic (via the pudendal nerve) mediated tonic contraction of the urethral sphincters. Voiding is usually under conscious control, and triggered by relaxation of tonic inhibition on the pontine micturition centre from higher centres, leading to relaxation of the pelvic floor muscles and external and internal urethral sphincters, along with parasympathetic-mediated detrusor contraction.

Personality and mood

The physiology and pathology of mood disorders are discussed elsewhere (Ch. 10) but it is important to remember that any process affecting brain function will have some effect on mood and affect. Conversely, mood disorder will have a significant effect on perception and function. It can be difficult to disentangle whether psychological and psychiatric changes are the cause or the effect of any neurological symptoms.

Sleep

The function of sleep is unknown but it is required for good health. Sleep is controlled by the reticular activating system in the upper brainstem and diencephalon. It is composed of different stages that can be visualised on electroencephalography (EEG). As drowsiness occurs, normal EEG background alpha rhythm disappears and activity becomes dominated by deepening slow-wave activity. As sleep deepens and dreaming begins, the limbs become flaccid, movements are 'blocked' and EEG signs of rapid eye movements (REM) are superimposed on the slow wave. REM sleep persists for a short spell before another slow-wave spell starts, the cycle repeating several times throughout the night. REM periods become longer as the sleep period progresses. REM sleep seems to be the most important part of the sleep cycle for refreshing cognitive processes, and REM sleep deprivation causes tiredness, irritability and impaired judgement.

Localising lesions in the brainstem

After taking a history and examining the patient, the clinician should have an idea of the nature and site of any pathology. Given the density of tracts and nuclei in the brainstem (see Fig. 26.5), detailed localisation may be possible on the basis of history and examination alone, to be confirmed or refuted by investigation.

Brainstem lesions typically present with symptoms due to cranial nerve, cerebellar and upper motor neuron dysfunction and are most commonly caused by vascular disease. Since the anatomy of the brainstem is very precisely organised, it is usually possible to localise the site of a lesion on the basis of careful history and examination in order to determine exactly which tracts/nuclei are affected, usually invoking the fewest number of lesions.

For example, in a patient presenting with sudden onset of upper motor neuron features affecting the right face, arm and leg in association with a left 3rd nerve palsy, the lesion will be in the left cerebral peduncle in the brainstem and the pathology is likely to have been a small stroke, as the onset was sudden. This combination of signs is known as Weber's syndrome, and is one of several well-described brainstem syndromes, which are listed in Box 26.3. The effects of individual cranial nerve deficits are discussed in the sections on eye movements (p. 1169) and on facial weakness, sensory loss in brainstem lesions, dysphonia and dysarthria, and bulbar symptoms (pp. 1163, 1165, 1168 and 1173).

26.3 Major focal brainstem syndromes

Name of syndrome	Site of lesions	Clinical features
Weber	Anterior cerebral peduncle (mid-brain)	Ipsilateral 3rd palsy Contralateral upper motor neuron 7th palsy Contralateral hemiplegia
Claude	Cerebral peduncle Involving red nucleus	Ipsilateral 3rd palsy Contralateral cerebellar signs
Parinaud	Dorsal mid-brain (tectum)	Vertical gaze palsy Convergence disorders Convergence retraction nystagmus Pupillary and lid disorders
Millard–Gubler	Ponto-medullary junction	Ipsilateral 6th palsy Ipsilateral lower motor neuron 7th palsy Contralateral hemiplegia
Wallenberg	Lateral medulla	Ipsilateral 5th, 9th, 10th, 11th palsy Ipsilateral Horner's syndrome Ipsilateral cerebellar signs Contralateral spinothalamic sensory loss Vestibular disturbance

INVESTIGATION OF NEUROLOGICAL DISEASE

Experienced clinicians will make around 90% of neurological diagnoses on history alone, with a lesser contribution from examination and investigation. As investigations become more complex and more easily available, it is tempting to adopt a 'scan first, think later' approach to neurology. The frequency of 'false-positive' results, the wide range of normality and the unnecessary expense, inconvenience and worry caused to patients should encourage a more thoughtful approach. Investigation may include assessment of structure (imaging) and function (neurophysiology). Neurophysiological testing has become so complex that in many countries it constitutes a separate specialty focusing on electroencephalography, evoked potentials, nerve conduction studies and electromyography.

Neuroimaging

Neurological imaging has traditionally allowed assessment of structure only. Various techniques are available, including X-rays (plain X-rays, computed tomography (CT), CT angiography, myelography and angiography), magnetic resonance (MR imaging (MRI), MR angiography (MRA)) and ultrasound (Doppler imaging of blood vessels). The uses and limitations of each of these are shown in Box 26.4.

It is now possible to use imaging techniques to assess CNS function. Single photon emission clinical tomography (SPECT) scanning can use the lipid-soluble properties of radioactive tracers to mark cerebral blood flow at the time of injection. This can be useful in investigating dementia or epilepsy. SPECT can also be used in the diagnosis of movement disorders: for example, by examining dopamine activity to assess the function of the basal ganglia in patients with possible parkinsonism.

Functional MRI (fMRI) can be used to assess blood flow during specific tasks (e.g. speaking, remembering, calculation), which can provide 'maps' of cortical function that are accurate enough to help plan lesionectomy and epilepsy surgery. Similarly, MR spectroscopy is being developed to identify the chemical composition of specific regions, providing clues as to whether lesions are ischaemic, neoplastic or inflammatory.

Head and orbit

Plain skull X-rays are now largely restricted to the diagnosis of fractures and sinus disease. CT or MRI is needed for intracranial imaging. CT will show bone and calcification well, and will easily image collections of blood. It will also detect abnormalities of the brain and ventricles, such as atrophy, tumours, cysts, abscesses, vascular lesions and hydrocephalus. Diagnostic yield is often improved by the use of intravenous contrast and thinner slicing using spiral CT. Surrounding bone structures render posterior fossa CT images less useful, and CT is less sensitive to white matter changes than MRI.

MRI resolution is unaffected by bone and so is more useful in the investigation of posterior fossa disease. Its sensitivity to cortical and white matter changes makes it effective in picking up inflammatory conditions such as multiple sclerosis, and in investigating epilepsy.

26.4 Imaging techniques for the nervous system

Technique	Applications	Advantages	Disadvantages	Comments
X-ray/CT	Plain X-rays, CT, CTA Radiculography Myelography Intra-arterial angiography	Widely available Relatively cheap Relatively quick	Ionising radiation Contrast reactions Invasive (myelography and angiography)	X-rays: used for fractures or foreign bodies CT: first line for stroke Intra-arterial angiography: gold standard for vascular lesions
MRI	Structural imaging MRA Functional MRI MR spectroscopy	High-quality soft tissue images, useful for posterior fossa and temporal lobes No ionising radiation Non-invasive	Expensive Less widely available MRA images blood flow, not vessel anatomy Claustrophobic Pacemakers contraindicate MRI Contrast (gadolinium) reactions	Functional MR and spectroscopy: mainly research tools
Ultrasound	Doppler Duplex scans	Cheap Quick Non-invasive	Operator-dependent Poor anatomical definition	Screening tool to assess need for carotid endarterectomy
Radio-isotope	Isotope brain scan SPECT PET	In vivo imaging of functional anatomy (ligand binding, blood flow)	Poor spatial resolution Ionising radiation Expensive Not widely available	Isotope scans obsolete. SPECT: useful in movement disorders, epilepsy and dementias PET: mainly research tool

(CT = computed tomography; CTA = computed tomographic angiography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PET = positron emission tomography; SPECT = single photon emission clinical tomography)

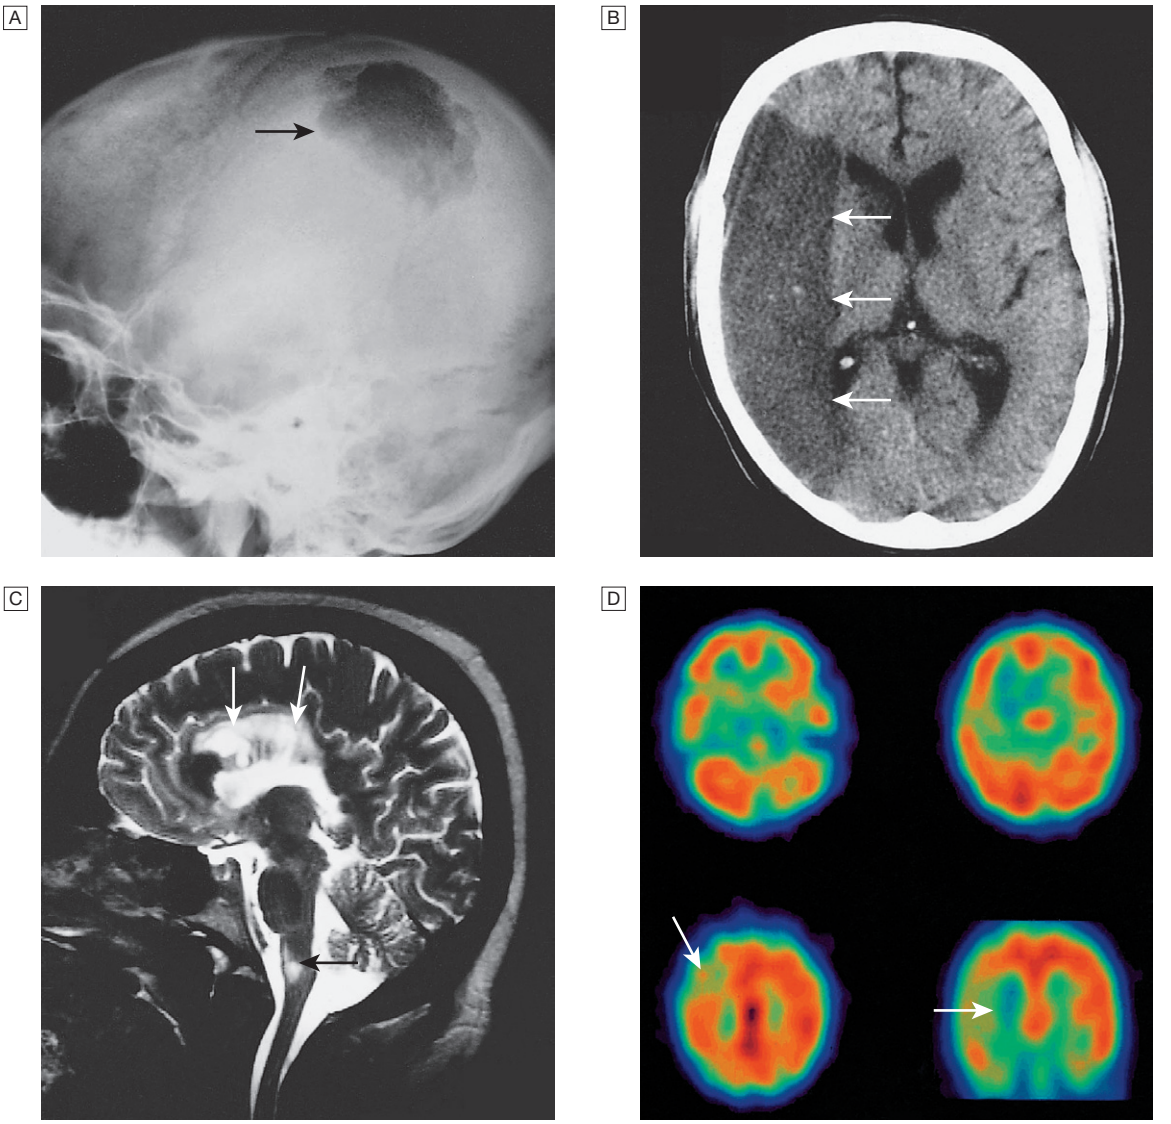

Fig. 26.12 Different techniques of imaging the head and brain. A Skull X-ray showing lytic skull lesion (eosinophilic granuloma – arrow). B CT showing complete middle cerebral artery infarct (arrows). C MRI showing widespread areas of high signal in multiple sclerosis (arrows). D SPECT after caudate infarct showing relative hypoperfusion of overlying right cerebral cortex (arrows).

Different MRI techniques will increase sensitivity to acute ischaemic stroke and may allow detection of abnormalities by filtering signals from other tissues (e.g. adipose tissues in the orbits).

Examples of brain imaged by the various techniques are shown in Figure 26.12.

Cervical, thoracic and lumbar spine

Plain X-rays are useful in the investigation of trauma to vertebrae, but their value in providing information about non-bony tissues is limited, which makes them far less helpful in the assessment of inflammatory and degenerative conditions of the spine. MRI has transformed the investigation of these areas, since it can give information not only about the vertebrae and intervertebral discs, but also about their effects on the spinal cord and nerve roots. Myelography is an invasive technique involving injection of contrast into the lumbar theca. While the outline of the nerve roots and spinal cord provides information about abnormal structure, the accuracy and wide availability of MRI have reduced the need for this. Myelography may still be used for technical reasons or where MRI is unavailable, contraindicated, or precluded by the patient's claustrophobia. Examples of the cervical spine imaged by plain X-rays, myelography and MRI are shown in Figure 26.13.

Blood vessels

Imaging of the extra- and intracranial blood vessels and disturbance of arterial or venous blood flow is described in Chapter 27.

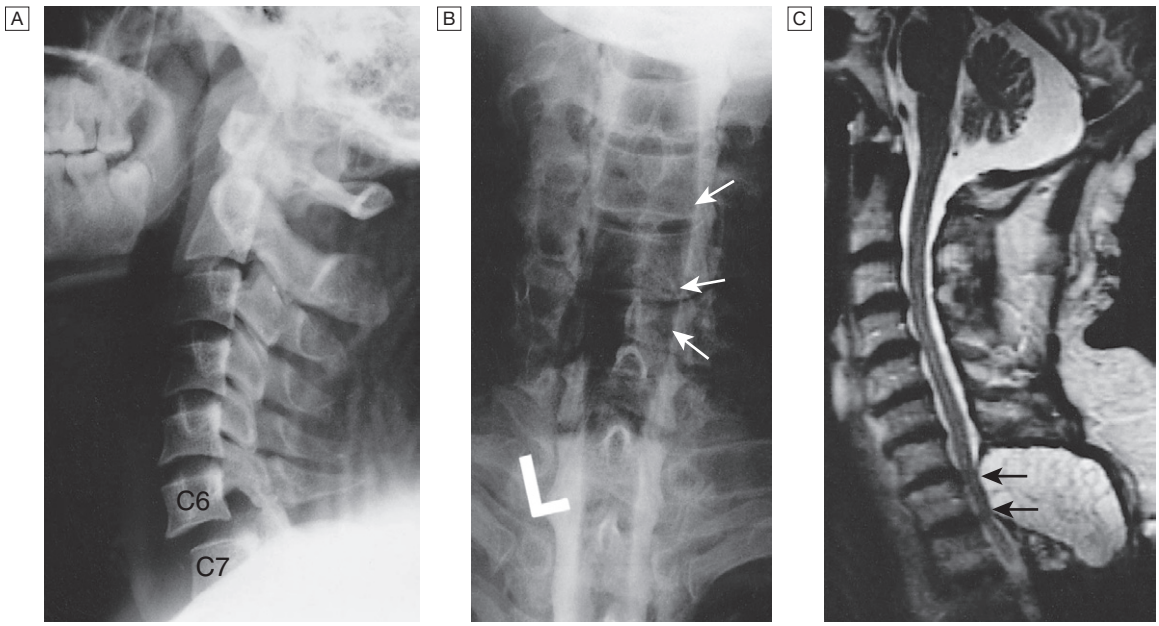

Fig. 26.13 Different techniques of imaging the cervical spine. A Lateral X-ray showing bilateral C6/7 facet dislocation. B Myelogram showing widening of cervical cord due to astrocytoma (arrows). C MRI showing posterior epidural compression from adenocarcinomatous metastasis to the posterior arch of T1 (arrows).

Neurophysiological testing

Electroencephalography

The electroencephalogram (EEG) is used to detect electrical activity arising in the cerebral cortex. The EEG involves placing electrodes on the scalp to record the amplitude and frequency of the resulting waveforms. With closed eyes, the normal background activity is 8–13 Hz (known as alpha rhythm), most prominent occipitally and suppressed on eye opening. Other frequency bands seen over different parts of the brain in different circumstances are beta (faster than 13/s), theta (4–8/s) and delta (slower than 4/s). Normal EEG changes evolve with age and with alertness; lower frequencies predominate in the very young and during sleep.

In recent years, digital technology has allowed longer, cleaner EEG recordings that can be analysed in a number of ways and recorded alongside contemporaneous video of any clinical 'event'. Meanwhile, the development of intracranial recording allows more sensitive monitoring via surgically placed electrodes in and around lesions to help increase the efficacy and improve the safety of epilepsy surgery.

Abnormalities in the EEG result from a number of conditions. Examples include an increase in fast frequencies (beta) seen with sedating drugs such as benzodiazepines, or marked focal slowing noted over a structural lesion such as a tumour or an infarct. Improved quality and accessibility of imaging have made EEG redundant in lesion localisation, except in the specialist investigation of epilepsy (p. 1182). EEG remains useful in progressive and continuous disorders such as reduced consciousness (p. 1159), in encephalitis (p. 1205), and in certain dementias such as Creutzfeldt–Jakob disease (p. 1211).

Since sleep induces marked changes in cerebral activity, EEG can be useful in characterising those conditions where sleep patterns are disturbed. In paroxysmal disorders such as epilepsy, EEG is at its most useful when it captures activity during one of the events in question. Up to 5% of some normal populations may demonstrate epileptiform discharges on EEG which prevent its use as a screening test for epilepsy. Over 50% of patients with proven epilepsy will have a normal 'routine' EEG, and, conversely, the presence of epileptiform features does not of itself make a diagnosis (most notably in younger patients with a family history of epilepsy). In view of this, the EEG should not be used where epilepsy is merely 'suspected'.

The EEG in epilepsy is predominantly used in its classification and prognosis, and in some patients to localise the seat of epileptiform discharges when surgery is being considered. During an epileptic seizure, high-voltage disturbances of background activity ('discharges') will often be noted. These may be generalised, as in the 3-Hz 'spike and wave' of childhood absence epilepsy, or more focal, as in localisation-related epilepsies (Fig. 26.14). Techniques such as hyperventilation or photic stimulation can be used to increase the yield of epileptiform changes, particularly in the generalised epilepsy syndromes. While some argue that it is possible to detect 'spikes' and 'sharp waves' to lend support to a clinical diagnosis, these are non-specific and therefore not diagnostic.

Nerve conduction studies

Electrical stimulation of a nerve causes an impulse to travel both efferently and afferently along the

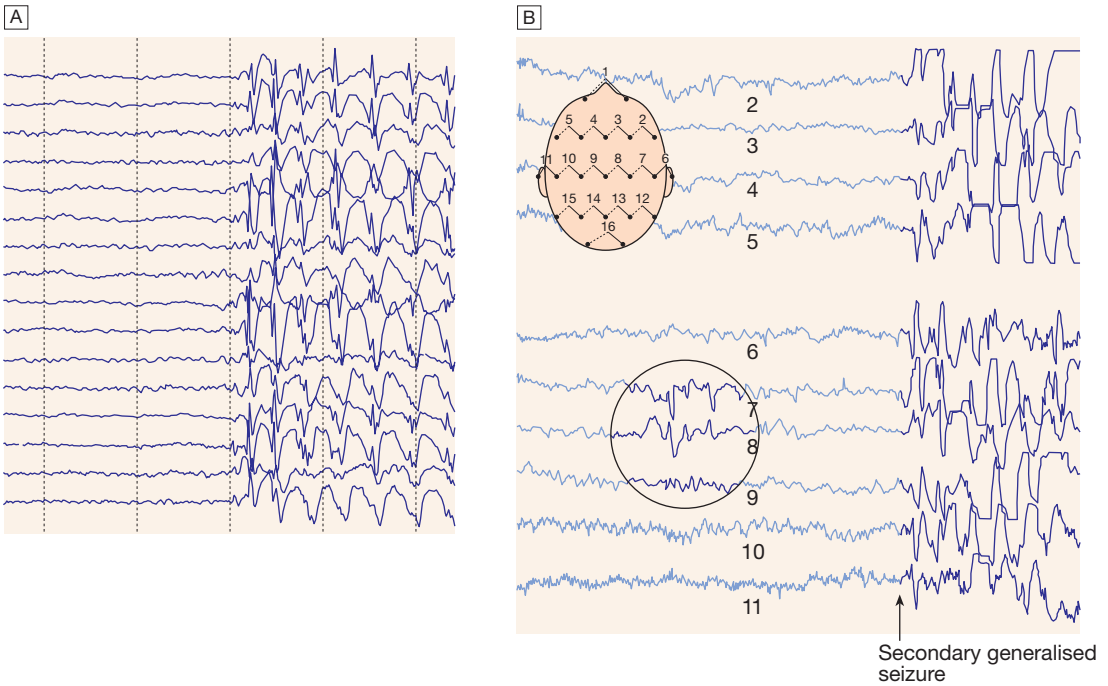

Fig. 26.14 EEGs in epilepsy. A Generalised epileptic discharge, as seen in epilepsy syndromes such as childhood absence or juvenile myoclonic epilepsy. B Focal sharp waves over the right parietal region (circled), with spread of discharge to cause a generalised tonic–clonic seizure.

underlying axons. Nerve conduction studies (NCS) make use of this, recording action potentials as they pass along peripheral nerves and (with motor nerves) as they pass into the muscle belly. Digital recording has enhanced sensitivity and reproducibility of these tiny potentials. By measuring the time taken to traverse a known distance, it is possible to calculate nerve conduction velocities (NCVs). Healthy nerves at room temperature will conduct at a speed of 40–50 m/s. If the recorded potential is smaller than expected, this provides evidence of a reduction in the overall number of functioning axons. Significant slowing of conduction velocity, in contrast, suggests impaired saltatory conduction due to peripheral nerve demyelination. Such changes in NCS may be diffuse (as in a hereditary demyelinating peripheral neuropathy, p. 1223), focal (as in pressure palsies, p. 1224) or multifocal (e.g. Guillain–Barré syndrome, p. 1224; mononeuritis multiplex, p. 1224). The information gained can allow the disease responsible for peripheral nerve dysfunction to be better deduced (see Box 26.99, p. 1223).

Stimulation of motor nerves allows for the recording of compound muscle action potentials (CMAPs) over muscles (Fig. 26.15). These are around 500 times larger than sensory nerve potentials, typically around 1–20 millivolts. Since a proportion of stimulated impulses in motor nerves will 'reflect' back to the anterior horn cell body (forming the 'F' wave), it is also possible to obtain some information about the condition of nerve roots.

Repetitive nerve stimulation (RNS) at 3–15/s provides consistent CMAPs in healthy muscle. In myasthenia gravis (p. 1226), where there is partial blockage of acetylcholine receptors, however, there is a diagnostic fall (decrement) in CMAP amplitude. In contrast, an increasing CMAP with high-frequency RNS is seen in Lambert–Eaton myasthenic syndrome (p. 1227).

Electromyography

Electromyography (EMG) is usually performed with NCS, and involves needle recording of muscle electrical potential during rest and contraction. At rest, muscle is electrically silent but loss of nerve supply causes muscle membrane to become unstable, manifest as fibrillations, positive sharp waves ('spontaneous activity') or fasciculations. During muscle contraction, motor unit action potentials are recorded. Axonal loss or destruction will result in fewer motor units. Resultant sprouting of remaining units will lead to increasing size of each individual unit on EMG. Myopathy, in contrast, will cause muscle fibre splitting, which will result in a large number of smaller units on EMG. Other abnormal activity, such as myotonic discharges, may signify abnormal ion channel conduction, as in myotonic dystrophy or myotonia congenita.

Specialised single fibre EMG (SFEMG) can be used to investigate neuromuscular junction transmission. Measuring 'jitter' and 'blocking' can identify the effect of antibodies in reducing the action of acetylcholine on the receptor.

Evoked potentials

The cortical response to visual, auditory or electrical stimulation can be measured on an EEG as an evoked potential (EP). If a stimulus is provided – for example, to the eye – the tiny EEG response can be discerned when averaging 100–1000 repeated stimuli. Assessing the latency (the time delay) and amplitude can give information about the integrity of the relevant pathway.

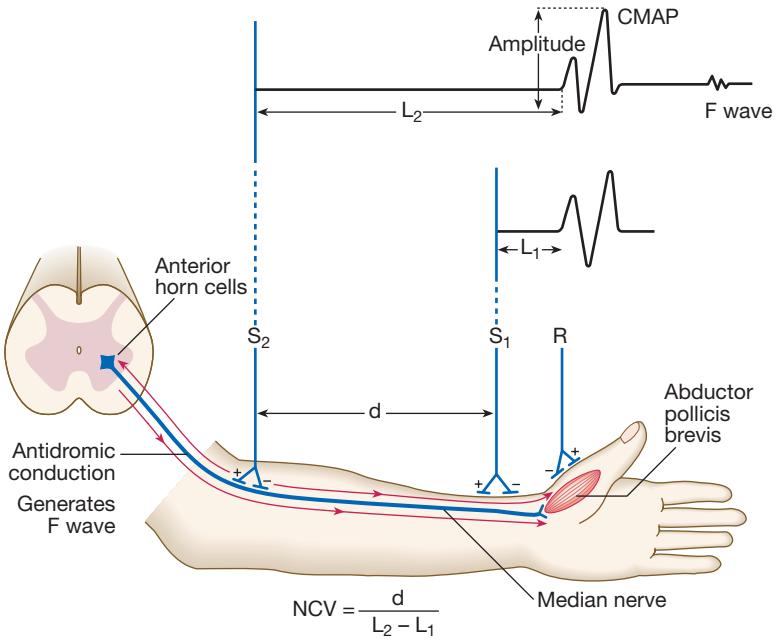

Fig. 26.15 Motor nerve conduction tests. Electrodes (R) on the muscle (abductor pollicis here) record the compound muscle action potential (CMAP) after stimulation at the median nerve at the wrist (S_1) and from the elbow (S_2). The velocity from elbow to wrist can be determined if the distance between the two stimulating electrodes (d) is known. A prolonged L_1 (L = latency) would be caused by dysfunction distally in the median nerve (e.g. in carpal tunnel syndrome). A prolonged L_2 is caused by slow nerve conduction (as in demyelinating neuropathy). The F wave is a small delayed response that appears when the electrical signal travels backwards to the anterior horn cell, sparking a second action potential in a minority of fibres (see text). (NCV = nerve conduction velocity)

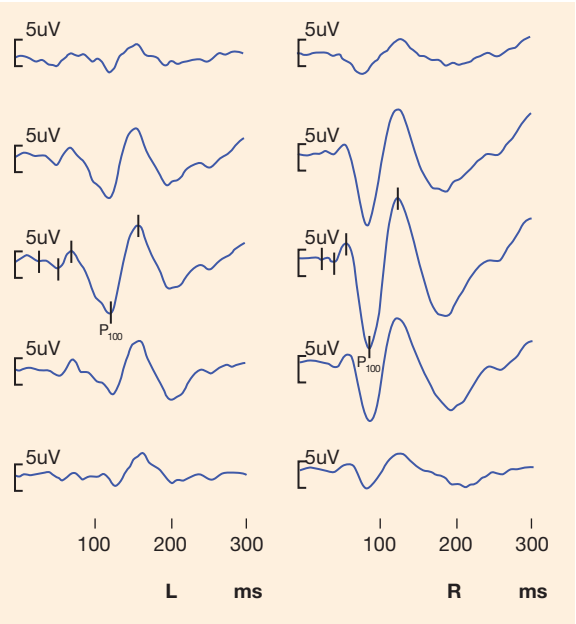

Fig. 26.16 Visual evoked responses (VER) recording. The abnormality is in the left hemisphere, with delay in latency and a reduction in signal of the P_{100}.

MRI now provides more information about CNS pathways, thus reducing reliance on EPs. In practice, visual evoked potentials (VEPs) are most commonly used to help differentiate CNS demyelination from small-vessel white-matter changes (Fig. 26.16).

Magnetic stimulation

Central conduction times can also be measured using electromagnetic induction of action potentials in the cortex or spinal cord by the local application of specialised coils. Again, MRI has made this largely redundant, other than for research.

Routine blood tests

Many systemic conditions that can affect the nervous system can be identified by simple blood tests. Nutritional deficiencies, metabolic disturbances, inflammatory conditions, or infections may all present or be associated with neurological symptoms, and basic blood tests (full blood count, erythrocyte sedimentation rate, C-reactive protein, biochemical screening) may provide clues. Specific blood tests will be highlighted in the relevant subsections of this chapter.

Immunological tests

Recent developments have seen a host of new immune-mediated conditions emerge in clinical neurology, with effects ranging from muscle and neuromuscular junction disturbance (causing weakness and muscle pain) to specific neuronal ion channels (causing cognitive decline, epilepsy and psychiatric changes). The last decade has seen the identification of many causative antibodies (see Boxes 26.62 and 26.63, p. 1194), and it is likely that further conditions will turn out to have an immune basis.

Genetic testing

An increasing number of inherited neurological conditions can now be diagnosed by DNA analysis (p. 60). These include diseases caused by increased numbers of trinucleotide repeats, such as Huntington's disease (p. 1198), myotonic dystrophy (p. 1228) and some types of spinocerebellar ataxia (p. 1199). Mitochondrial DNA can also be sequenced to diagnose relevant disorders (p. 60).

Lumbar puncture

Lumbar puncture (LP) is the technique used to obtain a CSF sample and provides an indirect measure of intracranial pressure. After local anaesthetic injection, a needle is inserted between lumbar spinous processes

26.5 How to interpret CSF results

	Normal	Subarachnoid haemorrhage	Acute bacterial meningitis	Viral meningitis	Tuberculous meningitis	Multiple sclerosis
Pressure	50–250 mm of water	Increased	Normal/ increased	Normal	Normal/increased	Normal
Colour	Clear	Blood-stained Xanthochromic	Cloudy	Clear	Clear/cloudy	Clear
Red cell count ($\times 10^6$/L)	0–4	Raised	Normal	Normal	Normal	Normal
White cell count ($\times 10^6$/L)	0–4	Normal/slightly raised	1000–5000 polymorphs	10–2000 lymphocytes	50–5000 lymphocytes	0–50 lymphocytes
Glucose	> 50–60% of blood level	Normal	Decreased	Normal	Decreased	Normal
Protein	< 0.45 g/L	Increased	Increased	Normal/ increased	Increased	Normal/ increased
Microbiology	Sterile	Sterile	Organisms on Gram stain and/or culture	Sterile/virus detected	Ziehl–Nielson/auramine stain or tuberculosis culture positive	Sterile
Oligoclonal bands	Negative	Negative	Can be positive	Can be positive	Can be positive	Often positive

(usually between L3 and L4) through the dura and into the spinal canal. Intracranial pressure can be deduced (if patients are lying on their side) and CSF removed for analysis. CSF pressure measurement is important in the diagnosis and monitoring of idiopathic intracranial hypertension (p. 1217). In this condition, the LP itself is therapeutic.

CSF is normally clear and colourless, and the tests that are usually performed include a naked eye examination of the CSF and centrifugation to determine the colour of the supernatant (yellow, or xanthochromic, some hours after subarachnoid haemorrhage (p. 1246). Routine analysis will involve a cell count, as well as assay of glucose and protein.

CSF assessment is important in investigating infections (meningitis or encephalitis), subarachnoid haemorrhage and inflammatory conditions (multiple sclerosis, sarcoidosis and cerebral lupus). Normal values and abnormalities found in specific conditions are shown in Box 26.5.

More sophisticated analysis allows measurement of antibody formation solely within the CNS (oligoclonal bands), genetic analysis (e.g. polymerase chain reaction (PCR) for herpes simplex or tuberculosis), immunological tests (paraneoplastic antibodies) and cytology (to detect malignant cells).

If there is a cranial space-occupying lesion causing raised intracranial pressure, LP presents a theoretical risk of downward shift of intracerebral contents, a potentially fatal process known as coning (p. 1212). Consequently, LP is contraindicated if there is any clinical suggestion of raised intracranial pressure (papilloedema), depressed level of consciousness, or focal neurological signs suggesting a cerebral lesion, until imaging (by CT or MRI) has excluded a space-occupying lesion or hydrocephalus. When there is a risk of local haemorrhage (thrombocytopenia, disseminated intravascular coagulation or anticoagulant treatment), then caution should be exercised or specific measures should be taken. LP can be safely performed in patients on antiplatelet drugs or low-dose heparin, but may be unsafe in patients who are fully anticoagulated due to the increased risk of epidural haematoma.

About 30% of LPs are followed by a postural headache, due to reduced CSF pressure. The frequency of headache can be reduced by using smaller or atraumatic needles. Other rarer complications involve transient radicular pain, and pain over the lumbar region during the procedure. Aseptic technique renders secondary infections such as meningitis extremely rare.

Biopsy

Biopsies of nervous tissue (peripheral nerve, muscle, meninges or brain) are occasionally required for diagnosis.

Nerve biopsy can help in the investigation of peripheral neuropathy. Usually, a distal sensory nerve (sural or radial) is targeted. Histological examination can help identify underlying causes, such as vasculitides or infiltrative disorders like amyloid. Nerve biopsy should not be undertaken lightly since there is an appreciable morbidity; it should be reserved for cases where the diagnosis is in doubt after routine investigations and where it will influence management.

Muscle biopsy is performed more frequently and is indicated for the differentiation of myositis and myopathies. These conditions can usually be distinguished by histological examination, and enzyme histochemistry can be useful when mitochondrial diseases and storage diseases are suspected. The quadriceps muscle is most commonly biopsied but other muscles may also be sampled if they are involved clinically. Although pain and infection can follow the procedure, these are less of a problem than after nerve biopsy.

Brain biopsy is required when imaging fails to clarify the nature of intracerebral lesions: for example, in unexplained degenerative diseases such as unusual cases of dementia and in patients with brain tumour. Most biopsies are performed stereotactically through a burr-hole in the skull, which lowers complication rates. Nevertheless, haemorrhage, infection and death still occur and brain biopsy should only be considered if a diagnosis is otherwise elusive.

PRESENTING PROBLEMS IN NEUROLOGICAL DISEASE

While history is important in all medical specialties, it is especially key in neurology, where many neurological diagnoses have no confirmatory test. History-taking allows doctor and patient to get to know one another – many neurological diseases follow chronic paths, and this may be the first of many such consultations. It also allows the clinician to obtain information about the patient's affect, cognition and psychiatric state.

History-taking is a highly active process and, whilst there are generic templates (Box 26.6), each individual story will follow its own course, and diagnostic considerations during the history will guide further questioning.

It is important to be clear about what patients mean by certain words. Patients may find it difficult to describe symptoms – for instance, weakness may be called 'numbness', while there are many possible interpretations of 'dizziness'. These must be clarified; even in emergency situations, a clear, accurate history is the foundation of any management plan. While the story should come primarily from the patient, input from eye-witnesses and family members is crucial if the patient is unable to provide details or if there has been loss of consciousness. This need for corroboration and clarification means the telephone is as important as any investigation.

The aim of the history is to answer two key issues: where is the lesion and what is the lesion (Box 26.7)? These should remain uppermost in the doctor's mind whilst eliciting the history. Some common combinations of symptoms may suggest particular locations for a lesion (Box 26.8). Enquiry about handedness is important; lateralisation of the dominant hand helps designate the dominant hemisphere, which in turn may help to localise any pathologies, or to plan rehabilitation or treatment strategies in asymmetrical disorders such as stroke or Parkinson's disease.

Epidemiology must be borne in mind; how likely is it that this particular patient has any specific condition under consideration? For example, a 20-year-old with right-sided headache and tenderness will not have temporal arteritis, but this is an important possibility if such symptoms present in a 78-year-old female.

Determining the evolution and speed of onset and progression of a disease is important (Box 26.9). For example, if right-hand weakness occurred overnight, it would suggest a stroke in an older person or an acute entrapment neuropathy in a younger one. Evolution over several days, however, might make demyelination (multiple sclerosis) a possible diagnosis, or perhaps a subdural haematoma if the weakness was preceded by a head injury in an older person taking warfarin. Progression over weeks might bring an intracranial mass lesion or motor neuron disease into the differential. Slow progression over a year or so, with difficulty in using the hand, could suggest a degenerative process such as Parkinson's disease. The impact on day-to-day activities, such as walking, climbing stairs and carrying out fine hand movements, should also be established in order to gauge the level of associated disability.

26.6 How to take a neurological history

Introduction

- Age and sex
- Handedness

Presenting complaint

- Symptoms (clarify: see text)
- Overall pattern: intermittent or persistent?
  - If intermittent, how often do symptoms occur and how long do they last?
- Speed of onset: seconds, minutes, hours, days, weeks, months, years, decades?
- Better, worse or the same over time?
- Associated symptoms (including non-neurological)
- Disability caused by symptoms
  - Change in walking
  - Difficulty with fine hand movements, e.g. writing, fastening buttons, using cutlery
- Effect on work, family life and leisure

Background

- Previous neurological symptoms and whether similar to current symptoms
- Previous medical history
- Domestic situation
- Driving licence status
- Medications (current and at time of symptom onset)
- Alcohol/smoking habits
- Recreational drug and other toxin exposure
- Family history and developmental history
- What are patient's thoughts/fears/concerns?

26.7 The key diagnostic questions

Where is the lesion?

- Is it neurological?
- If so, to which part of the nervous system does it localise?
  - Central versus peripheral
  - Sensory versus motor versus both

What is the lesion?

- Hereditary or congenital
- Acquired
  - Traumatic
  - Infective
  - Neoplastic
  - Degenerative
  - Inflammatory or immune-mediated
  - Vascular
  - Functional

26.8 How to 'localise' neurological disease

Combination of symptoms/signs	Probable site	Possible pathology	Other important information
Painless loss of hemilateral function	Cerebral cortex	Usually vascular, inflammatory or neoplastic	Associated systemic symptoms Tempo of evolution
Pyramidal weakness of all four limbs or both legs, bladder signs, sensory loss	Spinal cord	Usually vascular, inflammatory or neoplastic	Associated systemic symptoms Tempo of evolution
Cranial nerve lesions, with limb pyramidal signs or sensory loss ± sphincter disturbance	Brainstem Mid-brain Pons Medulla	Usually vascular or inflammatory Rarely neoplastic	Associated systemic symptoms Tempo of evolution
Visual loss + pyramidal signs and/or cerebellar signs	Widespread cerebral lesions	Usually inflammatory Less commonly vasculitic	Tempo of evolution
Weakness and/or sensory loss in a combination of individual peripheral nerves	Several peripheral nerves ('mononeuritis multiplex')	Usually inflammatory or diabetic	Associated systemic symptoms
Widespread LMN and UMN signs	Upper and lower motor neurons	Motor neuron disease Cervical myeloradiculopathy	Associated localised cervical symptoms
Distal loss of sensation and/or weakness	Generalised peripheral nerves	See causes of neuropathy (p. 1223)	Associated systemic symptoms

(LMN/UMN = lower/upper motor neuron)

26.9 The evolution of symptoms

Onset	Evolution	Possible causes
Sudden (minutes to hours)	Stable/improvement	Vascular (stroke/transient ischaemic attack (TIA)) Nerve entrapment syndromes Functional
Gradual	Progressive over days	Demyelination Infection
Gradual	Progressive over weeks to months	Neoplastic/paraneoplastic
Gradual	Progressive over months to years	Genetic Degenerative

Estimates of the frequency and duration of specific events are essential when taking details of a paroxysmal disorder such as migraine and epilepsy. Vague terms such as 'a lot' or 'sometimes' are unhelpful, and it can assist the patient if choices are given to estimate numbers, such as once a day, week or month.

Many neurological symptoms are not explained by disease. Describing these as 'functional' is less pejorative and more acceptable to patients than 'psychogenic' or 'hysterical'. Functional symptoms require considerable experience in diagnosis, and are frequently missed (p. 1175).

Headache and facial pain

Headache is common and causes considerable worry, but rarely represents sinister disease. The causes may be divided into primary (benign) or secondary, and most patients, whether presenting in clinic or as emergencies, have primary syndromes (Box 26.10). The tempo of evolution of headache is critical; sudden-onset headache, maximal immediately, is always a 'red flag' (Box 26.11) and should prompt rapid assessment in hospital for possible subarachnoid hemorrhage or other sinister causes, even though only 10–25% of patients harbour serious pathology. Clues to other possible causes (e.g. rash in meningitis) should be sought (p. 1201). Headache that evolves over hours to days is much less likely to be sinister.

26.10 Primary and secondary headache syndromes

Primary headache syndromes

- Migraine (with or without aura)
- Tension-type headache
- Trigeminal autonomic cephalalgia (including cluster headache)
- Primary stabbing/coughing/exertional/sex-related headache
- Thunderclap headache
- New daily persistent headache syndrome

Secondary causes of headache

- Medication overuse headache (chronic daily headache)
- Intracerebral bleeding (subdural haematoma, subarachnoid or intracerebral haemorrhage)
- Raised intracranial pressure (brain tumour, idiopathic intracranial hypertension)
- Infection (meningitis, encephalitis, brain abscess)
- Inflammatory disease (temporal arteritis, other vasculitis, arthritis)
- Referred pain from other structures (orbit, temporomandibular joint, neck)

For full diagnostic listings see www.ihs-classification.org/en/

26.11 'Red flag' symptoms in headache

Symptom	Possible explanation
Sudden onset (maximal immediately or within minutes)	Subarachnoid haemorrhage Cerebral venous sinus thrombosis Pituitary apoplexy Meningitis
Focal neurological symptoms (other than for typically migrainous)	Intracranial mass lesion Vascular Neoplastic Infection
Constitutional symptoms Weight loss General malaise Pyrexia Meningism Rash	Meningoencephalitis Neoplastic (lymphoma or metastases) Inflammatory (vasculitic)
Raised intracranial pressure (worse on wakening/lying down, associated vomiting)	Intracranial mass lesion
New onset aged > 60 yrs	Temporal arteritis

It is important to establish whether the headache comes and goes, with periods of no headache in between (usually migraine), or whether it is present all or almost all the time. Associated symptoms, such as preceding visual symptoms, nausea/vomiting or photophobia/phonophobia, may support a diagnosis of migraine, but others, such as progressive focal symptoms or constitutional upset like weight loss or fever, may suggest a more sinister cause (e.g. cancer or meningitis). The behaviour of the patient during headache is often instructive; migraine patients typically retire to bed to sleep in a dark room, whereas cluster headache often induces agitated and restless behaviour.

Headache duration may indicate a diagnosis; headaches that have been present for months or years are almost never sinister (although paradoxically worry patients), whereas new-onset headache, especially in the elderly, is more of a concern. In a patient over 60 years with head pain localised to one or both temples, temporal arteritis (p. 1117) should be considered, especially if temporal pulses are absent and/or the arteries are enlarged and tender. Most outpatients with headache will have migraine (intermittent, lasting a few hours, associated with migrainous symptoms) or chronic daily headache syndrome (often present for months to years, without associated symptoms and refractory to analgesia). These are easy to recognise but patients are often very worried about their symptoms, so it is important to elicit such concerns and to explain why sinister disease is unlikely and investigation is rarely required. Sinusitis, 'eye strain', food allergies and uncomplicated hypertension are almost never the explanation for persistent headache.

Ocular pain

Assuming ocular disease (such as acute glaucoma) has been excluded, ocular pain may be due to trigeminal autonomic cephalalgias (TACs) or, rarely, inflammatory or infiltrative lesions at the apex of the orbit or the cavernous sinus, when 3rd, 4th, 5th or 6th cranial nerve involvement is usually evident.

Facial pain

Pain in the face can be due to dental or temporomandibular joint problems. Acute sinusitis is usually apparent from other features of sinus congestion/infection and may cause localised pain over the affected sinus, but is almost never the explanation for persistent facial pain or headache.

Facial pain is not uncommon in migraine but some syndromes can present solely with facial pain. The most common neurological causes of facial pain are trigeminal neuralgia, herpes zoster (shingles) and post-herpetic neuralgia, all characterised by their extreme severity. In trigeminal neuralgia, the patient describes bouts of brief (seconds), lancinating pain ('electric shocks'), most frequently felt in the second and third divisions of the nerve and often triggered by talking or chewing. Facial shingles most commonly affects the first (ophthalmic) division of the trigeminal nerve, and pain usually precedes the rash. Post-herpetic neuralgia may follow, typically a continuous burning pain throughout the affected territory, with marked sensitivity to light touch (allodynia) and resistance to treatment. Destructive lesions of the trigeminal nerve usually cause numbness rather than pain.

Persistent idiopathic facial pain is most frequently seen in middle-aged women, who report persistent pain, with no abnormal signs or investigations, and is similar to other forms of idiopathic chronic pain.

Dizziness, blackouts and 'funny turns'

Episodic lost or altered consciousness is a frequent symptom in primary care and hospital practice. The terms used for such spells vary so much among patients that they should not be taken for granted. Some patients use 'blackout' to describe a purely visual symptom, rather than loss of consciousness. Some individuals may understand 'dizziness' to mean an abnormal perception of movement (vertigo), but others will mean a feeling of faintness, and yet others unsteadiness (Box 26.12). The clinician thus needs to elucidate the exact nature of the symptoms that the patient experiences (Fig. 26.17).

The history should always be supplemented by a direct eye-witness account if available. Often a history of 'shaking' as described to the first aider will become 'fitting' when described to the ambulance crew, which then is reported as 'definite seizure' in the emergency room. Careful history with corroboration will usually establish whether there has been full consciousness, altered consciousness, vertigo, transient amnesia or something else. Vertigo is caused by an alteration in function of the peripheral vestibular organs or the central control mechanisms of balance and posture, and will be discussed elsewhere (p. 1167).

Loss of consciousness

Consciousness may be defined as an awareness of the environment and ability to respond to it. Loss of consciousness (LOC), other than in sleep, suggests a global dysfunction of the brain. This most commonly occurs

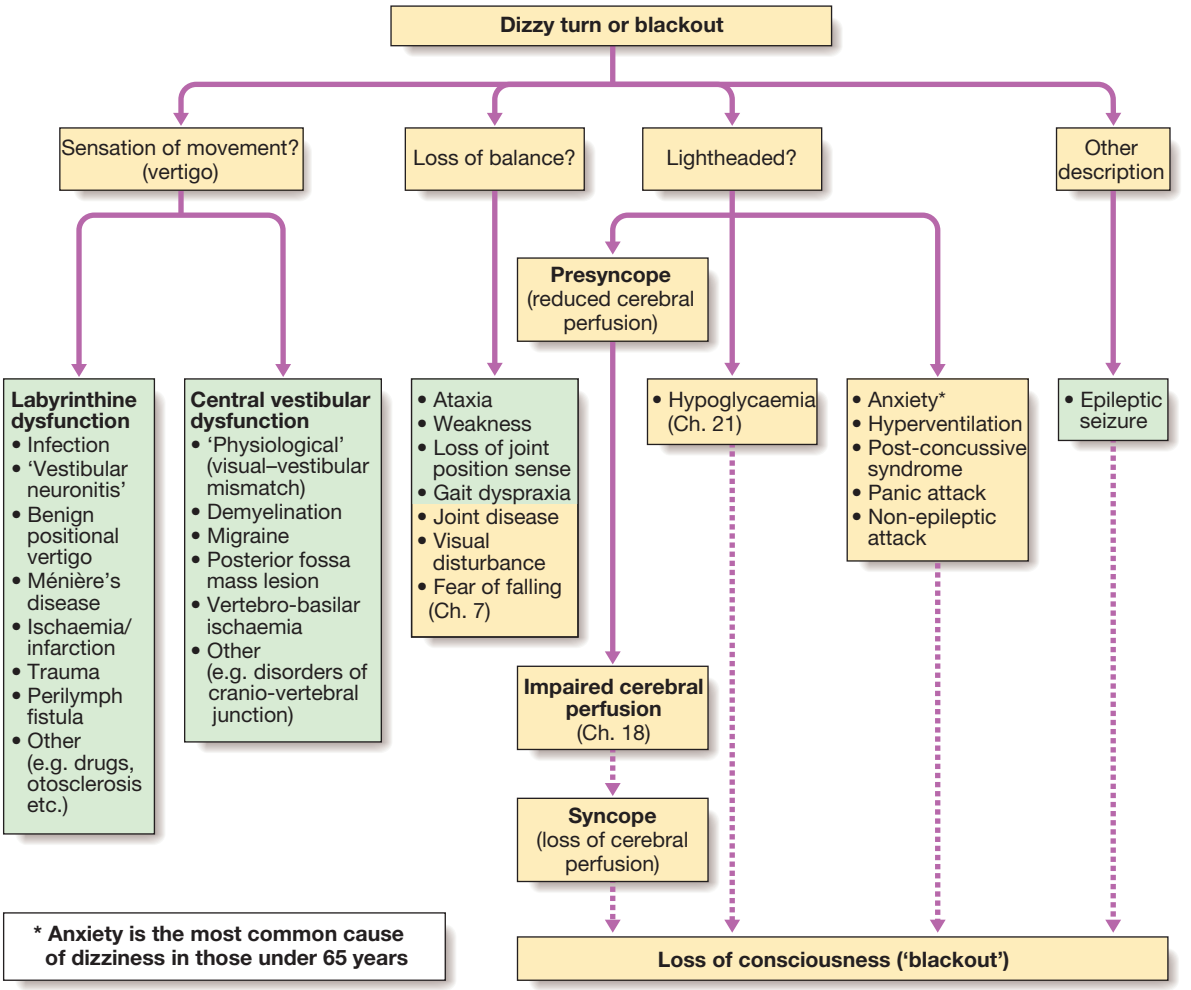

Fig. 26.17 **A diagnostic approach to the patient with dizziness, funny turns or blackouts.** (Neurological causes are shown in green.)

26.12 Dizziness in old age

- **Prevalence**: common, affecting up to 30% of people aged > 65 yrs.
- **Symptoms**: most frequently described as a combination of unsteadiness and lightheadedness.
- **Most common causes**: postural hypotension, cardiovascular disease, cervical spondylosis. Many patients have more than one underlying cause.
- **Arrhythmia**: can present with lightheadedness either at rest or on activity.
- **Anxiety**: frequently associated with dizziness but rarely the only cause.
- **Falls**: multidisciplinary workup is required if dizziness is associated with falls.

26.13 How to differentiate seizures from syncope

	Seizure	Syncope
Aura (e.g. olfactory)	+	–
Cyanosis	+	–
Tongue-biting	+	–/+
Post-ictal confusion	+	–
Post-ictal amnesia	+	–
Post-ictal headache	+	–
Rapid recovery	–	+

because of temporary loss of blood supply to the whole brain (syncope or faint). Alternatively, LOC can occur due to a sudden electrical dysfunction of the brain, as occurs during a seizure. Whilst most episodes of transient LOC are due to syncope or seizure, psychogenic blackouts (also known as non-epileptic seizure or pseudoseizure) need to be considered in the differential diagnosis.

No amount of investigation can replace a clear history in these circumstances. The subjective experience is important, but objective description from an eye-witness (even if only by telephone) is equally helpful. Features in the history useful in distinguishing a seizure from syncope are shown in Box 26.13.

Syncope

Typically, syncope is preceded by a brief feeling of lightheadedness. Neurocardiogenic syncope (p. 555) is more likely on standing, and may be provoked by pain or emotion. There may be darkening of vision, ringing in the ears, symptoms of hyperventilation, distal tingling, feelings of nausea, clamminess or sweating. The LOC is gradual and brief, and the patient recovers quickly without confusion as long as he or she has assumed a horizontal position. There is often some brief stiffening and limb twitching, which requires differentiation from seizure-like movements. It is rare for syncope to cause injury or to cause amnesia after regaining awareness. During a syncopal attack, incontinence of urine can occur. Tongue-biting is less common in syncope and, if present, usually involves little trauma.

Cardiac syncope (p. 555), caused by a sudden drop in cardiac output, may be provoked by exertion in those with severe aortic stenosis, ischaemia or hypertrophic obstructive cardiomyopathy, or without warning in patients with cardiac arrhythmia.

Seizures

The diagnosis of generalised tonic–clonic seizures, in which there is loss of consciousness, falling to the ground and clonic movements (p. 1180), is easy but lack of eyewitness accounts can leave uncertainty. Less dramatic seizures, such as absences (p. 1181) or some focal seizures (p. 1180), which cause alteration of consciousness without the patient falling to the ground, may merely be experienced as 'lost time'. Since epileptic seizures are the result of specific processes that vary from patient to patient, their manifestation tends to be intermittent and stereotyped and often clusters in time, for reasons incompletely understood.

Non-epileptic attack disorder, psychogenic seizures, pseudoseizures, psychogenic non-epileptic seizures

This disorder is recognised in all cultures but nomenclature has yet to be standardised. Around 10% of patients referred to a first seizure clinic will have LOC resulting from psychological reactions to circumstances or traumatic life events. Clinical pointers to the diagnosis include specific emotional triggers, partially retained awareness, dramatic movements or vocalisation, very prolonged duration (up to hours), rapid recovery or subsequent emotional distress. Diagnosis is important, as such patients are at significant risk of being harmed by inappropriate treatment if they are assumed to have epilepsy. Conversely, a hasty diagnosis may lead to treatment being withheld in atypical or prolonged seizures. Specialist help is necessary to plan management.

Status epilepticus

Status epilepticus is seizure activity not resolving spontaneously, or recurrent seizure with no recovery of consciousness in between. Persisting seizure activity has a recognised mortality and is a medical emergency.

Diagnosis is usually clinical and can be made on the basis of the description of prolonged rigidity and/or clonic movements with loss of awareness. As seizure activity becomes prolonged, movements may become more subtle. Cyanosis, pyrexia, acidosis and sweating may occur, and complications include aspiration, hypotension, cardiac arrhythmias and renal or hepatic failure.

In patients with pre-existing epilepsy, the most likely cause is a fall in anti-epileptic drug levels. In de novo status epilepticus, it is essential to exclude precipitants such as infection (meningitis, encephalitis), neoplasia and metabolic derangement (hypoglycaemia, hyponatraemia, hypocalcaemia). Treatment and investigation are outlined in Box 26.14.

26.14 Management of status epilepticus

Initial

- Ensure airway is patent; give oxygen to prevent cerebral hypoxia
- Check pulse, blood pressure, BM stix® and respiratory rate
- Secure intravenous access
- Send blood for:
  - Glucose, urea and electrolytes, calcium and magnesium, liver function, anti-epileptic drug levels
  - Full blood count and clotting screen
  - Storing a sample for future analysis (e.g. drug misuse)
- If seizures continue for > 5 mins: give diazepam 10 mg IV (or rectally) *or* lorazepam 4 mg IV; repeat *once only* after 15 mins
- Correct any metabolic trigger, e.g. hypoglycaemia

Ongoing

If seizures continue after 30 mins

- IV infusion (with cardiac monitoring) with one of:
  - Phenytoin: 15 mg/kg at 50 mg/min
  - Fosphenytoin: 15 mg/kg at 100 mg/min
  - Phenobarbital: 10 mg/kg at 100 mg/min
- Cardiac monitor and pulse oximetry
  - Monitor neurological condition, blood pressure, respiration; check blood gases

If seizures still continue after 30–60 mins

- Transfer to intensive care
  - Start treatment for refractory status with intubation, ventilation and general anaesthesia using propofol or thiopental
  - EEG monitor

Once status controlled

- Commence longer-term anticonvulsant medication with one of:
  - Sodium valproate 10 mg/kg IV over 3–5 mins, then 800–2000 mg/day
  - Phenytoin: give loading dose (if not already used as above) of 15 mg/kg, infuse at < 50 mg/min, then 300 mg/day
  - Carbamazepine 400 mg by nasogastric tube, then 400–1200 mg/day
- Investigate cause

Coma

Conscious level should be measured using the Glasgow Coma Scale (GCS, Box 26.15). Although developed for use in head injury, GCS is widely used in medical coma, but disorders that affect language or limb function (e.g. left hemisphere stroke, locked-in syndrome) may reduce its usefulness. Nevertheless, it provides useful prognostic information, and serial recordings

can plot improvement or deterioration. It is important to record the three components of the scale, rather than just the sum score. Thus, a description of eye-opening (E2) and withdrawing (M4) to pain and making sounds only (V2) provides a much more useful picture than GCS 8.

Persisting loss of consciousness or coma (defined as GCS ≤ 8) occurs if the arousal mechanisms in the brainstem and diencephalon are disturbed, and localises to either the brainstem or both cerebral hemispheres. There are many causes of coma (Box 26.16), including neurological (structural or non-structural brain disease) or non-neurological (e.g. type II respiratory failure). The mode of onset of coma and any precipitating event is crucial to establishing the cause, and should be obtained from family or other witnesses (by telephone if

26.15 Glasgow Coma Scale

Eye-opening (E)	
• Spontaneous	4
• To speech	3
• To pain	2
• Nil	1
Best motor response (M)	
• Obeys commands	6
• Localises	5
• Withdraws	4
• Abnormal flexion	3
• Extensor response	2
• Nil	1
Verbal response (V)	
• Orientated	5
• Confused conversation	4
• Inappropriate words	3
• Incomprehensible sounds	2
• Nil	1
Coma score = E + M + V	
Always present GCS as breakdown, not a sum score (unless 3 or 15)	
• Minimum sum	3
• Maximum sum	15

26.16 Causes of coma

Metabolic disturbance

- Drug overdose
- Diabetes mellitus
  - Hypoglycaemia
  - Ketoacidosis
  - Hyperosmolar coma
- Hyponatraemia
- Uraemia
- Hepatic failure
- Respiratory failure
- Hypothermia
- Hypothyroidism
- Thiamin deficiency

Trauma

- Cerebral contusion
- Extradural haematoma
- Subdural haematoma
- Global axonal injury (deceleration)

Vascular disease

- Subarachnoid haemorrhage
- Brainstem infarction/ haemorrhage
- Intracerebral haemorrhage
- Cerebral venous sinus thrombosis

Infections

- Meningitis
- Encephalitis
- Cerebral abscess
- Systemic sepsis

Others

- Epilepsy
- Brain tumour
- Functional ('pseudo-coma')

26.17 UK criteria for the diagnosis of brain death

Preconditions for considering a diagnosis of brain death

- The patient is deeply comatose
  (a) There must be no suspicion that coma is due to depressant drugs, such as narcotics, hypnotics, tranquillisers
  (b) Hypothermia has been excluded – rectal temperature must exceed 35°C
  (c) There is no profound abnormality of serum electrolytes, acid–base balance or blood glucose concentrations, and any metabolic or endocrine cause of coma has been excluded
- The patient is maintained on a ventilator because spontaneous respiration has been inadequate or has ceased. Drugs, including neuromuscular blocking agents, must have been excluded as a cause of the respiratory failure
- The diagnosis of the disorder leading to brain death has been firmly established. There must be no doubt that the patient is suffering from irremediable structural brain damage

Tests for confirming brain death

- All brainstem reflexes are absent
  (a) The pupils are fixed and unreactive to light
  (b) The corneal reflexes are absent
  (c) The vestibulo-ocular reflexes are absent – there is no eye movement following the injection of 20 mL of ice-cold water into each external auditory meatus in turn
  (d) There are no motor responses to adequate stimulation within the cranial nerve distribution
  (e) There is no gag reflex and no reflex response to a suction catheter in the trachea
- No respiratory movement occurs when the patient is disconnected from the ventilator long enough to allow the carbon dioxide tension to rise above the threshold for stimulating respiration ($PaCO_2$ must reach 6.7 kPa (50 mmHg))

The diagnosis of brain death should be made by two experienced doctors, one of whom should be a consultant and the other a consultant or specialist registrar. The tests are usually repeated after an interval of 24 hours, depending on the clinical circumstances, before brain death is finally confirmed.

necessary). Failure to obtain an adequate history for patients in coma is a common cause of diagnostic delay. Once the patient is stable from a cardiorespiratory perspective, examination should include accurate assessment of conscious level (see below) and thorough general medical examination, looking for clues such as needle tracks indicating drug abuse, rashes, fever and focal signs of infection, including neck stiffness or evidence of head injury. Focal neurological signs may suggest a structural explanation (stroke or tumour) or may be falsely localising (p. 1212).

Brain death and minimally conscious states

Coma is loss of consciousness related to loss of brain function. Brain death is a state in which cortical and brainstem function is irreversibly lost. Diagnostic criteria for brain death vary between countries (Box 26.17); if satisfied, these criteria allow support to be withdrawn and natural death to occur. Diagnosing brain death is complex and should only be done by a clinician with appropriate expertise, as clinical differentiation from reduced consciousness can be challenging (Box 26.18). The 'locked-in' syndrome, in which the patient is paralysed except for eye movements, requires preserved hemisphere function (and thus consciousness), but a strategically placed lesion in the ventral pons (usually infarction) causes complete paralysis. The vegetative state implies some retention of brainstem function and minimal cortical function, with loss of awareness of the environment. Minimally conscious states imply retention of awareness and intact brainstem function. Confident distinction between these states is important and requires careful assessment, often over a period of time. Brain death is, by definition, irreversible, but other states may offer hope for improvement. Difficult ethical issues regarding management often arise.

Delirium

Delirium is a common result of cortical impairment and is more common in old age. It manifests as a disturbance of arousal with global impairment of mental function causing drowsiness with disorientation, perceptual errors and muddled thinking. Fluctuation is typical and confusion is often worse at night. Emotional disturbance (anxiety, irritability or depression) and psychomotor changes (agitation, restlessness or retardation) are common. The assessment and management of this condition are covered in more detail on page 173.

Amnesia

Memory disturbance is a common symptom. In the absence of significant functional impairment (e.g. inability to work, dyspraxias, loss of daily function), many patients will prove to have benign memory dysfunction related to age, mood or psychiatric disorders. Investigation and treatment of the dementias are discussed elsewhere (p. 250).

Temporary loss of memory may be due to a transient toxic confusional state, the post-ictal period after seizure, or transient global amnesia. These are usually distinguished on the basis of the history.

Transient global amnesia

This predominantly affects middle-aged patients with an abrupt, discrete loss of anterograde memory function lasting up to a few hours. During the episode, patients are unable to record new memories, and this results in repetitive questioning, the hallmark of this condition. Consciousness is preserved and patients may perform even complex motor acts normally. During the attack there is retrograde amnesia for the events of the past

26.18 Classification of brain death and reduced conscious states

Diagnosis	Features	Investigation	Prognosis
Brain death	See Box 26.17	Cranial imaging for primary cause EEG – no electrical activity Cranial Doppler – no cortical blood flow	Invariably fatal
Vegetative state (VS) 'Persistent VS' > 1 mth 'Permanent VS' > 1 yr	No reaction to verbal stimuli Some reaction to noxious stimuli Sleep–wake cycles (periods of eye opening) Maintained respiratory drive Intact brainstem reflexes Occasional automatic movements (yawning, swallowing)	Cranial imaging for primary cause Maintained cortical blood flow	Prognosis better post trauma
Minimally conscious state	Some reaction to verbal stimuli Some reaction to noxious stimuli Spontaneous movements Intact brainstem reflexes	EEG demonstrates reactivity	
Locked-in syndrome	Some retained cranial nerve reflexes Some response to verbal stimuli (e.g. eye movements to communicate) No limb movement to noxious stimuli	Imaging for primary cause	Depends on cause – recovery unlikely to progress beyond 6 mths

few days, weeks or years. After 4–6 hours, memory function and behaviour return to normal but the patient has persistent, complete amnesia for the duration of the attack itself. There are no seizure markers and, unlike epileptic amnesia, transient global amnesia recurs in around 10–20% only. A vascular aetiology is unlikely and amnesia may be due to a benign process similar to migraine, occurring in the hippocampus. The patient has no physical signs and, if imaging is normal and no seizure markers are present, then the patient can be reassured.

Persistent amnesia

Patients with persistent memory disturbance must have serious neurological disease excluded. Symptoms corroborated by relatives or colleagues are likely to be more significant than those noted by the patient only. Where poor concentration is at the heart of cognitive deterioration, it is more likely to be due to an underlying mood disorder.

It is important to assess the timing of onset and to establish which aspects of memory are affected. Complaints of getting lost or of losing complex abilities are more pathological than word-finding difficulties. Disturbance of episodic or working memory (previously called 'short-term memory') must be distinguished from semantic memory (memory for concept-based knowledge unrelated to specific experiences). Episodic memory is selectively impaired in Korsakoff's syndrome (often secondary to alcohol) or bilateral temporal lobe damage. It can also be seen in conjunction with other types of dementia. Progressive deterioration over months suggests an underlying dementia, but it is important to perform a full medical assessment to detect any underlying medical problem.

It is important to identify and treat depression (p. 243) in patients with memory loss. Depression may present as a 'pseudo-dementia', with concentration and memory impairment as dominant features, and this is often reversible with antidepressant medication. However, any patient with dementia (particularly of the Alzheimer's type) may develop depression in the early stages of their illness. Specific causes of progressive dementia, with their treatment and investigation, are listed elsewhere (p. 250).

Weakness

The assessment of weakness requires the application of basic anatomy, physiology and some pathology to the interpretation of the history and clinical findings. Points to consider are shown in Boxes 26.19 and 26.20, and in Figure 26.18. The pattern and evolution of weakness and the clinical signs provide clues to the site and nature of the lesion.

26.19 Distinguishing signs in upper versus lower motor neuron syndromes

	Upper motor neuron lesion	Lower motor neuron lesion
Inspection	Normal (may be wasting in chronic lesions)	Wasting, fasciculation
Tone	Increased with clonus	Normal or decreased, no clonus
Pattern of weakness	Preferentially affects extensors in arms, flexors in leg Hemiparesis, paraparesis or tetraparesis	Typically focal, in distribution of nerve root or peripheral nerve, with associated sensory changes
Deep tendon reflexes	Increased	Decreased/absent
Plantar response	Extensor (Babinski sign)	Flexor

26.20 How to assess weakness

Clinical finding	Likely level of lesion/diagnosis
Pattern and distribution	
Isolated muscles	Radiculopathy or mononeuropathy
Both limbs on one side (hemiparesis)	Cerebral hemisphere, less likely cord or brainstem
One limb	Neuronopathy, plexopathy, cord/brain
Both lower limbs (paraparesis)	Spinal cord; look for a sensory level
Fatigability	Mysasthenia gravis
Bizarre, fluctuating, not following anatomical rules	Functional
Signs	
Upper motor neuron	Brain/spinal cord
Lower motor neuron	Peripheral nervous system
Evolution of the weakness	
Sudden and improving	Stroke/mononeuropathy
Evolving over months or years	Meningioma, cervical spondylotic myelopathy
Gradually worsening over days or weeks	Cerebral mass, demyelination
Associated symptoms	
Absence of sensory involvement	Motor neuron disease, myopathy, myasthenia

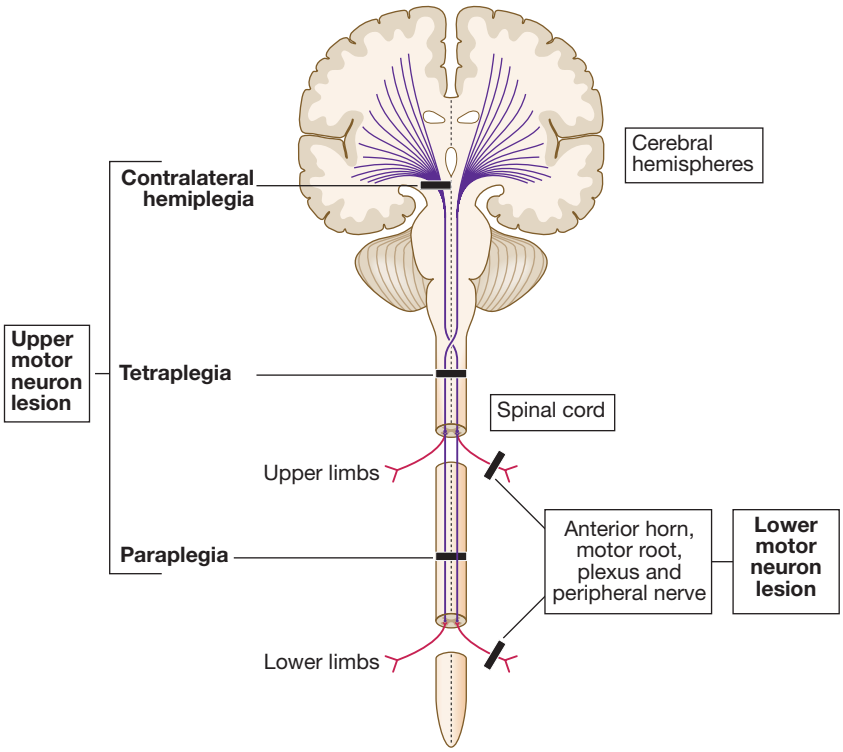

Fig. 26.18 Patterns of motor loss according to the anatomical site of the lesion.

It is important to establish whether the patient has loss of power rather than reduced sensation or generalised fatigue. Pain may restrict movement and thus mimic weakness. Paradoxically, sensory neglect (p. 1164) may leave patients unaware of even severe weakness.

Patients with parkinsonism may complain of weakness; extrapyramidal signs of rigidity (cogwheel or lead pipe) and bradykinesia should be evident, and a resting tremor, usually asymmetrical, may provide a further clue (p. 1194). Observation is as important as formal strength testing. Movement restricted by pain should be apparent, and other features (contractures, wasting, fasciculations, abnormal movements/postures) all provide diagnostic clues. Simple observation of the patient walking into the consulting room may be diagnostic.

Weakness is a common functional symptom. Functional weakness does not conform to typical organic patterns, and the signs in Box 26.19 are absent. On examination, the signs are often variable (e.g. the patient can walk but appears to have no leg movement when assessed on the couch), and strength may appear to 'give way', with the patient able to achieve full power for brief bursts. This does not occur in disease. Hoover's sign is useful to confirm functional weakness, and relies on the normal phenomenon of simultaneous hip extension when the contralateral hip flexes. In functional weakness, one may see hip extension weakness (rare in organic disease), which then returns to full strength on testing contralateral hip flexion. This sign may be demonstrated to the patient in a non-confrontational manner, to show that the potential limb power is intact.

Facial weakness

Facial nerve palsy (Bell's palsy)

One of the most common causes of facial weakness is Bell's palsy, a lower motor neuron lesion of the 7th (facial) nerve, affecting all ages and both sexes.

The lesion is within the facial canal. Symptoms usually develop subacutely over a few hours, with pain around the ear preceding the unilateral facial weakness. Patients often describe the face as 'numb', but there is no objective sensory loss (except to taste if the chorda tympani is involved). Hyperacusis may occur if the nerve to stapedius is involved, and there may be diminished salivation and tear secretion. Examination reveals an ipsilateral lower motor neuron facial nerve palsy. Vesicles in the ear or on the palate may indicate primary herpes zoster infection (p. 318).

Steroids improve recovery rates if started within 72 hours of onset but antiviral drugs are not effective. Taping the eye shut overnight helps prevent exposure keratitis and corneal abrasion. About 80% of patients recover spontaneously within 12 weeks. Plastic surgery may be considered for the minority left with facial disfigurement after 12 months. Recurrence is unusual and should prompt further investigation. Aberrant re-innervation may occur during recovery, producing unwanted facial movements, such as eye closure when the mouth is moved (synkinesis), or 'crocodile tears' (tearing during salivation).

Unlike Bell's palsy, lesions with an upper motor neuron origin partly spare the upper face. Cortical lesions may cause a facial weakness either in isolation or with associated hemiparesis and speech difficulties.

Sensory disturbance

Sensory symptoms are common and are frequently benign. Patients often find sensory symptoms difficult to describe, and sensory examination is difficult for both doctor and patient. While neurological disease can cause sensory symptoms, systemic disorders can also be responsible. Tingling in both hands and around the mouth can occur as the result of hyperventilation (p. 657) or hypocalcaemia (p. 768). When there is dysfunction of the relevant cerebral cortex, the patient's perception of the wholeness or actual presence of the relevant part of the body may be distorted.

Numbness and paraesthesia

The history may give the best clues to localisation and pathology. Certain common patterns are recognised: in migraine, the aura may consist of spreading tingling or paraesthesia, followed by numbness evolving over 20–30 minutes over one half of the body, often splitting the tongue. Sensory loss caused by a stroke or transient ischaemic attack (TIA) occurs much more rapidly and is typically negative (numbness) rather than positive (tingling). Rarely, unpleasant paraesthesia of sensory epilepsy spreads within seconds. The sensory alteration of inflammatory spinal cord lesions often ascends from one or both lower limbs to a distinct level on the trunk over hours to days. Psychogenic sensory change can occur as a manifestation of anxiety or as part of a conversion disorder (p. 246). In such cases, the distribution usually does not conform to a known anatomical pattern nor fit with any organic disease. Care must be taken in diagnosing non-organic sensory problems; a careful history and examination will ensure there is no other objective neurological deficit.

Sensory neurological examination needs to be undertaken and interpreted with care since the findings depend, by definition, on subjective reports. However, the reported distribution of sensory loss can be useful when combined with the coexisting deficits of motor and/or cranial nerve function (Fig. 26.19).

Sensory loss in peripheral nerve lesions

Here the symptoms are usually of sensory loss and paraesthesia. Single nerve lesions cause disturbance in the sensory distribution of the nerve, whereas in diffuse neuropathies the longest neurons are affected first, giving a characteristic 'glove and stocking' distribution. If smaller nerve fibres are preferentially affected (e.g. in diabetic neuropathy), temperature and pin-prick (pain) are reduced, whilst vibration sense and proprioception (modalities served by the larger, well-myelinated, sensory nerves) may be spared. In contrast, vibration and proprioception are particularly affected if the neuropathy is demyelinating in character (p. 1224), producing symptoms of tightness and swelling with impairment of proprioception and vibration sensation.

Sensory loss in nerve root lesions

These typically present with pain as a prominent feature, either within the spine or in the limb plexuses. It is often felt in the myotome rather than the dermatome. The

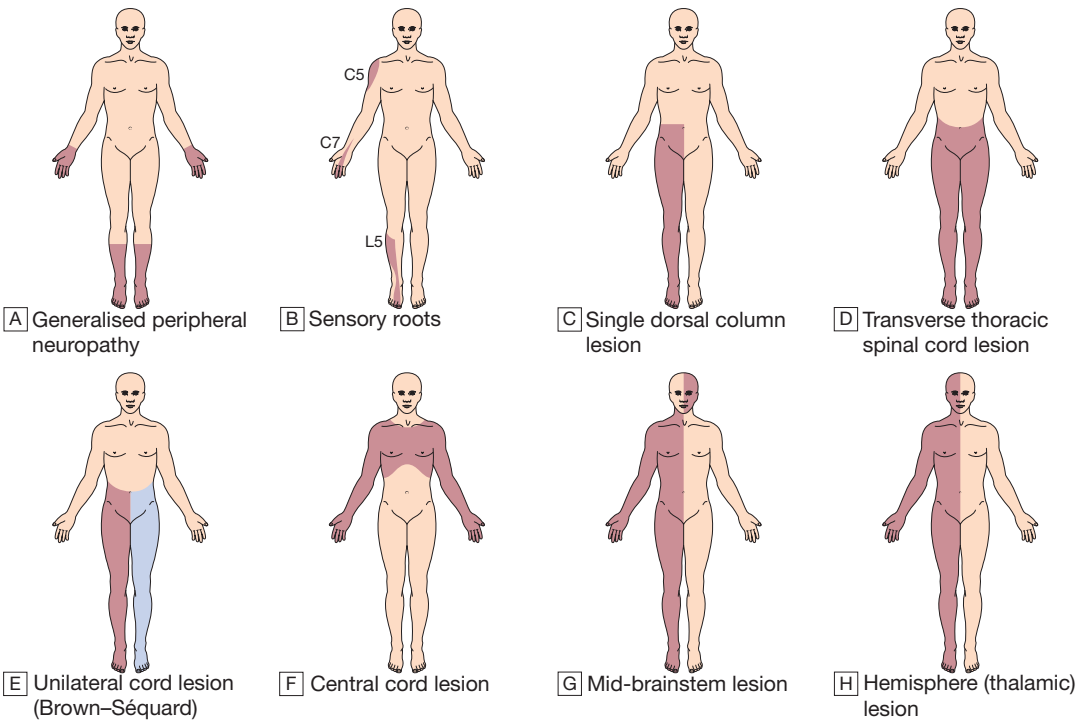

Fig. 26.19 Patterns of sensory loss. A Generalised peripheral neuropathy. B Sensory roots: some common examples. C Single dorsal column lesion (proprioception and some touch loss). D Transverse thoracic spinal cord lesion. E Unilateral cord lesion (Brown–Séquard): ipsilateral dorsal column (and motor) deficit and contralateral spinothalamic deficit. F Central cord lesion: 'cape' distribution of spinothalamic loss. G Mid-brainstem lesion: ipsilateral facial sensory loss and contralateral loss on body below the vertex. H Hemisphere (thalamic) lesion: contralateral loss on one side of face and body.

nerve root involved may be deduced from the dermatomal pattern of sensory loss, although overlap may lead to this being smaller than expected.

Sensory loss in spinal cord lesions

Transverse lesions of the spinal cord produce loss of all sensory modalities below that segmental level, although the clinical level may only be manifest 2–3 segments lower than the anatomical site of the lesion. Very often, there is a band of paraesthesia or hyperaesthesia at the top of the area of sensory loss. Clinical examination may reveal dissociated sensory loss, i.e. different patterns in the spinothalamic and dorsal columnar pathways. If the transverse lesion is vascular due to anterior spinal artery thrombosis, the spinothalamic pathways may be affected while the posterior one-third of the spinal cord (the dorsal column modalities) may be spared.

Lesions damaging one side of the spinal cord will produce loss of spinothalamic modalities (pain and temperature) on the opposite side, and of dorsal column modalities (joint position and vibration sense) on the same side of the body – the Brown–Séquard syndrome (p. 1221).

Lesions in the centre of the spinal cord (such as syringomyelia: see Box 26.98 and Fig. 26.46, p. 1222) spare the dorsal columns but involve the spinothalamic fibres crossing the cord from both sides over the length of the lesion. There is no sensory loss in segments above and below the lesion; this is described as 'suspended' sensory loss. There is sometimes reflex loss at the level of the lesion if afferent fibres of the reflex arc are affected.

An isolated lesion of the dorsal columns is not uncommon in multiple sclerosis. This produces a characteristic unpleasant, tight feeling over the limb(s) involved and, while there is no loss of pin-prick or temperature sensation, the associated loss of proprioception may severely limit function of the affected limb(s).

Sensory loss in brainstem lesions

Lesions in the brainstem can be associated with sensory loss, but the distribution depends on the site of the lesion. A lesion limited to the trigeminal nucleus or its sensory projections will cause ipsilateral facial sensory disturbance. For example, pain resembling trigeminal neuralgia can be seen in patients with multiple sclerosis. The anatomy of the trigeminal connections means that lesions in the medulla or spinal cord can give rise to 'balaclava' patterns of sensory loss (p. 1147). Sensory pathways running up from the spinal cord can also be damaged in the brainstem, resulting in simultaneous sensory loss in arm(s) and/or leg(s).

Sensory loss in hemispheric lesions

The temporal, parietal and occipital lobes receive sensory information regarding the various modalities of touch, vision, hearing and balance (see Box 26.2, p. 1142). The initial points of entry into the cortex are the respective primary cortical areas (see Fig. 26.4, p. 1143). Damage to any of these primary areas will result in reduction or loss of the ability to perceive that particular modality: 'negative' symptomatology. Abnormal excitation of these areas can result in a false perception ('positive' symptoms), the most common of which is migrainous visual aura (flashing lights or teichopsiae).

Cortical lesions are more likely to cause a mixed motor and sensory loss. Substantial lesions of the parietal cortex (as in large strokes) can cause severe loss of proprioception and may even abolish conscious awareness of the existence of the affected limb(s). The resulting loss of function in the limb may be impossible to distinguish from paralysis. Pathways are so tightly packed in the thalamus that even small lacunar strokes can cause isolated contralateral hemisensory loss.

Neuropathic pain

Neuropathic pain is a positive neurological symptom caused by dysfunction of the pain perception apparatus, in contrast to nociceptive pain, which is secondary to pathological processes such as inflammation. Neuropathic pain has distinctive features and typically provokes a very unpleasant, persistent, burning sensation. There is often increased sensitivity to touch, so that light brushing of the affected area causes exquisite pain (allodynia). Painful stimuli are felt as though they arise from a larger area than that touched, and spontaneous bursts of pain may also occur. Pain may be elicited by other modalities (allodynia) and is considerably affected by emotional influences. The most common causes of neuropathic pain are diabetic neuropathies, trigeminal and post-herpetic neuralgias, and trauma to a peripheral nerve. Treatment of these syndromes can be difficult. Drugs that modulate various parts of the nociceptive system, such as gabapentin, carbamazepine or tricyclic antidepressants, may help. Localised treatment (topical treatment or nerve blocks) sometimes succeeds but may increase the sensory deficit and worsen the situation. Electrical stimulation has occasionally proved successful. For further information, see Chapter 12.

Abnormal movements

Disorders of movement lead to either extra, unwanted movement (hyperkinetic disorders) or too little movement (hypokinetic disorders) (Box 26.21). In either case, the lesion often localises to the basal ganglia, although some tremors are related to cerebellar or brainstem disturbance. Functional movement disorders are common, and may mimic all of the organic syndromes below. The most important hypokinetic disorder is Parkinson's disease (p. 1194). Parkinsonism is a clinical description of a collection of symptoms, including tremor, bradykinesia and rigidity. Whilst the history is always important, observation is clearly vital; much of the skill in diagnosing movement disorders lies in pattern recognition. Once it is established whether the problem is hypo- or hyperkinetic, the next task is to categorise the movements further, accepting that there is often overlap. Videoing the movements (with the patient's permission), so that they can be shown to a movement disorder expert, may provide a quick diagnosis in cases of uncertainty.

Tremor

Tremor is caused by alternating agonist/antagonist muscle contractions and produces a rhythmical oscillation of the body part affected. In the assessment of tremor, the position, body part affected, frequency and

26.21 Movement disorders

Description	Features	Examples
Hypokinetic disorders		
Parkinsonism	Akinesia Rigidity Tremor Loss of postural reflexes Other features depending on cause	Idiopathic Parkinson's disease Other degenerative syndromes Drug-induced (See Box 26.64)
Catatonia	Mutism Sustained posturing and waxy flexibility	Usually psychiatric; if neurological, is most commonly of vascular origin
Hyperkinetic disorders		
Tremor	Rhythmical oscillation of body part (see Box 26.22)	Essential tremor Parkinson's disease Drug-induced
Chorea	Jerky, brief, involuntary movements	Huntington's disease Drug-induced
Tics	Stereotyped, repetitive movements, briefly suppressible	Tourette's syndrome
Myoclonus	Shock-like muscle jerks	Epilepsy Hypnic jerks (p. 1187) Focal cortical disease
Dystonia	Sustained muscle contraction causing abnormal postures ± tremor	Genetic Generalised dystonic syndromes Focal dystonias in adults (e.g. torticollis)
Others	Various	Paroxysmal hyperkinetic dyskinesias Hemifacial spasm Tardive syndromes

26.22 Causes and characteristics of tremors

	Body part affected	Position	Frequency	Amplitude	Character
Physiological	Both arms > legs	Posture, movement	High	Small (fine)	Enhanced by anxiety, emotion, drugs, toxins
Parkinsonism	Unilateral or asymmetrical Arm > leg, chin, never head	Rest Postural and re-emergent may occur	Low (3–4 Hz)	Moderate	Typically pill-rolling, thumb and index finger, other features of parkinsonism
Essential tremor	Bilateral arms, head	Movement	High (8–10 Hz)	Low to moderate	Family history; 50% respond to alcohol
Dystonic	Head, arms, legs	Posture	Variable	Variable	Other features of dystonia, often jerky tremors
Functional	Any	Any	Variable	Variable	Distractible

amplitude should be considered, as these provide diagnostic clues (Box 26.22).

Other hyperkinetic syndromes

Non-rhythmic involuntary movements include chorea, athetosis, ballism, dystonia, myoclonus and tics. They are categorised by clinical appearance, and coexistence and overlap are common, such as in choreoathetosis.

- *Chorea*: jerky, brief, purposeless involuntary movements, appearing as fidgety movements affecting different areas; they suggest disease in the caudate nucleus (as in Huntington's disease, p. 1198) and are a common complication of prolonged levodopa treatment for Parkinson's disease. Other causes are shown in Box 26.23.
- *Athetosis*: slower, writhing movement of the limbs, often combined with chorea and having similar causes.
- *Ballism*: a more dramatic form of chorea, causing often-violent flinging movements of one limb (monoballism) or one side of the body (hemiballism). The lesion localises to the contralateral subthalamic nucleus and the most common cause is stroke.
- *Dystonia*: sustained involuntary muscle contraction that causes abnormal postures or movement. It may

26.23 Causes of chorea

Hereditary
- Huntington's disease (HD) and HD-like syndromes
- Wilson's disease
- Neuroacanthocytosis
- Dentato-rubro-pallidoluysian atrophy
- Benign hereditary chorea
- Paroxysmal dyskinesias

Cerebral birth injury (including kernicterus)

Cerebral trauma

Drugs
- Levodopa
- Antipsychotics
- Anticonvulsants
- Oral contraceptive

Metabolic
- Disorders affecting thyroid, parathyroid, glucose, sodium, calcium and magnesium balance
- Pregnancy

Autoimmune
- Post-streptococcal (Sydenham's chorea)
- Antiphospholipid antibody syndrome
- Systemic lupus erythematosus (SLE)

Structural lesions of basal ganglia (usually caudate)
- Vascular
- Demyelination
- Brain tumour

be generalised (usually in childhood-onset genetic syndromes) or, more commonly, focal/segmental (such as in torticollis, when the head is twisted repeatedly to one side). Some dystonias only occur with specific tasks, such as writer's cramp or other occupational 'cramps'. Dystonic tremor is associated, and is asymmetrical and of large amplitude.

- *Myoclonus*: brief, isolated, random jerks of muscle groups. This is physiological at the onset of sleep (hypnic jerks). Similarly, a myoclonic jerk is a component of the normal startle response, which may be exaggerated in some rare (mostly genetic) disorders. Myoclonus may occur in disorders of the cerebral cortex, such as some forms of epilepsy. Alternatively, myoclonus can arise from subcortical structures or, more rarely, from segments of the spinal cord.
- *Tics*: stereotyped repetitive movements, such as blinking, winking, head shaking or shoulder shrugging. Unlike dyskinesias, the patient may be able to suppress them, although only for a short time. Isolated tics are common in childhood and usually disappear. Tourette's syndrome is defined by the presence of multiple motor and vocal tics that may evolve over time; it is frequently associated with psychiatric disease, including obsessive compulsions, depression, self-harm or attention deficit disorder. Tics may also occur in Huntington's and Wilson's diseases, or after streptococcal infection.

Abnormal perception

The parietal lobes are involved in the higher processing and integration of the primary sensory information. This takes place in areas referred to as 'association' cortex, damage to which gives rise to sensory (including visual) inattention, disorders of spatial perception, and disruption of spatially orientated behaviour, leading to apraxia. Apraxia is the inability to perform complex, organised activity in the presence of normal basic motor, sensory and cerebellar function (after weakness, numbness and ataxia have been excluded as causes). Examples of complex motor activities include dressing, using cutlery and geographical orientation. Other abnormalities that can result from damage to the association cortex involve difficulty reading (dyslexia) or writing (dysgraphia), or the inability to recognise familiar objects (agnosia). The results of damage to particular lobes of the brain are given in Box 26.2 (p. 1142).

Altered balance and vertigo

Balance is a complicated dynamic process that requires ongoing modification of both axial and limb muscles to compensate for the effects of gravity and alterations in body position and load (and hence centre of gravity) in order to prevent a person from falling. This requires input from a variety of sensory modalities (visual, vestibular and proprioceptive), processing by the cerebellum and brainstem, and output via a number of descending pathways (e.g. vestibulospinal, rubrospinal and reticulospinal tracts).

Disorders of balance can therefore arise from any part of this process. Disordered input (loss of vision, vestibular disorders or lack of joint position sense), processing (damage to vestibular nuclei or cerebellum) or motor function (spinal cord lesions, leg weakness of any cause) can all impair balance. The patient may complain of different symptoms, depending on the location of the lesion. For example, loss of joint position sense or cerebellar function may result in a sensation of unsteadiness, while damage to the vestibular nuclei or labyrinth may result in an illusion of movement such as vertigo (see below). A careful history is vital. Since vision can often compensate for lack of joint position sense, patients with peripheral neuropathies or dorsal column loss will often find their problem more noticeable in the dark.

Examination of such patients may yield physical signs that again depend on the site of the lesion. Sensory abnormalities may be manifest as altered visual acuities or visual fields, possibly with abnormalities on fundoscopy, altered eye movements (including nystagmus, p. 1171), impaired vestibular function (p. 1186) or lack of joint position sense. Disturbance of cerebellar function may be manifest as nystagmus, dysarthria or ataxia, or difficulty with gait (unsteadiness or inability to perform tandem gait, p. 1168). Leg weakness, if present, will be detectable on examination of the limbs.

Vertigo

Vertigo is defined as an abnormal perception of movement of the environment or self, and occurs because of conflicting visual, proprioceptive and vestibular information about a person's position in space. Vertigo commonly arises from imbalance of vestibular input and is within the experience of most people, since this is the 'dizziness' that occurs after someone has spun round vigorously and then stops. Bilateral labyrinthine

dysfunction often causes some unsteadiness. Labyrinthine vertigo usually lasts days at a time, though it may recur, whilst vertigo arising from central (brainstem) disorders is often persistent and accompanied by other brainstem signs. Benign paroxysmal positional vertigo (p. 1186) lasts a few seconds on head movement. A careful history will reveal the likely cause in most patients.

Abnormal gait

Many neurological disorders can affect gait. Observing patients as they walk into the consulting room can be very informative, although formal examination is also important. Neurogenic gait disorders need to be distinguished from those due to skeletal abnormalities, usually characterised by pain producing an antalgic gait, or limp. Gait alteration incompatible with any anatomical or physiological deficit may be due to functional disorders.

Pyramidal gait

Upper motor neuron lesions cause characteristic extension of the affected leg. The resultant tendency for the toes to strike the ground on walking requires the leg to swing outwards at the hip (circumduction). Nevertheless, a shoe on the affected side worn down at the toes may provide evidence of this type of gait. In hemiplegia, the asymmetry between affected and normal sides is obvious on walking, but in paraparesis both lower limbs swing slowly from the hips in extension and are dragged stiffly over the ground – described as 'walking in mud'.

Foot drop

In normal walking, the heel is the first part of the foot to hit the ground. A lower motor neuron lesion affecting the leg will cause weakness of ankle dorsiflexion, resulting in a less controlled descent of the foot, which makes a slapping noise as it hits the ground. In severe cases, the foot will have to be lifted higher at the knee to allow room for the inadequately dorsiflexed foot to swing through, resulting in a high-stepping gait.

Myopathic gait

During walking, alternating transfer of the body's weight through each leg requires adequate hip abduction. In proximal muscle weakness, usually caused by muscle disease, the hips are not properly fixed by these muscles and trunk movements are exaggerated, producing a rolling or waddling gait.

Ataxic gait

An ataxic gait can result from lesions in the cerebellum, vestibular apparatus or peripheral nerves. Patients with lesions of the central portion of the cerebellum (the vermis) walk with a characteristic broad-based gait 'as if drunk' (cerebellar function is particularly sensitive to alcohol). Patients with acute vestibular disturbances walk similarly but the accompanying vertigo is characteristic. Inability to walk heel to toe may be the only sign of less severe cerebellar dysfunction.

Proprioceptive defects can also cause an ataxic gait. The impairment of joint position sense makes walking unreliable, especially in poor light. The feet tend to be placed on the ground with greater emphasis, presumably to enhance proprioceptive input, resulting in a 'stamping' gait.

Apraxic gait

In an apraxic gait, power, cerebellar function and proprioception are normal on examination of the legs. The patient may be able to carry out complex motor tasks (e.g. bicycling motion) while recumbent and yet cannot formulate the motor act of walking. In this higher cerebral dysfunction, the feet appear stuck to the floor and the patient cannot walk. Gait apraxia is a sign of diffuse bilateral hemisphere disease (such as normal pressure hydrocephalus) or diffuse frontal lobe disease.

Marche à petits pas

This gait is characterised by small, slow steps and marked instability. It differs from the festination found in Parkinson's disease (see below) in that it lacks increasing pace and freezing. The usual cause is small-vessel cerebrovascular disease, and there are accompanying bilateral upper motor neuron signs.

Extrapyramidal gait

The rigidity and bradykinesia of basal ganglia dysfunction (p. 1194) lead to a stooped posture and characteristic gait difficulties, with problems initiating walking and controlling the pace of the gait. Patients may become stuck whilst trying to start walking or when walking through doorways ('freezing'). The centre of gravity will be moved forwards to aid propulsion, which, with poor axial control, can lead to an accelerating pace of shuffling and difficulty stopping. This produces the festinant gait: initial stuttering steps that quickly increase in frequency while decreasing in length.

Abnormal speech and language

Speech disturbance may be isolated to disruption of sound output (dysarthria) or may involve language disturbance (dysphasia). Dysphonia (reduction in the sound/volume) is usually due to mechanical laryngeal disruption, whereas dysarthria is more typically neurological in origin. Dysphasia is always neurological and localises to the dominant cerebral hemisphere (usually left, regardless of handedness). Combinations of speech and swallowing problems are explained below (p. 1173).

Dysphonia

Dysphonia describes hoarse or whispered speech. The most common cause is laryngitis, but dysphonia can also result from a lesion of the 10th cranial nerve or disease of the vocal cords, including laryngeal dystonia. Parkinsonism may cause hypophonia with marked reduction in speech volume, often in association with dysarthria, making speech difficult to understand.

Dysarthria

Dysarthria is characterised by poorly articulated or slurred speech and can occur in association with lesions of the cerebellum, brainstem and lower cranial nerves, as well as in myasthenia or myopathic disease. Language function is not affected. The quality of the speech tends to differ depending on the cause, but it can be very

26.24 Causes of dysarthria

Type	Site	Characteristics	Associated features
Myopathic	Muscles of speech	Indistinct, poor articulation	Weakness of face, tongue and neck
Myasthenic	Motor end plate	Indistinct with fatigue and dysphonia Fluctuating severity	Ptosis, diplopia, facial and neck weakness
Bulbar	Brainstem	Indistinct, slurred, often nasal	Dysphagia, diplopia, ataxia
'Scanning'	Cerebellum	Slurred, impaired timing and cadence, 'sing-song'	Ataxia of limbs and gait, tremor of head/limbs Nystagmus
Spastic ('pseudo-bulbar')	Pyramidal tracts	Indistinct, breathy, mumbling	Poor rapid tongue movements, increased reflexes and jaw jerk
Parkinsonian	Basal ganglia	Indistinct, rapid, stammering, quiet	Tremor, rigidity, slow shuffling gait
Dystonic	Basal ganglia	Strained, slow, high-pitched	Dystonia, athetosis

difficult to distinguish the different types clinically (Box 26.24). Dysarthria is discussed further in the section on bulbar symptoms (p. 1173).

Dysphasia

Dysphasia (or aphasia) is a disorder of the language content of speech. It can occur with lesions over a wide area of the dominant hemisphere (Fig. 26.20). Dysphasia may be categorised according to whether the speech output is fluent or non-fluent. Fluent aphasias, also called receptive aphasias, are impairments related mostly to the input or reception of language, with difficulties either in auditory verbal comprehension or in the repetition of words, phrases or sentences spoken by others. Speech is easy and fluent, but there are difficulties related to the output of language as well, such as paraphasia (either substitution of similar-sounding non-words, or incorrect words) and neologisms (non-existent words). Examples include Wernicke's aphasia (which localises to the superior posterior temporal lobe), transcortical sensory aphasia, conduction aphasia and anomic aphasia.

Non-fluent aphasias, also called expressive aphasias, are difficulties in articulating, but in most cases there is relatively good auditory verbal comprehension. Examples include Broca's aphasia (associated with pathologies in the inferior frontal region), transcortical motor aphasia and global aphasia.

'Pure' aphasias are selective impairments in reading, writing or the recognition of words. These disorders may be quite selective. For example, a person is able to read but not write, or is able to write but not read. Examples include pure alexia, agraphia and pure word deafness.

Dysphasia (a focal symptom) is frequently misinterpreted as confusion (which is non-focal). Dysphasia can be misheard/misspelt as dysphagia, and for this reason some prefer to use 'aphasia' to avoid confusion.

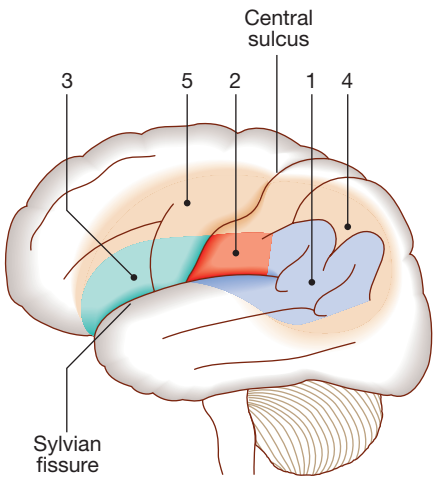

Fig. 26.20 Classification of cortical speech problems.
(1) Wernicke's aphasia: fluent dysphasia with poor comprehension and poor repetition. (2) Conduction aphasia: fluent aphasia with good comprehension and poor repetition. (3) Broca's aphasia: non-fluent aphasia with good comprehension and poor repetition. (4) Transcortical sensory aphasia: fluent aphasia with poor comprehension and good repetition. (5) Transcortical motor aphasia: non-fluent aphasia with good comprehension and good repetition. Large lesions affecting all of regions 1–5 cause global aphasia.

Disturbance of smell

Symptomatic olfactory loss almost always is due to local causes (nasal obstruction), follows head injury or is idiopathic. Hyposmia may occur early in Parkinson's disease. Frontal lobe lesions are a rare cause. Positive olfactory symptoms may arise from Alzheimer's disease or epilepsy.

Visual disturbance and ocular abnormalities

Disturbances of vision may be due to primary ocular disease or to disorders of the central connections and visual cortex. Visual symptoms are usually negative (loss of vision) but sometimes are positive, most commonly in migraine. Eye movements may be disturbed, giving rise to double vision (diplopia) or blurred vision.

Visual loss

Visual loss can occur as the result of lesions in any areas between the retina and the visual cortex. Patterns of

26.25 Clinical manifestations of visual field loss

Site of lesion	Common causes	Complaint	Visual field loss	Associated physical signs
Retina/optic disc	Vascular disease (including vasculitis) Glaucoma Inflammation	Partial/complete visual loss depending on site, involving one or both eyes	Altitudinal field defect Arcuate scotoma	Reduced acuity Visual distortion (macula) Abnormal retinal appearance
Optic nerve	Optic neuritis Sarcoidosis Tumour Leber's hereditary optic neuropathy	Partial/complete loss of vision in one eye Often painful Central vision particularly affected	Central or paracentral scotoma Monocular blindness	Reduced acuity Reduced colour vision Relative afferent pupillary defect Optic atrophy (late)
Optic chiasm	Pituitary tumour Craniopharyngioma Sarcoidosis	May be none Rarely diplopia ('hemifield slide')	Bitemporal hemianopia	Pituitary function abnormalities
Optic tract	Tumour Inflammatory disease	Disturbed vision to one side of midline	Incongruous contralateral homonymous hemianopia	
Temporal lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline	Contralateral homonymous upper quadrantanopia	Memory/language disorders
Parietal lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline Bumping into things	Contralateral homonymous lower quadrantanopia	Contralateral sensory disturbance Asymmetry of optokinetic nystagmus
Occipital lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline Difficulty reading Bumping into things	Homonymous hemianopia (may be macula-sparing)	Damage to other structures supplied by posterior cerebral circulation

visual field loss are explained by the anatomy of the visual pathways (see Fig. 26.7, p. 1145). Associated clinical manifestations are described in Box 26.25. Visual symptoms affecting one eye only are liable to be due to lesions anterior to the optic chiasm.

Transient visual loss is quite common and sudden-onset visual loss lasting less than 15 minutes is likely to have a vascular origin. It may be difficult to know whether the visual loss was monocular (carotid circulation) or binocular (vertebrobasilar circulation), and it can help to ask if the patient tried closing each eye in turn to see whether the symptom affected one eye or both. Visual field testing is an important part of the examination, either at the bedside or formally with perimetry. Field defects become more symmetrical (congruous), the closer the lesion comes to the visual cortex.

Migrainous visual symptoms are very common and, when associated with typical headache and other migraine features, rarely pose a diagnostic challenge. However, they may occur in isolation, making distinction from TIA difficult, but TIAs typically cause negative (transient blindness) symptoms, whereas migraine causes positive phenomena (see below). TIAs often last for a shorter time (a few minutes), compared to the 10–60-minute duration of migraine aura, and will have an abrupt onset and end, unlike the gradual evolution of a migraine aura.

Positive visual phenomena

The most common cause is migraine; patients may describe silvery zigzag lines (fortification spectra) or flashing coloured lights (teichopsia), usually preceding the headache. Simple flashes of light (phosphenes) may indicate damage to the retina (e.g. detachment) or to the primary visual cortex. Formed visual hallucinations may be caused by drugs, or may be due to epilepsy or 'release phenomena' in a blind visual field (Charles Bonnet's syndrome).

Double vision

Subtle double vision (diplopia) may be reported as blurred rather than double vision and most commonly arises from misalignment of the eyes. Monocular diplopia is rare and indicates ocular disease, while binocular diplopia suggests a probable neurological cause. Closing either eye in turn will abort binocular diplopia. Once the presence of binocular diplopia is confirmed, it should be established whether the diplopia is maximal in any particular direction of gaze, whether the images are separated horizontally or vertically, and whether there are any associated symptoms or signs, such as ptosis or pupillary disturbance.

Binocular diplopia occurs when eye movement is impaired, so that the image is not projected to the same points on the two retinae. It may result from central disorders or from disturbance of the ocular motor nerves, muscles or the neuromuscular junction (see Fig. 26.8, p. 1146). The pattern of double vision, along with any associated features, usually allows inference of which nerves/muscles are affected, whilst the mode of onset and other features (e.g. fatigability in myasthenia) provide further clues about the cause.

The causes of ocular motor nerve palsies are listed in Box 26.26.

26.26 Common causes of damage to cranial nerves 3, 4 and 6

Site	Common pathology	Nerve(s) involved	Associated features
Brainstem	Infarction Haemorrhage Demyelination Intrinsic tumour	3 (mid-brain) 6 (ponto-medullary junction)	Contralateral pyramidal signs Ipsilateral lower motor neuron facial palsy Other brainstem/cerebellar signs
Intrameningeal	Meningitis (infective/malignant)	3, 4 and/or 6	Meningism, features of primary disease course
	Raised intracranial pressure	6 3 (uncal herniation)	Papilloedema Features of space-occupying lesion
	Aneurysms	3 (posterior communicating artery) 6 (basilar artery)	Pain Features of subarachnoid haemorrhage
	Cerebello-pontine angle tumour	6	8, 7, 5 nerve lesions (order of likelihood) Ipsilateral cerebellar signs
	Trauma	3, 4 and/or 6	Other features of trauma
Cavernous sinus	Infection/thrombosis Carotid artery aneurysm Caroticocavernous fistula	3, 4 and/or 6	May be 5 nerve involvement also Pupil may be fixed, mid-position (sympathetic plexus on carotid may also be affected)
Superior orbital fissure	Tumour (e.g. sphenoid wing meningioma) Granuloma	3, 4 and/or 6	May be proptosis, chemosis
Orbit	Vascular (e.g. diabetes, vasculitis) Infections Tumour Granuloma Trauma	3, 4 and/or 6	Pain Pupil often spared in vascular 3rd nerve palsy

Nystagmus

Nystagmus describes a repetitive to-and-fro movement of the eyes. Usually slow drifts are the primary abnormal movement, each followed by fast (corrective) phases. Nystagmus occurs because the control systems of the eyes are defective, causing them to drift off target; corrections then become necessary to return fixation to the object of interest, causing nystagmus. The direction of the fast phase is usually designated as the direction of the nystagmus because it is easier to see. Nystagmus may be horizontal, vertical or torsional, and usually involves both eyes synchronously. It may be a physiological phenomenon in response to sustained vestibular stimulation or movement of the visual world (optokinetic nystagmus). There are many causes of pathological nystagmus, the most common sites of lesions being the vestibular system, brainstem and cerebellum.

In vestibular lesions, damage to one of the horizontal canals or its connections will allow the tonic output from the healthy, contralateral side to cause the eyes to drift towards the side of the lesion. This elicits recurrent compensatory fast movements away from the side of the lesion, manifest as unidirectional horizontal nystagmus. Vertical and torsional components can be seen with damage to other parts of the vestibular apparatus. The nystagmus of peripheral labyrinthine lesions is accompanied by vertigo and usually by nausea, vomiting and unsteadiness, but as the CNS habituates, the nystagmus disappears (fatigues) quite quickly. Central vestibular nystagmus is more persistent.

The brainstem and the cerebellum are involved in maintaining eccentric positions of gaze. Lesions will therefore allow the eyes to drift back in towards primary position, producing nystagmus with fast component beats in the direction of gaze (gaze-evoked nystagmus). This is the most common type of 'central' nystagmus; it is most commonly bidirectional and not usually accompanied by vertigo. Other signs of brainstem dysfunction may be evident. Brainstem disease may also cause vertical nystagmus.

Unilateral cerebellar lesions may result in gaze-evoked nystagmus when looking in the direction of the lesion, where the fast phases are directed towards the side of the lesion. Cerebellar hemisphere lesions also cause 'ocular dysmetria', an overshoot of target-directed, fast eye movements (saccades) resembling 'past-pointing' in limbs.

Nystagmus also occurs as a consequence of drug toxicity and nutritional deficiency (e.g. thiamin). The severity is variable, and it may or may not result in visual degradation, though it may be associated with a sensation of movement of the visual world (oscillopsia). Nystagmus may occur as a congenital phenomenon, in which case both phases are equal and 'pendular' rather than having alternating fast and slow components.

Ptosis

Various disorders may cause drooping of the eyelids (ptosis) and these are listed in Box 26.27.

26.27 Common causes of ptosis

Mechanism	Causes	Associated clinical features
3rd nerve palsy	Isolated palsy (see Box 26.26) Central/supranuclear lesion	Ptosis is usually complete Extraocular muscle palsy (eye 'down and out') Depending on site of lesion, other cranial nerve palsies (e.g. 4, 5 and 6) or contralateral upper motor neuron signs
Sympathetic lesion (Horner's syndrome: see Fig. 26.21**)**	Central (hypothalamus/brainstem) Peripheral (lung apex, carotid artery pathology) Idiopathic	Ptosis is partial Lack of sweating on affected side Depending on site of lesion, brainstem signs, signs of apical lung/brachial plexus disease, or ipsilateral carotid artery stroke
Myopathic	Myasthenia gravis Dystrophia myotonica	Extraocular muscle palsies More widespread muscle weakness, with fatigability in myasthenia Progressive external ophthalmoplegia Other characteristic features of individual causes
Other	Pseudo-ptosis (e.g. blepharospasm) Local orbital/lid disease Age-related levator dehiscence	Eyebrows depressed rather than raised May be local orbital abnormality

26.28 Pupillary disorders

Disorder	Cause	Ophthalmological features	Associated features
3rd nerve palsy	See Box 26.27	Dilated pupil Extraocular muscle palsy (eye is typically 'down and out') Complete ptosis	Other features of 3rd nerve palsy (see Box 26.27)
Horner's syndrome (see Fig. 26.21)	Lesion to sympathetic supply	Small pupil Partial ptosis Iris heterochromia (if congenital)	Ipsilateral failure of sweating (anhidrosis)
Holmes–Adie syndrome (tonic pupil)	Lesion of ciliary ganglion (usually idiopathic)	Dilated pupil Light-near dissociation (accommodate but do not react to light) Vermiform movement of iris during contraction Disturbance of accommodation	Generalised areflexia
Argyll Robertson pupil	Dorsal mid-brain lesion (syphilis or diabetes)	Small, irregular pupils Light-near dissociation	Other features of tabes dorsalis (p. 1209)
Local pupillary damage	Trauma/inflammatory disease	Irregular pupils, often with adhesions to lens (synechiae) Variable degree of reactivity	Other features of trauma/underlying inflammatory disease (e.g. cataract, blindness etc.)
Relative afferent pupillary defect (Marcus Gunn pupil)	Damage to optic nerve	Pupils symmetrical but degree of dilatation depends on which eye stimulated	Decreased visual acuity/colour vision Central scotoma Papilloedema/optic disc pallor

Abnormal pupillary responses

Abnormal pupillary responses may arise from lesions at several points between the retina and brainstem. Lesions of the oculomotor nerve, ciliary ganglion and sympathetic supply produce characteristic ipsilateral disorders of pupillary function. 'Afferent' defects result from damage to an optic nerve, impairing the direct response of a pupil to light, although leaving the consensual response from stimulation of the normal eye intact. Structural damage to the iris itself can also result in pupillary abnormalities. Causes are given in Box 26.28. An example is shown in Figure 26.21.

Fig. 26.21 Right-sided Horner's syndrome due to paravertebral metastasis at T1. There is ipsilateral partial ptosis and a small pupil.

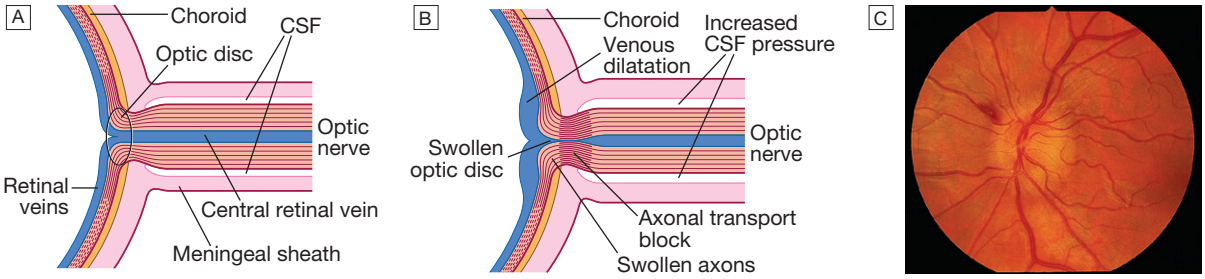

Fig. 26.22 Mechanism of optic disc oedema (papilloedema). A Normal. B Disc oedema (e.g. due to cerebral tumour). C Fundus photograph of the left eye showing optic disc oedema with a small haemorrhage on the nasal side of the disc.

26.29 Common causes of optic disc swelling

Raised intracranial pressure (papilloedema)

- Cerebral mass lesion (tumour, abscess)
- Obstructive hydrocephalus
- Idiopathic intracranial hypertension

Obstruction of ocular venous drainage

- Central retinal vein occlusion
- Cavernous sinus thrombosis

Systemic disorders affecting retinal vessels

- Hypertension
- Vasculitis
- Hypercapnia

Optic nerve damage

- Demyelination (optic neuritis/papillitis)
- Leber's hereditary optic neuropathy
- Anterior ischaemic optic neuropathy
- Toxins (e.g. methanol)
- Infiltration of optic disc
- Sarcoidosis
- Glioma
- Lymphoma

Papilloedema

There are several causes of swelling of the optic disc, but the term 'papilloedema' is reserved for swelling secondary to raised intracranial pressure, when obstructed axoplasmic flow from retinal ganglion cells results in swollen nerve fibres, which in turn cause capillary and venous congestion, producing papilloedema. The earliest sign is the cessation of venous pulsation seen at the disc, progression causing the disc margins to become red (hyperaemic). Disc margins become indistinct and haemorrhages may occur in the retina (Fig. 26.22). Lack of papilloedema never excludes raised intracranial pressure. Other causes of optic disc swelling are listed in Box 26.29. Some normal variations of disc appearance (e.g. optic nerve drusen) can mimic disc swelling.

Optic atrophy

Loss of nerve fibres causes the optic disc to appear pale, as the choroid becomes visible (Fig. 26.23). A pale disc (optic atrophy) follows optic nerve damage, and causes include previous optic neuritis or ischaemic damage, long-standing papilloedema, optic nerve compression, trauma and degenerative conditions (e.g. Friedreich's ataxia, p. 1199).

Fig. 26.23 Fundus photograph of the left eye of a patient with familial optic atrophy. Note marked pallor of optic disc.

Hearing disturbance

Each cochlear organ has bilateral cortical representation, so unilateral hearing loss is a result of peripheral organ damage. Bilateral hearing dysfunction is usual, and is most commonly due to age-related degeneration or noise damage, although infection and drugs (particularly diuretics and aminoglycoside antibiotics) can be a primary cause. Prominent deafness may suggest a mitochondrial disorder (see Box 26.109, p. 1229).

Bulbar symptoms – dysphagia and dysarthria

Swallowing is a complex activity involving the coordinated action of lips, tongue, soft palate, pharynx and larynx, which are innervated by cranial nerves 7, 9, 10, 11 and 12. Structural causes of dysphagia are considered on page 851. Neurological mechanisms are vulnerable to damage at different points, resulting in dysphagia that is usually accompanied by dysarthria. Tempo is again crucial: acute onset of dysphagia may occur as a result of brainstem stroke or a rapidly developing neuropathy,

26.30 Causes of pseudobulbar and bulbar palsy

	Pseudobulbar	Bulbar
Genetic	–	Kennedy's disease (X-linked bulbospinal neuronopathy)
Vascular	Bilateral hemisphere (lacunar) infarction	Medullary infarction (see Box 26.3, p. 1148)
Degenerative	Motor neuron disease (p. 1200)	Motor neuron disease Syringobulbia
Inflammatory/infective	Multiple sclerosis (p. 1188) Cerebral vasculitis	Myasthenia (p. 1226) Guillain–Barré syndrome (p. 1224) Poliomyelitis (p. 1207) Lyme disease (p. 334) Vasculitis
Neoplastic	High brainstem tumours	Brainstem glioma Malignant meningitis

such as Guillain–Barré syndrome or diphtheria. Intermittent fatigable muscle weakness (including dysphagia) would suggest myasthenia gravis. Dysphagia developing over weeks or months may be seen in motor neuron disease, polymyositis, basal meningitis and inflammatory brainstem disease. More slowly developing dysphagia suggests a myopathy or possibly a brainstem or skull-base tumour.

Pathologies affecting lower cranial nerves (9, 10, 11 and 12) frequently manifest bilaterally, producing dysphagia and dysarthria. The term 'bulbar palsy' is used to describe lower motor neuron lesions, either within the medulla or outside the brainstem. The tongue is wasted and fasciculating, and palatal movement is reduced.

Upper motor neuron innervation of swallowing is bilateral, so persistent dysphagia is unusual with a unilateral upper motor lesion (the exception being in the acute stages of, for example, a hemispheric stroke). Widespread lesions above the medulla will cause upper motor neuron bulbar paralysis, known as 'pseudobulbar palsy'. Here the tongue is small and contracted, and moves slowly; the jaw jerk is brisk. Causes of bulbar and pseudobulbar palsies are shown in Box 26.30.

Bladder, bowel and sexual disturbance

Whilst isolated disturbances of bladder, bowel and sexual function are rarely the sole presenting features of neurological disease, they are common complications of many chronic disorders such as multiple sclerosis, stroke and dementia, and are frequently found post head injury. Abnormalities in these functions considerably reduce quality of life for patients. Incontinence and its management are discussed elsewhere (pp. 472, 918 and 175).

Bladder dysfunction

The anatomy and physiology involved in controlling bladder functions are discussed on page 466 but it is worth emphasising the role of the pontine micturition centre, which is itself under higher control via inputs from the pre-frontal cortex, mid-brain and hypothalamus.

In the absence of conscious control (e.g. in coma or dementia), distension of the bladder to near-capacity evokes reflex detrusor contraction (analogous to the muscle stretch reflex), and reciprocal changes in sympathetic activation and relaxation of the distal sphincter result in coordinated bladder emptying.

Damage to the lower motor neuron pathways (the pelvic and pudendal nerves) produces a flaccid bladder and sphincter with overflow incontinence, often accompanied by loss of pudendal sensation. Such damage may be due to disease of the conus medullaris or sacral nerve roots, either within the dura (as in inflammatory or carcinomatous meningitis) or as they pass through the sacrum (trauma or malignancy), or due to damage to the nerves themselves in the pelvis (infection, haematoma, trauma or malignancy).

Damage to the pons or spinal cord results in an 'upper motor neuron' pattern of bladder dysfunction due to uncontrolled over-activity of the parasympathetic supply. The bladder is small and highly sensitive to being stretched. This results in frequency, urgency and urge incontinence. Loss of the coordinating control of the pontine micturition centre will also result in the phenomenon of detrusor–sphincter dyssynergia, in which detrusor contraction and sphincter relaxation are not coordinated; the spastic bladder will often try to empty against a closed sphincter. This manifests as both urgency and an inability to pass urine, which is distressing and painful. The resultant incomplete bladder emptying predisposes to urinary infection, and the prolonged high bladder pressure may result in renal failure; post-micturition bladder ultrasound may confirm incomplete bladder emptying. More severe lesions of the spinal cord, as in spinal cord compression or trauma, can result in painless urinary retention, as bladder sensation, normally carried in the lateral spinothalamic tracts, will be cut off.

Damage to the frontal lobes gives rise to loss of awareness of bladder fullness and consequent incontinence. Coexisting cognitive impairment may result in inappropriate micturition. These features are seen typically in hydrocephalus, frontal tumours, dementia and bifrontal subdural haematomas.

When a patient presents with bladder symptoms, it is important to try to localise the lesion on the basis of history and examination, remembering that most bladder problems are not neurological unless there are overt neurological signs. Clinical features and management are summarised in Box 26.31.

26.31 Neurogenic bladder: clinical features and treatment

	Site of lesion	Result	Treatment
Atonic (lower motor neuron)	Lesions of sacral segments of cord (conus medullaris) Lesions of sacral roots and nerves	Loss of detrusor contraction Difficulty initiating micturition Bladder distension with overflow	Intermittent self-catheterisation In-dwelling catheterisation
Hypertonic (upper motor neuron)	Pyramidal tract lesion in spinal cord or brainstem	Urgency with urge incontinence Bladder sphincter incoordination (dyssynergia) Incomplete bladder emptying	Anticholinergics: Solifenacin Tolterodine Imipramine Intermittent self-catheterisation
Cortical	Post-central Pre-central Frontal	Loss of awareness of bladder fullness Difficulty initiating micturition Inappropriate micturition Loss of social control	Intermittent or in-dwelling catheterisation

Rectal dysfunction

The rectum has an excitatory cholinergic input from the parasympathetic sacral outflow, and inhibitory sympathetic supply similar to the bladder. Continence depends largely on skeletal muscle contraction in the puborectalis and pelvic floor muscles supplied by the pudendal nerves, as well as the internal and external anal sphincters. Damage to the autonomic components usually causes constipation (a common early symptom in Parkinson's disease) but diabetic neuropathy can be associated with diarrhoea. Lesions affecting the conus medullaris, the somatic S2–4 roots and the pudendal nerves may cause faecal incontinence.

Erectile failure and ejaculatory failure

These related functions are under autonomic control via the pelvic nerves (parasympathetic, S2–4) and hypogastric nerves (sympathetic, L1–2). Descending influences from the cerebrum are important for erection, but it can occur as a reflex phenomenon in response to genital stimulation. Erection is largely parasympathetic, and may be impaired by a number of drugs, including anticholinergic, antihypertensive and antidepressant agents. Sympathetic activity is important for ejaculation, and may be inhibited by α-adrenoceptor antagonists (α-blockers). For further information on erectile failure, see page 474.

Personality change

While this is often due to psychiatric illness, neurological conditions that alter the function of the frontal lobes can cause personality change and mood disorder (see Box 26.2, p. 1142). Personality change due to a frontal lobe disorder may occur as the result of structural damage due to stroke, trauma, tumour or hydrocephalus. The nature of any change may help localise the lesion.

Patients with mesial frontal lesions become increasingly withdrawn, unresponsive and mute (abulic), often in association with urinary incontinence, gait apraxia and an increase in tone known as gegenhalten, in which the patient varies the resistance to movement in proportion to the force exerted by the examiner.

Patients with lesions of the dorsolateral pre-frontal cortex develop a dysexecutive syndrome, which involves difficulties with speech, motor planning and organisation. Those with orbitofrontal lesions of the frontal lobes, in contrast, become disinhibited, displaying grandiosity or irresponsible behaviour. Memory is substantially intact but frontal release signs may emerge, such as a grasp reflex, palmomental response or pout. Proximity to the olfactory bulb and tracts means that inferior frontal lobe tumours may be associated with anosmia.

Disturbance to the cortical areas responsible for speech or memory can result in changes that may be interpreted as changes in personality.

Sleep disturbance

Disturbances of sleep are common and are not usually due to neurological disease. Patients may complain of insomnia (difficulty sleeping), excessive daytime sleepiness, disturbed behaviour during night-time sleep, parasomnia (sleep walking and talking, or night terrors) or disturbing subjective experiences during sleep and/or its onset (nightmares, hypnagogic hallucinations, sleep paralysis). A careful history (from the bed-partner as well as the patient) usually allows specific causes of sleep disturbance to be identified and these are discussed in more detail on page 1187.

Psychiatric disorders

Psychiatric disorders are described in Chapter 10 but may cause or result from neurological problems. Care is needed in their identification, as effective management will help the underlying neurological illness.

FUNCTIONAL SYMPTOMS

Many patients presenting with neurological symptoms do not have a defined neurological disease and are best described as having functional symptoms (p. 236). Some

26.32 Clinical features suggestive of functional disorder

- Situational provocation
- Associated psychological disorders
  - Anxiety
  - Depression
- Lack of anatomical coherence to neurological symptoms
- Florid or bizarre descriptions of individual symptoms
- History of other medically unexplained symptoms
- Hoover's sign (p. 1163)
- Predisposing history of childhood neglect or abuse

of these are psychogenic (or conversion) disorders. Such patients often have unexplained symptoms affecting multiple systems and a long list of consultations and negative tests from other medical specialties when they present. Considering the possibility of a functional origin may save the patient further unnecessary, invasive and inconvenient investigation and anxiety.

Weakness and sensory symptoms predominate among functional symptoms, but pain or loss of consciousness can occur. Associated symptoms, such as tiredness, lethargy, poor concentration, bowel upset (irritable bowel syndrome) and gynaecological complaints, are common. A functional origin of neurological problems should always be considered, as it can allow for more rapid diagnosis and avoid unnecessarily painful or hazardous investigation. Some clinical features may hint at a functional origin for symptoms (Box 26.32). It is the clinician's job to elicit the context of the patient's symptoms in a sensitive and non-judgemental way. Whatever the illness, it is important to acknowledge that mood and sleep disturbance will exacerbate neurological symptoms, thus increasing disability resulting from neurological disorders. The best practitioners have the skill to carry the patient with them when describing the patterns of behaviour contributing to symptoms.

Assessment to detect an underlying or exacerbating mood disorder is vital in all patients, ensuring that depression and anxiety are managed to minimise their secondary effects on neurological symptoms.

HEADACHE SYNDROMES

Headaches may be classified as primary or secondary, depending on the underlying cause (see Box 26.10, p. 1156). Secondary headache may be due to structural, infective, inflammatory or vascular conditions, which are discussed later in this chapter. The primary headache syndromes are described here.

Tension-type headache

This is the most common type of headache and is experienced to some degree by the majority of the population.

Pathophysiology

Tension headache is incompletely understood. Emotions and anxiety are common precipitants and there is sometimes an associated depressive illness. Anxiety about the headache itself may lead to continuation of symptoms, and patients often become convinced of a serious underlying condition. Muscular spasms may worsen this in some patients.

Clinical features

The pain of tension headache is usually characterised as 'dull', 'tight' or like a 'pressure', and there may be a sensation of a band round the head or pressure at the vertex. It is of constant character and generalised, but often radiates forwards from the occipital region. In contrast to migraine, the pain can remain unabated for weeks or months without interruption, although the severity may vary, and there is no associated vomiting or photophobia. Activities are usually continued throughout, and the pain may be less noticeable when the patient is occupied. The pain is usually less severe in the early part of the day, becoming more troublesome as the day goes on. Tenderness may be present over the skull vault or in the occiput but is easily distinguished from the triggered pains of trigeminal neuralgia and the exquisite tenderness of temporal arteritis. Analgesics may be taken with chronic regularity despite little effect, and may serve to perpetuate the symptoms (see 'Medication overuse headache' below).

Management

Most benefit is given by providing a careful assessment, followed by discussion of likely precipitants and reassurance that the prognosis is good. Excessive use of analgesia, particularly those containing codeine, may maintain and exacerbate the headache (analgesic headache). Physiotherapy (with muscle relaxation and stress management) may help and low-dose amitriptyline can provide benefit. There is evidence that patients benefit from a perception that their problem has been taken seriously and rigorously assessed. Investigation may contribute to such reassurance, especially if concerns about an underlying lesion are strong, but patients should understand the purpose and likely outcome of such imaging.

Migraine

Migraine usually appears before middle age; it affects about 20% of females and 6% of males at some point in life. Some patients assume that migraine is a term encompassing any severe headache but it has a characteristic presentation, discussed below.

Pathophysiology

The cause of migraine is unknown but there is increasing evidence that the aura (see below) is due to dysfunction of ion channels causing a spreading front of cortical depolarisation (excitation) followed by hyperpolarisation (depression of activity). This process (the 'spreading depression of Leão') spreads over the cortex at a rate of about 3 mm/minute, corresponding to the aura's symptomatic spread. The headache phase is associated with vasodilatation of extracranial vessels and may be relayed by hypothalamic activity. Activation of the trigeminovascular system is probably important. A genetic contribution is implied by frequently positive family history, and similar phenomena occurring in disorders such as CADASIL (p. 1242). The female preponderance and the frequency of migraine attacks at certain points in the menstrual cycle also

suggest hormonal influences. Oestrogen-containing oral contraception sometimes exacerbates migraine, and increases the small risk of stroke in patients who suffer from migraine with aura. Doctors and patients often over-estimate the role of dietary precipitants such as cheese, chocolate or red wine. When psychological factors contribute, the migraine attack often occurs after a period of stress, being more likely on Friday evening at the end of the working week or at the beginning of a holiday.

Clinical features

Some patients report a prodrome of malaise, irritability or behavioural change for some hours or days. Around 20% of patients experience an aura, and are said to have migraine with aura (previously known as classical migraine). The aura is most often visual, consisting of fortification spectra, which are shimmering, silvery zigzag lines that march across the visual fields for up to 40 minutes, sometimes leaving a trail of temporary visual field loss (scotoma). In some there is a sensory aura of tingling followed by numbness, spreading over 20–30 minutes, from one part of the body to another. Dominant hemisphere involvement may also cause transient speech disturbance. The 80% of patients with characteristic headache but no 'aura' are said to have migraine without aura (previously called 'common' migraine).

Migraine headache is usually severe and throbbing, with photophobia, phonophobia and vomiting lasting from 4 to 72 hours. Movement makes the pain worse, and patients prefer to lie in a quiet, dark room.

Caution should be taken in ascribing the cause of an individual's limb weakness or isolated aura without headache to migraine. In such cases, other structural disorders of the brain, or even focal epilepsy, need to be considered.

In a smaller number of patients, the symptoms of the aura do not resolve, leaving more permanent neurological disturbance. This persistent migrainous aura may occur with or without evidence of brain infarction.

Management

Avoidance of identified triggers or exacerbating factors (such as the combined contraceptive pill) may prevent attacks. Treatment of an acute attack consists of simple analgesia with aspirin, paracetamol or non-steroidal anti-inflammatory agents. Nausea may require an antiemetic such as metoclopramide or domperidone. Severe attacks can be aborted by one of the increasing number of 'triptans' (e.g. sumatriptan), which are potent 5-hydroxytryptamine (5-HT) agonists. These can be administered orally, by subcutaneous injection or by nasal spray. Care should be taken to avoid accelerating use. Caution is needed with ergotamine preparations since they may lead to dependence. Overuse of any analgesia, including triptans, may contribute to associated medication overuse headache.

If attacks are frequent (more than 3–4 per month), prophylaxis should be considered. Many drugs can be used, but the most frequently used are vasoactive drugs (calcium channel blockers and β-adrenoceptor antagonists (β-blockers)), antidepressants (amitriptyline, dosulepin) and anti-epileptic drugs (valproate, topiramate). Women with aura should avoid oestrogen treatment for either oral contraception or hormone replacement, although the increased risk of ischaemic stroke is minimal.

Medication overuse headache

With increasing availability of over-the-counter medication, headache syndromes perpetuated by analgesia intake are becoming much more common. Medication overuse headache (MOH) can complicate any other headache syndrome, but is especially associated with migraine and tension headache. The medications that are the most common culprits are compound analgesia (particularly codeine and other opiate-containing preparations) and triptans, and MOH is usually associated with use on more than 10–15 days per month.

Management is by withdrawal of the responsible analgesics; patients should be warned that the initial effect will be to exacerbate the headache. Migraine prophylactics may be helpful in reducing the rebound headaches. In severe cases, hospital admission with or without a course of corticosteroids may be helpful.

Cluster headache

Cluster headaches (also known as migrainous neuralgia) are much less common than migraine. There is a 5:1 male predominance and onset is usually in the third decade.

Pathophysiology

The cause is unknown, but this type of headache differs from migraine in its character, lack of genetic predisposition, lack of provoking dietary factors, opposing gender imbalance and different drug effect. Functional imaging studies have suggested abnormal hypothalamic activity. Patients are more often smokers with a higher than average alcohol consumption.

Clinical features

Cluster headache is strikingly periodic, featuring runs of identical headaches beginning at the same hour for weeks at a time (the eponymous 'cluster'). Patients may experience either one or several attacks within a 24-hour period. Cluster headache causes severe, unilateral periorbital pain with autonomic features, such as unilateral lacrimation, nasal congestion and conjunctival injection (occasionally with the other features of Horner's syndrome). The pain, though severe, is characteristically brief (30–90 minutes). In contrast to the behaviour of those with migraine, patients are often highly agitated during the headache phase. The cluster period is typically a few weeks, followed by remission for months to years, but a small proportion do not experience remission.

Management

Acute attacks can usually be halted by subcutaneous injections of sumatriptan or by inhalation of 100% oxygen. The brevity of the attack probably prevents other migraine therapies from being effective. Migraine prophylaxis is often ineffective too but attacks can be prevented in some patients by sodium valproate, verapamil, methysergide or short courses of oral corticosteroids. Patients with severe debilitating clusters can be helped with lithium therapy, although this requires monitoring (p. 245).

26.33 Benign paroxysmal headaches

	Character of pain	Duration	Location	Comment
Ice pick	Stabbing	Very brief (split-second)	Variable, usually temporoparietal	Benign, more common in migraine
Ice cream	Sharp, severe	30–120 secs	Bitemporal/occipital	Obvious trigger by cold stimuli
Exertional/ coital	Bursting, thunderclap	Severe for mins then less severe for hrs	Generalised	Subarachnoid haemorrhage needs to be excluded
Cough	Bursting	Secs to mins	Occipital or generalised	Intracranial pathology needs to be excluded (especially craniocervical junction)
Cluster headache (migrainous neuralgia)	Severe unilateral, with ptosis, tearing, conjunctival injection, unilateral nasal congestion	30–90 mins 1–3 times per day	Periorbital	Usually in men, occurring in clusters over weeks/ months
Chronic paroxysmal hemicrania	Severe unilateral with cluster headache-like autonomic features (see above)	5–20 mins, frequently through day	Periorbital/temporal	Usually in women, responds to indometacin
SUNCT*	Severe, sharp, triggered by touch or neck movements	15–120 secs, repetitive through day	Periorbital	May respond to carbamazepine

*__S__hort-lasting, __U__nilateral, __N__euralgiform headache with __C__onjunctival injection, __T__earing, rhinorrhoea and forehead sweating.

Trigeminal neuralgia

This is characterised by unilateral lancinating facial pain, most commonly involving the second and/or third divisions of the trigeminal nerve territory, usually in patients over the age of 50 years.

Pathophysiology

Trigeminal neuralgia is thought to be caused by an irritative lesion involving the trigeminal root zone, in some cases an aberrant loop of artery. Other compressive lesions, usually benign, are occasionally found. Trigeminal neuralgia associated with multiple sclerosis may result from a plaque of demyelination in the brainstem.

Clinical features

The pain is repetitive, severe and very brief. It may be triggered by touch, a cold wind or eating. Physical signs are usually absent, although the spasms may make the patient wince and sit silently (tic douloureux). Similar symptoms may occur in multiple sclerosis or with other brainstem lesions, in which case there may be associated sensory changes in the trigeminal nerve territory or elsewhere. There is a tendency for the condition to remit and relapse over many years.

Management

The pain usually responds at least partially to carbamazepine. It is wise to start with a low dose and increase gradually, according to effect. In patients who cannot tolerate carbamazepine, gabapentin, pregabalin, amitriptyline or steroids may be effective. The possibility of surgical treatment should be entertained, especially where response is incomplete in younger patients. Decompression of the vascular loop encroaching on the trigeminal root is said to have a 90% success rate. Otherwise, localised injection of alcohol or phenol into a peripheral branch of the nerve may be effective.

Headaches associated with specific activities

These usually affect men in their thirties and forties. Patients develop a sudden, severe headache with exertion, including sexual activity. There is usually no vomiting and no neck stiffness, and the headache lasts less than 10–15 minutes, though a less severe dullness may persist for some hours. Subarachnoid haemorrhage needs to be excluded by CT and/or CSF examination (see Fig. 27.12, p. 1246) after a first event. The pathogenesis of these headaches is unknown. Although frightening, attacks are usually brief and patients may only need reassurance and simple analgesia for the residual headache. The syndrome may recur, and prevention may be necessary with propranolol or indometacin.

Other headache syndromes

A number of rare headache syndromes produce pains about the eye similar to cluster headaches (Box 26.33). These include chronic paroxysmal hemicrania and SUNCT (short-lasting unilateral neuralgiform headaches with conjunctival injection and tearing). The recognition of these syndromes is useful since they often respond to specific treatments such as indometacin.

EPILEPSY

A seizure can be defined as the occurrence of signs and/or symptoms due to abnormal, excessive or synchronous

26.34 Classification of seizures (2010 ILAE Classification)

Generalised seizures

- Tonic–clonic (in any combination)
- Absence
  - Typical
  - Atypical
  - Absence with special features
- Myoclonic absence
- Eyelid myoclonia
- Myoclonic
  - Myoclonic
  - Myoclonic atonic
  - Myoclonic tonic
- Clonic
- Tonic
- Atonic

Focal seizures

- Without impairment of consciousness or awareness (was 'simple partial')
  - Focal motor
  - Focal sensory
- With impairment of consciousness or awareness (was 'complex partial')
- Evolving to a bilateral, convulsive seizure (was 'secondarily generalised seizure')
  - Tonic
  - Clonic
  - Tonic–clonic

Unknown

- Epileptic spasms

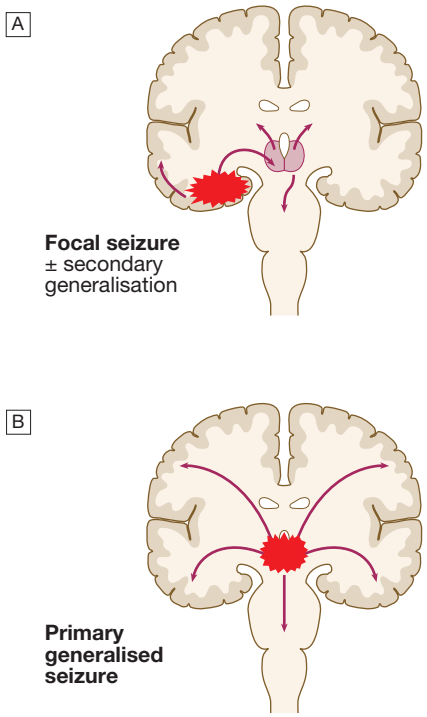

Fig. 26.24 The pathophysiological classification of seizures. A A focal seizure originates from a paroxysmal discharge in a focal area of the cerebral cortex (often the temporal lobe); the seizure may subsequently spread to the rest of the brain (secondary generalisation) via diencephalic activating pathways. B In primary generalised seizures the abnormal electrical discharges originate from the diencephalic activating system and spread simultaneously to all areas of the cortex.

neuronal activity in the brain. 'Epilepsy' is the tendency to have unprovoked seizures. The lifetime risk of seizure is about 5%, although incidence is highest at the extremes of age. Whilst the prevalence of active epilepsy in European countries is about 0.5%, the figure in developing countries may be higher because of parasitic illnesses such as cysticercosis (p. 380).

Historical terms such as 'grand mal' (implying tonic–clonic seizures) and 'petit mal' (intended by its originators to mean 'absence seizures' but commonly used to describe 'anything other than grand mal') have been superseded. Subsequent revisions, including terms such as 'complex partial' and 'simple partial', have been imprecise and confusing, carrying little information about underlying pathology, treatment or prognosis. The modern equivalents for these terms will be given below, but it is preferable to adhere to the 2010 iteration of the International League Against Epilepsy's classification (Box 26.34).

Pathophysiology

To function normally, the brain must achieve an ongoing balance between excitation and inhibition, in order to remain responsive to the environment without continued unrestrained spontaneous activity. The inhibitory transmitter gamma-aminobutyric acid (GABA) is particularly important, acting on ion channels to enhance chloride inflow and reduce the chances of action potential formation. Excitatory amino acids (glutamate and aspartate) allow influx of sodium and calcium, producing the opposite effect. It is likely that many seizures result from an imbalance between this excitation and inhibition. Intracellular recordings during seizures demonstrate a paroxysmal depolarisation shift in neuronal membrane potential, predisposing to recurrent action potentials. In vivo, epileptic cortex shows repetitive discharges involving large groups of neurons.

Seizures may be related to a localised disturbance in the cortex, becoming manifest in the first instance as focal seizures. Any disturbance of cortical architecture and function can precipitate this, whether focal infection, tumour, hamartoma or trauma-related scarring. If focal seizures remain localised, the symptoms experienced depend on which cortical area is affected. If areas in the temporal lobes become involved, then awareness of the environment becomes impaired but without associated tonic–clonic movements. When both hemispheres are involved, either at onset or after spread, the seizure becomes generalised (Fig. 26.24).

In seizures that are generalised at onset, the abnormal activity probably originates in the central mechanisms controlling cortical activation (see Fig. 26.24) and spreads rapidly. Such epilepsies constitute around 30% of all epilepsy, and are likely to reflect widespread disturbance of structure or function. Animal models have revealed mutations in genes for ion channels and receptors that cause seizures. In humans, many generalised epilepsies will have a genetic basis, and these almost always become apparent before the age of 35.

Seizure activity is usually apparent on EEG as spike and wave discharges (see Fig. 26.14, p. 1152). Other generalised seizure activity may involve merely brief loss of awareness (absence seizures), single jerks (myoclonus) or loss of tone (atonic seizures), as detailed in Box 26.34.

Clinical features

Seizure type and epilepsy type

To classify seizure type, the clinician should ask first whether there is a focal onset, and second whether the seizures conform to one of the recognised patterns (see Box 26.34). Epilepsy that starts in patients beyond their mid-thirties will almost invariably reflect a focal cerebral event. Where activity remains focal, this will be obvious. Even when generalised tonic–clonic seizures occur, seizures beginning in one cortical area will cause positive neurological symptoms and signs corresponding to the normal function of that area. Occipital onset will cause visual changes (lights and blobs of colour), temporal lobe onset will cause false recognition (déjà vu), sensory strip involvement will cause sensory alteration (burning, tingling), and motor strip involvement will cause jerking.

Patients can experience more than one type of seizure attack, and it is important to document each attack type and the patient's age at its onset, along with its frequency, duration and typical features. Any triggers should be identified (Box 26.35). The type of seizure, other clinical features and investigations can then be used to determine the epilepsy syndrome, as discussed below. Where there is doubt about the type, this is best stated and a full classification should be deferred until the evolution of the clinical features clarifies the picture.

Some patients will give a history of a previous local cortical insult, and it can be reasonably (but not invariably) inferred that this is the seat of epileptogenesis.

Focal seizures

The classification of focal seizures is shown in Box 26.34. They are caused by localised cortical activity with retained awareness. The localisation of such symptoms is described above. A spreading pattern of seizure may occur, the abnormal sensation spreading much faster (in seconds) than a migrainous focal sensory attack.

Awareness may become impaired if spread occurs to the temporal lobes (previously 'complex partial seizure'). Patients stop and stare blankly, often blinking repetitively, making smacking movements of their lips or displaying other automatisms, such as picking at their clothes. After a few minutes, consciousness returns but the patient may be muddled and feel drowsy for a period of up to an hour. The age of onset, preceding aura, longer duration and post-ictal symptoms usually make these easy to differentiate from childhood absence seizures (see below).

26.35 Trigger factors for seizures

- Sleep deprivation
- Missed doses of anti-epileptic drugs in treated patients
- Alcohol (particularly withdrawal)
- Recreational drug misuse
- Physical and mental exhaustion
- Flickering lights, including TV and computer screens (generalised epilepsy syndromes only)
- Intercurrent infections and metabolic disturbances
- Uncommon: loud noises, music, reading, hot baths

26.36 Causes of focal seizures

Idiopathic

- Benign Rolandic epilepsy of childhood
- Benign occipital epilepsy of childhood

Focal structural lesions

Genetic

- Tuberous sclerosis (p. 1302)
- Autosomal dominant frontal lobe epilepsy
- Autosomal dominant partial epilepsy with auditory features (ADPEAF)
- von Hippel–Lindau disease (p. 1216)
- Neurofibromatosis (p. 1215)
- Cerebral migration abnormalities

Infantile hemiplegia

Dysembryonic

- Cortical dysgenesis
- Sturge–Weber syndrome

Mesial temporal sclerosis (associated with febrile convulsions)

Cerebrovascular disease (Ch. 27)

- Intracerebral haemorrhage
- Cerebral infarction
- Arteriovenous malformation
- Cavernous haemangioma

Tumours (primary and secondary) (p. 1213)

Trauma (including neurosurgery)

Infective (p. 1201)

- Cerebral abscess (pyogenic)
- Toxoplasmosis
- Cysticercosis
- Tuberculoma
- Subdural empyema
- Encephalitis
- Human immunodeficiency virus (HIV)

Inflammatory

- Sarcoidosis
- Vasculitis

Seizures arising from the anterior parts of the frontal lobe may produce bizarre behaviour patterns, including limb posturing, sleep walking, or even frenetic ill-directed motor activity with incoherent screaming. Video EEG may be necessary to differentiate these from psychogenic attacks (which are more common), but abruptness of onset, stereotyped nature, relative brevity and nocturnal preponderance may indicate the frontal onset. Causes of focal seizures are given in Box 26.36.

Generalised seizures

Tonic–clonic seizures. An initial 'aura' may be experienced by the patient, depending on the cortical area from which the seizure originates (as above). The patient then becomes rigid (tonic) and unconscious, falling heavily if standing ('like a log') and risking facial injury. During this phase, breathing stops and central cyanosis may occur. As cortical discharges reduce in frequency, the limbs produce jerking (clonic) movements for a variable time. Afterwards, there is a flaccid state of deep coma, which can persist for some minutes. The patient may be confused, disorientated and/or amnesic after regaining consciousness. During the attack, urinary incontinence and tongue-biting may occur. A severely bitten, bleeding tongue after an attack of loss of consciousness is pathognomonic of a generalised seizure. Subsequently, the patient usually feels unwell and sleepy, with headache and myalgia.

26.37 Causes of generalised tonic–clonic seizures

Generalisation from focal seizures
- See Box 26.36

Genetic
- Inborn errors of metabolism (p. 64)
- Storage diseases (p. 450)
- Phakomatoses (e.g. tuberous sclerosis, p. 1302)

Cerebral birth injury

Hydrocephalus

Cerebral anoxia

Drugs
- Antibiotics: penicillin, isoniazid, metronidazole
- Antimalarials: chloroquine, mefloquine
- Ciclosporin
- Cardiac anti-arrhythmics: lidocaine, disopyramide
- Psychotropic agents: phenothiazines, tricyclic antidepressants, lithium
- Amphetamines (withdrawal)

Alcohol (especially withdrawal)

Toxins
- Organophosphates (sarin)
- Heavy metals (lead, tin)

Metabolic disease
- Hypocalcaemia
- Hyponatraemia
- Hypomagnesaemia
- Hypoglycaemia
- Renal failure
- Liver failure

Infective
- Post-infectious encephalopathy
- Meningitis (p. 1201)

Inflammatory
- Multiple sclerosis (uncommon) (p. 1188)
- SLE (p. 1109)

Diffuse degenerative diseases
- Alzheimer's disease (uncommonly) (p. 251)
- Creutzfeldt–Jakob disease (rarely) (p. 1211)

Witnesses are usually frightened by the event, often believe the person to be dying, and may struggle to give a clear account of the episode. Some may not describe the tonic or clonic phase, and may not mention cyanosis or tongue-biting. In less typical episodes, post-ictal confusion, or sequelae such as headache or myalgia, may be the main pointers to the diagnosis. Causes of generalised tonic–clonic seizures are listed in Box 26.37.

Absence seizures. Absence seizures (previously 'petit mal') always start in childhood. The attacks are rarely mistaken for focal seizures because of their brevity. They can occur so frequently (20–30 times a day) that they are mistaken for daydreaming or poor concentration in school.

Myoclonic seizures. These are typically brief, jerking movements, predominating in the arms. In epilepsy, they are more marked in the morning or on awakening from sleep, and tend to be provoked by fatigue, alcohol or sleep deprivation.

Atonic seizures. These are seizures involving brief loss of muscle tone, usually resulting in heavy falls with or without loss of consciousness. They only occur in the context of epilepsy syndromes that involve other forms of seizure.

Tonic seizures. These are associated with a generalised increase in tone and an associated loss of awareness. They are usually seen as part of an epilepsy syndrome and are unlikely to be isolated.

Clonic seizures. Clonic seizures are similar to tonic–clonic seizures. The clinical manifestations are similar but without a preceding tonic phase.

Seizures of uncertain generalised or focal nature

Epileptic spasms. While these are highlighted in the classification system, they are unusual in adult practice and occur mainly in infancy. They signify widespread cortical disturbance and take the form of marked contractions of the axial musculature, lasting a fraction of a second but recurring in clusters of 5–50, often on awakening.

Epilepsy syndromes

Many patients with epilepsy fall into specific patterns, depending on seizure type(s), age of onset and treatment responsiveness: the so-called electroclinical syndromes (Box 26.38). It is anticipated that genetic testing will ultimately demonstrate similarities in molecular pathophysiology.

Box 26.39 highlights the more common epilepsy syndromes, which are largely of early onset and are sensitive to sleep deprivation, hyperventilation, alcohol and

26.38 Electroclinical epilepsy syndromes

Adolescence to adulthood
- Juvenile absence epilepsy (JAE)
- Juvenile myoclonic epilepsy (JME)
- Epilepsy with generalised tonic–clonic seizures alone
- Progressive myoclonus epilepsies (PME)
- Autosomal dominant epilepsy with auditory features (ADEAF)
- Other familial temporal lobe epilepsies

Less specific age relationship
- Familial focal epilepsy with variable foci (childhood to adult)
- Reflex epilepsies

Distinctive constellations
- Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS)
- Rasmussen's syndrome
- Gelastic (from the Greek word for laughter) seizures with hypothalamic hamartoma
- Hemiconvulsion–hemiplegia–epilepsy

Epilepsies with structural–metabolic causes
- Malformations of cortical development (hemimegalencephaly, heterotopias etc.)
- Neurocutaneous syndromes (tuberous sclerosis complex, Sturge–Weber etc.)
- Tumour
- Infection
- Trauma
- Angioma
- Perinatal insults
- Stroke etc.

Epilepsies of unknown cause

Conditions with epileptic seizures traditionally not diagnosed
- Benign neonatal seizures (BNS)
- Febrile seizures (FS)

26.39 Common epilepsy syndromes

	Age of onset	Type of seizure	EEG features	Treatment	Prognosis
Childhood absence epilepsy	4–8 yrs	Frequent brief absences	3/sec spike and wave	Ethosuximide Sodium valproate Levetiracetam	40% develop GTCS, 80% remit in adulthood
Juvenile absence epilepsy	10–15 yrs	Less frequent absences than childhood absence	Poly-spike and wave	Sodium valproate Levetiracetam	80% develop GTCS, 80% seizure-free in adulthood
Juvenile myoclonic epilepsy	15–20 yrs	GTCS, absences, morning myoclonus	Poly-spike and wave, photosensitivity	Sodium valproate Levetiracetam	90% remit with AEDs but relapse if AED withdrawn
GTCS on awakening	10–25 yrs	GTCS, sometimes myoclonus	Spike and wave on waking and sleep onset	Sodium valproate Levetiracetam	65% controlled with AEDs but relapse off treatment

(AED = anti-epileptic drug; GTCS = generalised tonic–clonic seizures)

photic stimulation. Epilepsies that do not fit into any of these diagnostic categories can be delineated first on the basis of the presence or absence of a known structural or metabolic condition (presumed cause), and then on the basis of the primary mode of seizure onset (generalised versus focal).

Investigations

Single seizure

All patients with transient loss of consciousness should have a 12-lead ECG. Where seizure is suspected or definite, patients should have imaging with either CT or MRI, although the yield is low unless focal signs are present. EEG may help to assess prognosis once a firm diagnosis has been made. The recurrence rate after a first seizure is approximately 40%, and most recurrent attacks occur within a month or two of the first. Further seizures are less likely if an identified trigger can be avoided (see Box 26.35).

Other investigations for infective, toxic and metabolic causes (Box 26.40) may be appropriate. An EEG performed immediately after a seizure may be more helpful in showing focal features than if performed after a delay.

Epilepsy

The same investigations are required in a patient with suspected epilepsy (Box 26.40). Where more than one seizure has occurred, an EEG may help to establish the type of epilepsy and guide therapy. As imaging becomes more sensitive, focal changes are picked up more often. Investigations should be revisited if the epilepsy is intractable to treatment.

Inter-ictal EEG is abnormal in only about 50% of patients with recurrent seizures, so it cannot be used to exclude epilepsy. The sensitivity can be increased to about 85% by prolonging recording time and including a period of natural or drug-induced sleep, but this does not replace a well-taken history. Ambulatory EEG recording or video EEG monitoring may help with differentiation of epilepsy from other attack disorders if these are sufficiently frequent.

Indications for imaging are summarised in Box 26.41. Imaging cannot establish a diagnosis of epilepsy but identifies any structural cause. It is not required if a confident diagnosis of a recognised epilepsy syndrome (e.g. juvenile myoclonic epilepsy) can be made. While CT will exclude a major structural cause of epilepsy, MRI is required to demonstrate subtle changes such as hippocampal sclerosis, which may direct or inform surgical intervention.

26.40 Investigation of epilepsy

From where is the epilepsy arising?

- Standard EEG
- Sleep EEG
- EEG with special electrodes (foramen ovale, subdural)

What is the cause of the epilepsy?

Structural lesion?

- CT
- MRI

Metabolic disorder?

- Urea and electrolytes
- Liver function tests
- Blood glucose
- Serum calcium, magnesium

Inflammatory or infective disorder?

- Full blood count, erythrocyte sedimentation rate, C-reactive protein
- Chest X-ray
- Serology for syphilis, HIV, collagen disease
- CSF examination

Are the attacks truly epileptic?

- Ambulatory EEG
- Videotelemetry

26.41 Indications for brain imaging in epilepsy

- Epilepsy starting after the age of 16 yrs
- Seizures having focal features clinically
- EEG showing a focal seizure source
- Control of seizures difficult or deteriorating

Management

It is important to explain the nature and cause of seizures to patients and their relatives, and to instruct relatives in the first aid management of seizures (Box 26.42).

26.42 How to administer first aid for seizures

- Move person away from danger (fire, water, machinery, furniture)
- After convulsions cease, turn person into 'recovery' position (semi-prone)
- Ensure airway is clear but do **NOT** insert anything in mouth (tongue-biting occurs at seizure onset and cannot be prevented by observers)
- If convulsions continue for more than 5 mins or recur without person regaining consciousness, summon urgent medical attention
- Do not leave person alone until fully recovered (drowsiness and confusion can persist for up to 1 hr)

26.43 Epilepsy: outcome after 20 years

- 50% are seizure-free, without drugs, for the previous 5 yrs
- 20% are seizure-free for the previous 5 yrs but continue to take medication
- 30% continue to have seizures in spite of anti-epileptic therapy

Many people with epilepsy feel stigmatised and may become unnecessarily isolated from work and social life. It should be emphasised that epilepsy is a common disorder that affects 0.5–1% of the population, and that full control of seizures can be expected in approximately 70% of patients (Box 26.43).

Immediate care

Little can or needs to be done for a person during a major seizure except for first aid and common-sense manœuvres to limit damage or secondary complications (see Box 26.42). Advice should be given that on no account should anything be inserted into the patient's mouth. The management of status epilepticus is described on page 1159.

Lifestyle advice

Patients should be advised to avoid activities where they might place themselves or others at risk if they have a seizure. This applies at work, at home and at leisure. At home, only shallow baths (or showers) should be taken. Prolonged cycle journeys should be discouraged until reasonable freedom from seizures has been achieved. Activities requiring prolonged proximity to water (swimming, fishing or boating) should always be carried out in the company of someone who is aware of the risks and the potential need for rescue measures. Driving regulations vary between countries, and the patient should be made aware of these (Box 26.44). Certain occupations, such as firefighter or airline pilot, are not open to anyone who has a previous or active diagnosis of epilepsy; further information is available from epilepsy support organisations.

The recognised mortality of epilepsy should be discussed at around the time of diagnosis. This should be done with care and sensitivity, and with the aim of motivating the patient to adapt habits and lifestyle to optimise epilepsy control.

26.44 UK driving regulations

Private use

Single seizure

- Cease driving until at least 6 mths have passed without recurrence. Driver and Vehicle Licensing Authority (DVLA) may restore a full licence sooner if recurrence risk is low

Epilepsy (i.e. more than one seizure over the age of 5 yrs)

- Cease driving immediately
- Licence restored when patient is free from all types of seizure for 1 yr *or* seizures have occurred *exclusively* during sleep for a period of at least 3 yrs
- Licence will require renewal every 3 yrs thereafter until patient is seizure-free for 10 yrs

Withdrawal of anticonvulsants

- Cease driving during withdrawal period and for 6 mths thereafter

Vocational drivers (heavy goods and public service vehicles)

- No licence permitted if any seizure has occurred after the age of 5 yrs until patient is off medication and seizure-free for more than 10 yrs, and has no potentially epileptogenic brain lesion

26.45 Guidelines for anticonvulsant therapy

- Start with one first-line drug (see Box 26.46)
- Start at a low dose; gradually increase dose until effective control of seizures is achieved or side-effects develop (drug levels may be helpful)
- Optimise compliance (use minimum number of doses per day)
- If first drug fails (seizures continue or side-effects develop), start second first-line drug, followed if possible by gradual withdrawal of first
- If second drug fails (seizures continue or side-effects develop), start second-line drug in combination with preferred first-line drug at maximum tolerated dose (beware interactions)
- If this combination fails (seizures continue or side-effects develop), replace second-line drug with alternative second-line drug
- If this combination fails, check compliance and reconsider diagnosis (Are events seizures? Occult lesion? Treatment compliance/alcohol/drugs confounding response?)
- Consider alternative, non-drug treatments (e.g. epilepsy surgery, vagal nerve stimulation)
- Use minimum number of drugs in combination at any one time

Anticonvulsant therapy

Anticonvulsant drug treatment (anti-epileptic drugs, or AEDs) should be considered after more than one unprovoked seizure. The decision to start treatment should be shared with the patient, to enhance compliance. A wide range of drugs is available. These agents either increase inhibitory neurotransmission in the brain or alter neuronal sodium channels to prevent abnormally rapid transmission of impulses. In the majority of patients, full control is achieved with a single drug. Dose regimens should be kept as simple as possible. Guidelines are listed in Box 26.45. For seizures of focal onset, one large

26.46 Guidelines for choice of anti-epileptic drug

Epilepsy type	First-line	Second-line	Third-line
Focal onset and/or secondary GTCS	Lamotrigine	Carbamazepine Levetiracetam Sodium valproate Topiramate Zonisamide Lacosamide	Clobazam Gabapentin Oxcarbazepine Phenobarbital Phenytoin Pregabalin Primidone Tiagabine
GTCS	Sodium valproate Levetiracetam	Lamotrigine Topiramate Zonisamide	Carbamazepine Phenytoin Primidone Phenobarbital Acetazolamide
Absence	Ethosuximide	Sodium valproate	Lamotrigine Clonazepam
Myoclonic	Sodium valproate	Levetiracetam Clonazepam	Lamotrigine Phenobarbital

N.B. Use as few drugs as possible at the lowest possible dose.

study suggests that lamotrigine is the best-tolerated monotherapy, which, alongside its favourable side-effect profile and relative lack of pharmacokinetic interactions, makes it a good first-line drug, although caution must be exercised with oral contraceptive use. Unclassified or specific syndromes respond best to valproate. Problems in pregnancy mean that sodium valproate should not be used in women of reproductive age unless the benefits outweigh the risks. The first choice should be an established first-line drug (Box 26.46), with more recently introduced drugs as second choice.

Monitoring therapy

Some practitioners confuse epilepsy care with serum level monitoring. The newer drugs have much more predictable pharmacokinetics than the older ones, and the only indication for measuring serum levels is if there is doubt that the patient is taking the medication. Blood levels need to be interpreted carefully, and dose changes made to treat the patient rather than to bring a serum level into the 'therapeutic range'. Some centres advocate serum level monitoring during pregnancy (notably with lamotrigine) but the evidence of benefit for this is not strong.

Epilepsy surgery

Some patients with drug-resistant epilepsy benefit from surgical resection of epileptogenic brain tissue. Less invasive treatments, including vagal nerve stimulation or deep brain stimulation, may also be helpful in some patients. All those who continue to experience seizures despite appropriate drug treatment should be considered for surgical treatment. Planning such interventions will require intensive specialist assessment and investigation to identify the site of seizure onset and the dispensability of any targets for resection, i.e. whether the area of brain involved is necessary for a critical function such as vision or motor function.

Withdrawing anticonvulsant therapy

Withdrawal of medication may be considered after a patient has been seizure-free for more than 2 years. Childhood-onset epilepsy, particularly classical absence seizures, carries the best prognosis for successful drug withdrawal. Other epilepsy syndromes, such as juvenile myoclonic epilepsy, have a marked tendency to recur after drug withdrawal.

Seizures that begin in adult life, particularly those with partial features, are also likely to recur, especially if there is an identified structural lesion. Overall, the recurrence rate after drug withdrawal depends on the individual's epilepsy history. An individualised estimate may be gained from the SIGN guideline tables (see 'Further information', p. 1230).

Patients should be advised of the risks of recurrence, to allow them to decide whether or not they wish to withdraw. If undertaken, withdrawal should be done slowly, reducing the drug dose gradually over weeks or months. Withdrawal may necessitate precautions around driving or occupation (see Box 26.44).

Contraception

Some AEDs induce hepatic enzymes that metabolise synthetic hormones, increasing the risk of contraceptive failure. This is most marked with carbamazepine, phenytoin and barbiturates, but clinically significant effects can be seen with lamotrigine and topiramate. If the AED cannot be changed, this can be overcome by giving higher-dose preparations of the oral contraceptive. Sodium valproate and levetiracetam have no interaction with hormonal contraception.

Pregnancy and reproduction

Epilepsy presents specific management problems during pregnancy (Box 26.47). There is usually great concern about teratogenesis associated with AEDs. It is important to recognise that the background risk of severe fetal

26.47 Epilepsy in pregnancy

- **Provision of pre-conception counselling is best practice**: start folic acid 5 mg daily for 2 mths before conception to reduce the risk of fetal malformations.
- **Fetal malformation**: risk is minimised if a single drug is used.
  Carbamazepine and lamotrigine have the lowest incidence of major fetal malformations.
  The risk with sodium valproate is higher but should be carefully balanced against its benefits.
  Levetiracetam may be safe, but avoid other newer drugs if possible.
- **Learning difficulties in children**: IQ may be lower when children are exposed to valproate in utero, so its use should always be considered carefully.
- **Haemorrhagic disease of the newborn**: anticonvulsants increase risk. Give oral vitamin K 20 mg daily to the mother during the last month of pregnancy and give IM vitamin K 1 mg to the infant at birth.
- **Increased frequency of seizures**: where breakthrough seizures occur, monitor anticonvulsant levels and adjust the dose regimen accordingly.
- **Pharmacokinetic effects of pregnancy**: carbamazepine levels may fall in the third trimester. Lamotrigine and levetiracetam levels may fall early in pregnancy. Some advocate monitoring of levels.

26.48 Epilepsy in old age

- **Incidence and prevalence**: late-onset epilepsy is very common and the annual incidence in those over 60 yrs is rising.
- **Fits and faints**: the features that usually differentiate these may be less definitive than in younger patients.
- **Non-convulsive status epilepticus**: can present as confusion in the elderly.
- **Cerebrovascular disease**: the underlying cause of seizures in 30–50% of patients over the age of 50 yrs. A seizure may occur with an overt stroke or with occult vascular disease.
- **AED regimens**: keep as simple as possible and take care to avoid interactions with other drugs being prescribed.
- **Carbamazepine-induced hyponatraemia**: increases significantly with age; particularly important in patients on diuretics or those with heart failure.
- **Withdrawal of anticonvulsant therapy**: late-onset epilepsy often recurs when drug treatment is stopped, so drug withdrawal should not be attempted where it was commenced appropriately.

26.49 Epilepsy in adolescence

- **Effect on school/education**: seizures, AEDs and psychological complications of epilepsy may hamper education. Fear may make some educational institutions unduly restrictive.
- **Effect on family relationships**: parents may adopt a protective role, which can lead to epilepsy (and AEDs) becoming a point of assertion and rebellion.
- **Effect on career choice**: epilepsy may exclude or restrict employment in the emergency services and armed forces.
- **Alcohol**: may affect sleep pattern; excess may be associated with poor AED compliance.
- **Illicit drugs**: may affect seizure threshold and be associated with poor AED compliance.
- **Sleep disturbance**: may be worsened by social activities and computer games.
- **Oral contraception**: interactions with AED can occur. Use may not always be disclosed to parents.

malformation in the population is around 2–3%. The modern AED most associated with teratogenesis is sodium valproate, which, at high dose, increases the risk to around 6–7%. Long-term observational studies show that most of the commonly used AEDs can be given safely in pregnancy.

Pre-conception treatment with folic acid (5 mg daily), along with use of the smallest effective doses of as few AEDs as possible, may reduce the risk of fetal abnormalities. The risks of abrupt AED withdrawal to the mother should be stressed.

Seizures may become more frequent during pregnancy, particularly if pharmacokinetic changes decrease serum levels of AEDs (see Box 26.47).

Menstrual irregularities and reduced fertility are more common in women with epilepsy, and are also increased by sodium valproate. Patients with epilepsy are at greater risk of osteoporosis, almost independently of the drug used. Some centres advocate vitamin D supplementation in any patient with epilepsy, but the higher female risk of osteoporosis makes this most important in women.

Prognosis

The outcome of newly diagnosed epilepsy is generally good. Overall, generalised seizures are more readily controlled than focal seizures. The presence of a structural lesion reduces the chances of freedom from seizures. The overall prognosis for epilepsy is shown in Box 26.43.

Status epilepticus

Presentation and management are described on page 1159. While generalised status epilepticus is most easily recognised, non-convulsive status may be less dramatic and less easily diagnosed. It may cause only altered awareness, confusion or wandering with automatisms. In an intensive care unit setting, EEG monitoring is essential to ensure that diagnosis and treatment are optimised.

Non-epileptic attack disorder

The difficulty with nomenclature is discussed on page 1179. Patients may present with attacks that resemble epileptic seizures but which are caused by psychological phenomena and have no abnormal epileptic discharges. Such attacks may be very prolonged, sometimes mimicking status epilepticus. Epileptic and non-epileptic attacks may coexist, and time and effort are needed to clarify the relative contribution of each, allowing more accurate and comprehensive treatment.

Non-epileptic attack disorder (NEAD) may be accompanied by dramatic flailing of the limbs and arching of the back, with side-to-side head movements and vocalising. Cyanosis and severe biting of the tongue are rare, but urinary incontinence can occur. Distress and crying

are common following non-epileptic attacks. The distinction between epileptic attacks originating in the frontal lobes and non-epileptic attacks may be especially difficult, and may require videotelemetry with prolonged EEG recordings. Non-epileptic attacks are three times more common in women than in men and have been linked with a history of past or ongoing life trauma. They are not necessarily associated with formal psychiatric illness. Patients and carers may need reassurance that hospital admission is not required for every attack. Prevention requires psychotherapeutic interventions rather than drug therapy (p. 246).

VESTIBULAR DISORDERS

Vertigo is the typical symptom caused by vestibular dysfunction, and most patients with vertigo have acute vestibular failure, benign paroxysmal positional vertigo or Ménière's disease. Central (brain) causes of vertigo are rare by comparison, with the exception of migraine (p. 1176).

Acute vestibular failure

Although commonly called 'labyrinthitis' or 'vestibular neuronitis', acute vestibular failure is a more accurate term, as most cases are idiopathic. It usually presents as isolated severe vertigo with vomiting and unsteadiness. It begins abruptly, often on waking, and many patients are initially bed-bound. The vertigo settles within a few days, though head movement may continue to provoke transient symptoms (positional vertigo) for some time. During the acute attack, nystagmus (p. 1171) will be present for a few days.

Cinnarizine, prochlorperazine or betahistine provides symptomatic relief but should not be used long-term as this may delay recovery. A small proportion of patients fail to recover fully, and complain of ongoing imbalance and dysequilibrium rather than vertigo; vestibular rehabilitation by a physiotherapist may help.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is due to the presence of otolithic debris from the saccule or utricle affecting the free flow of endolymph in the semicircular canals (cupulolithiasis). It may follow minor head injury but typically is spontaneous. The history is diagnostic, with transient (seconds) vertigo precipitated by movement (typically, rolling over in bed or getting into or out of bed). Although benign, and usually self-limiting after a few weeks or months, patients are often very alarmed by the symptoms. The diagnosis can be confirmed by the 'Hallpike manœuvre' to demonstrate positional nystagmus (Fig. 26.25). Treatment comprises explanation and reassurance, along with positioning procedures designed to return otolithic debris from the semicircular canal to saccule or utricle (such as the Epley manœuvre) and/or to re-educate the brain to cope with the inappropriate signals from the labyrinth (such as Cawthorne–Cooksey exercises: see 'Further information').

Ménière's disease

This is due to an abnormality of the endolymph that causes episodes of vertigo accompanied by tinnitus and fullness in the ear, each attack typically lasting a few hours. Over the years, patients may develop progressive deafness (typically low-tone on audiometry). Examination is typically normal in between attacks. The diagnosis is clinical, supported by abnormal audiometry. Ménière's disease is idiopathic, but a similar syndrome may be caused by middle ear trauma or infection. Management includes a low-salt diet, vestibular sedatives for acute attacks, and occasionally surgery.

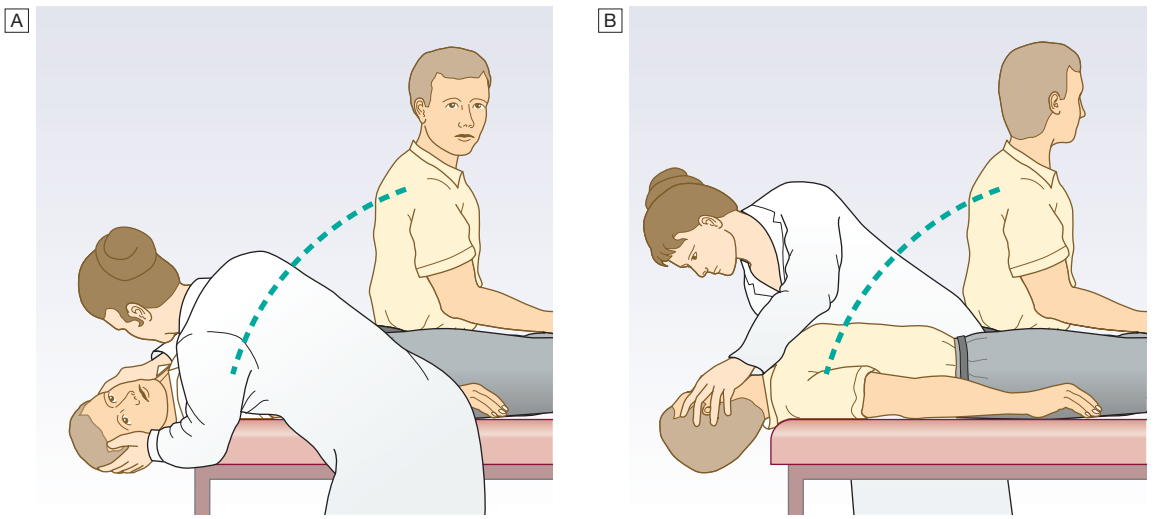

Fig. 26.25 The Hallpike manœuvre for diagnosis of benign paroxysmal positional vertigo (BPPV). Patients are asked to keep their eyes open and look at the examiner as their head is swung briskly backwards through 120° to overhang the edge of the couch. **A** Perform first with the right ear down. **B** Perform next with the left ear down. The examiner looks for nystagmus (usually accompanied by vertigo). In BPPV, the nystagmus typically occurs in A or B only and is torsional, the fast phase beating towards the lower ear. Its onset is usually delayed a few seconds, and it lasts 10–20 seconds. As the patient is returned to the upright position, transient nystagmus may occur in the opposite direction. Both nystagmus and vertigo typically decrease (fatigue) on repeat testing.

DISORDERS OF SLEEP

Sleep disturbances include too much sleep (hypersomnolence or excessive daytime sleepiness), insufficient or poor-quality sleep (insomnia), and abnormal behaviour during sleep (parasomnias). Insomnia is usually caused by psychological or psychiatric disorders, shift work and other environmental causes, pain and so on, and will not be discussed further. Many symptoms and disorders may affect sleep and sleep quality (e.g. pain, depression/anxiety, parkinsonism).

Excessive daytime sleepiness (hypersomnolence)

There are primary and secondary causes (Box 26.50). The most common causes are impaired sleep due to lifestyle issues or sleep-disordered breathing (p. 725). Sleepiness may be measured using the Epworth Sleepiness Score (see Box 19.98, p. 726). Most causes will be identified by a detailed history from the patient and their bed partner, and a 2-week sleep diary.

Narcolepsy

This has a prevalence of about 1 in 2000, with peak onset in adolescence and early middle age. The key symptom is sudden, irresistible 'sleep attacks', often in inappropriate circumstances such as whilst eating or talking. Other characteristic features help distinguish this from excessive daytime sleepiness (Box 26.51). Symptoms may be due to loss of hypocretin-secreting hypothalamic neurons. Diagnosis requires sleep study with sleep latency testing (demonstrating rapid onset of REM sleep). Treatment is with sodium oxybate, modafinil, dexamfetamine or methylphenidate. Cataplexy may respond to sodium oxybate, clomipramine or venlafaxine.

26.50 Causes of hypersomnolence

Primary causes

- Narcolepsy
- Idiopathic hypersomnolence
- Brain injury

Secondary causes (due to poor-quality sleep)

- Obstructive sleep apnoea
- Pain
- Restless legs/periodic limb movements of sleep
- Parkinsonism and other neurodegenerative diseases
- Depression/anxiety
- Medication
- Environmental factors (noise, temperature etc.)

26.51 Narcolepsy symptoms

Sleep attacks

- Brief, frequent and unlike normal somnolence

Cataplexy

- Sudden loss of muscle tone triggered by surprise, laughter, strong emotion etc.

Hypnagogic or hypnapompic hallucinations

- Frightening hallucinations experienced during sleep onset or waking due to intrusion of REM sleep during wakefulness (can occur in normal people)

Sleep paralysis

- Brief paralysis on waking (can occur in normal people)

Parasomnias

Parasomnias are abnormal motor behaviours that occur around sleep. They may arise in either REM or non-REM sleep, with characteristic features and timing. Non-REM parasomnias tend to occur early in sleep. Parasomnias should be distinguished from other motor disturbances (such as periodic limb movements, hypnic jerks or sleep talking) and sleep-onset epileptic seizures (p. 1182). History from a sleeping partner or other witness is essential.

Non-REM parasomnias

These are due to incomplete arousal from non-REM sleep, and manifest as night terrors, sleep walking and confusional arousals (sleep drunkenness). They typically occur within an hour or two of sleep onset, are common in children, and usually of no pathological significance. Rarely, they persist into adulthood and may become increasingly complex, including dressing, moving objects, eating, drinking or even acts of violence. Patients have little or no recollection of the episodes, even though they appear 'awake'. They may be triggered by alcohol or unfamiliar sleeping situations, and can be familial. Treatment is usually not required, but clonazepam can be used.

REM sleep behaviour disorder

In REM sleep behaviour disorder (RBD), patients 'act out' their dreams during REM sleep, due to failure of the usual muscle atonia. Sleep partners provide typical histories of patients 'fighting' or 'struggling' in their sleep, sometimes causing injury to themselves or to their partner. They are easily roused from this state, with recollection of their dream, unlike in non-REM states. RBD is more common in men, and may be an early symptom of neurodegenerative diseases such as alpha synucleinopathies (p. 1195), perhaps preceding more typical symptoms of these conditions by years. Polysomnography will confirm absence of atonia during REM sleep. Clonazepam is the most successful treatment.

Restless legs syndrome

Restless legs syndrome (RLS) is common, with a prevalence of up to 10%, but many patients never seek medical attention. It is characterised by unpleasant leg (and sometimes arm) sensations that are eased by movement (motor restlessness); the diagnosis is clinical (Box 26.52). It has a strong familial tendency and can present with daytime somnolence due to poor sleep. It is usually idiopathic, but may be associated with haematinic deficiency, pregnancy, peripheral neuropathy, Parkinson's disease or uraemia. It should be distinguished from

26.52 Diagnostic criteria for restless legs syndrome

A need to move the legs, usually accompanied or caused by uncomfortable, unpleasant sensations in the legs, with the following features:

- only present or worse during periods of rest or inactivity such as lying or sitting
- partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues
- generally worse or occurs only in the evening or night.

akathisia, the daytime motor restlessness that is an adverse effect of anti-psychotic drugs. Treatment, if required, is with dopaminergic drugs (dopamine agonists or levodopa, p. 1196) or benzodiazepines.

Periodic limb movements in sleep

Unlike RLS, period limb movements in sleep (PLMS) only occurs during sleep and causes repetitive flexion movements of the limbs, usually in the early (non-REM) stages of sleep. Although patients are unaware of the symptoms, they may disturb sleep quality and often disturb partners. The pathological significance of PLMS is uncertain and it often occurs in normal health. There is an overlap with RLS. Treatment is most successful with clonazepam or dopaminergic drugs.

NEURO-INFLAMMATORY DISEASES

Multiple sclerosis

Multiple sclerosis (MS) is an important cause of long-term disability in adults, especially in the UK, where the prevalence is about 120 per 100 000. The annual incidence is around 7 per 100 000, while the lifetime risk of developing MS is about 1 in 400. The incidence of MS is higher in Northern Europeans, and the disease is about twice as common in females.

Pathophysiology

There is evidence that both genetic and environmental factors play a causative role. The prevalence of MS is low near the equator and increases in the temperate zones of both hemispheres. Most importantly, people retain the risk of developing the disease in the zone in which they grew up, indicating that environmental exposures during growth and development are important. Prevalence also correlates with environmental factors, such as sunlight exposure, vitamin D and exposure to Epstein–Barr virus (EBV), although causative mechanisms remain unclear. Genetic factors are also relevant; the risk of familial recurrence in MS is 15%, with highest risk in first-degree relatives (age-adjusted risk: 4–5% for siblings and 2–3% for parents or offspring). Monozygotic twins have a concordance rate of 30%. The genes that predispose to MS are incompletely defined but inheritance appears to be polygenic, with influences from genes for human leucocyte antigen (HLA) typing, interleukin receptors, *CLEC16A* (C-type lectin domain family 16 member A) and *CD226* genes. An immune hypothesis is supported by increased levels of activated T lymphocytes in the CSF and increased immunoglobulin synthesis within the CNS.

Initial CNS inflammation in MS involves entry of activated T lymphocytes across the blood–brain barrier.

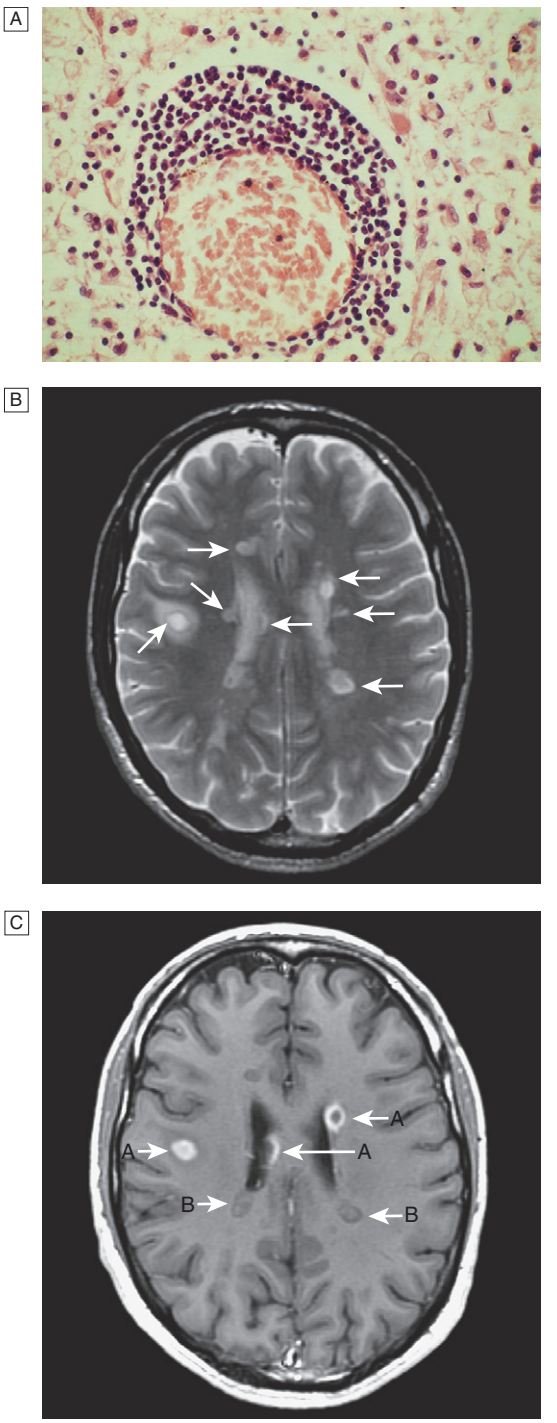

Fig. 26.26 Multiple sclerosis. A Photomicrograph from demyelinating plaque, showing perivascular cuffing of blood vessel by lymphocytes. B Brain MRI in multiple sclerosis. Multiple high-signal lesions (arrows) seen particularly in the paraventricular region on T2 image. C In T1 image with gadolinium enhancement, recent lesions (A arrows) show enhancement, suggesting active inflammation (enhancement persists for 4 weeks); older lesions (B arrows) show no enhancement but low signal, suggesting gliosis.

These recognise myelin-derived antigens on the surface of the nervous system's antigen-presenting cells, the microglia, and undergo clonal proliferation. The resulting inflammatory cascade releases cytokines and initiates destruction of the oligodendrocyte–myelin unit by macrophages. Histologically, the resultant lesion is a plaque of inflammatory demyelination, most commonly in the periventricular regions of the brain, the optic nerves, and the subpial regions of the spinal cord (Fig. 26.26). This begins as a circumscribed area of disintegration of the myelin sheath, accompanied by infiltration by activated lymphocytes and macrophages, often with conspicuous perivascular inflammation. After the acute attack, gliosis follows, leaving a shrunken grey scar.

Much of the initial acute clinical deficit is caused by the effect of inflammatory cytokines on transmission of the nervous impulse rather than structural disruption of the myelin, and may explain the rapid recovery of some deficits and probably the acute benefit from corticosteroids. In the long term, accumulating myelin loss reduces the efficiency of impulse propagation or causes complete conduction block, contributing to sustained impairment of CNS functions. Inflammatory mediators released during the acute attack (particularly nitric oxide) probably also initiate axonal damage, which is a feature of the latter stages of the disease. In established MS there is progressive axonal loss, probably due to the successive damage from acute attacks and the subsequent loss of neurotrophic factors from oligodendrocytes. This axonal loss may account for the phase of the disease characterised by progressive and persistent disability (Fig. 26.27).

Clinical features

A diagnosis of MS requires the demonstration of otherwise unexplained CNS lesions separated in time and space (Box 26.53). The peak age of onset of MS is the

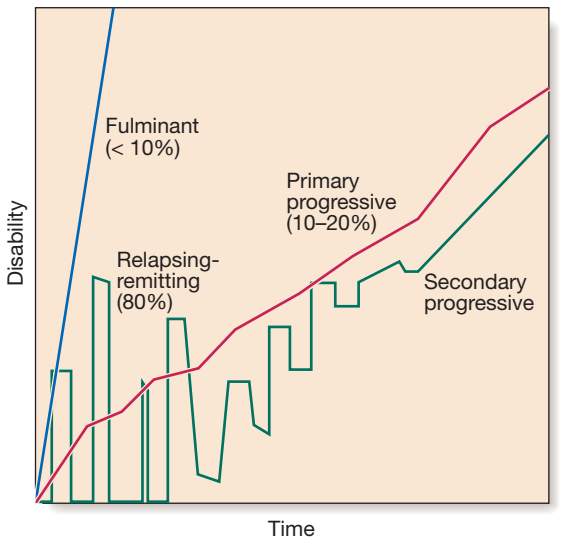

Fig. 26.27 **The progression of disability in fulminant, relapsing–remitting and progressive multiple sclerosis.**

26.53 The Macdonald criteria for the diagnosis of multiple sclerosis (2011)[1]

Clinical presentation[2]	Additional evidence required for diagnosis of MS
Two or more attacks with either Objective clinical evidence of at least 2 lesions *or* Objective clinical evidence of 1 attack with reasonable evidence (on clinical history) of at least 1 prior attack	None
Two or more attacks with objective clinical evidence of 1 lesion	Dissemination in 'space' demonstrated by MRI ≥ 1 lesion in at least 2 of the MS-typical regions[3] (multiple lesions in different sites) *or* Await further clinical attack at different anatomical site
One attack with objective clinical evidence of ≥ 2 lesions	Dissemination in 'time' demonstrated by Evolving MRI showing combined enhancing (new) and non-enhancing (old) lesions *or* New T2 or enhancing lesion on repeat MRI *or* Await further (second) clinical attack at different anatomical site
One attack with clinical evidence of only 1 lesion (clinically isolated syndrome)	Dissemination in 'space' demonstrated by ≥ 1 T2 lesion in at least 2 MS-typical regions *or* Dissemination in 'time', demonstrated by simultaneous enhancing and non-enhancing lesions *or* New T2 or enhancing lesions on repeat MRI *or* Await further (second) clinical attack
Insidious neurological progression suggestive of MS	1 yr of progression plus 2 of the following: Evidence for dissemination in space with ≥ 1 T2 lesions in MS-typical regions Evidence for dissemination in space based on ≥ 2 lesions in the spinal cord Positive CSF (evidence of oligoclonal band and/or elevated immunoglobulin (Ig) G index)

[1]Published by the International Panel on MS Diagnosis (Ann Neurol 2011; 69:292–302). If the clinical presentation in the left-hand column is associated with the features in the right-hand column, the diagnosis is MS. If there is incomplete association, the diagnosis is 'possible MS'.
[2]Assumes other possible causes for CNS inflammation (e.g. sarcoidosis, SLE) have been excluded.
[3]MS-typical regions = periventricular, juxtacortical, infratentorial, spinal cord.

fourth decade; onset before puberty or after the age of 60 years is rare. Where there is widespread inflammation, this usually leads to widespread symptoms and/or signs. Symptoms and signs of MS usually come on over days or weeks, resolving over weeks or months. Rarely, a more rapid stroke-like presentation may occur. Around 80% of patients have a relapsing and remitting clinical course of episodic dysfunction of the CNS with variable intervening recovery. Of the remaining 20%, most follow a slowly progressive clinical course, while a tiny minority have a fulminant variety leading to early death (see Fig. 26.27). Frequent relapses with incomplete recovery indicate a poor prognosis for the patient. Some milder cases have an interval of years or even decades between attacks, while in others (particularly if optic neuritis is the initial manifestation) there is no recurrence of disease. In some individuals, a phase of secondary progression, caused by secondary axonal degeneration, supersedes the phase of relapse and remission.

There are a number of clinical symptoms and syndromes suggestive of MS, occurring either at presentation or during the course of the illness (Box 26.54). The physical signs observed in MS are determined by the anatomical site of demyelination. Combined spinal cord and brainstem signs are common, although evidence of previous optic neuritis may be found in the form of an afferent pupillary deficit. Significant intellectual impairment only supervenes late in the disease, when loss of frontal functions and impairment of memory are common.

The prognosis for patients with MS is difficult to predict with confidence, especially early in the disease. About 15% of patients have a single attack of demyelination and do not suffer further events, whilst those with relapsing and remitting MS experience, on average, 1–2 events every 2 years. Approximately 5% of patients die within 5 years of disease onset, whilst others have a benign outcome. Prognosis is good for patients with optic neuritis and only sensory relapses. Overall, about one-third of patients are disabled to the point of needing help with walking after 10 years, and this proportion rises to about one-half after 15 years. It would appear likely (though this is as yet unproven) that disease-modifying drugs will have an effect on future prognostication.

Investigations

There is no single diagnostic test that is definitive for MS, and the results of investigation need to be combined with the clinical picture in order to make a diagnosis (Box 26.55). Other conditions should be excluded, and investigations should provide support for the diagnosis, with evidence for a chronic widespread inflammatory condition. Following the first clinical event, investigations may help prognosis by confirming the disseminated nature of the disease. MRI is the most sensitive technique for imaging lesions in brain and spinal cord (Fig. 26.28) and in excluding other causes that have provoked the neurological deficit. However, the MRI appearances in MS may be confused with those of small-vessel disease or cerebral vasculitis, and these diagnoses should be considered and excluded. Visual evoked potentials (p. 1152) can detect clinically silent lesions in up to 70% of patients, but auditory and somatosensory evoked potentials are seldom of diagnostic value.

The CSF may show a lymphocytic pleocytosis in the acute phase and oligoclonal bands of IgG in 70–90% of patients between attacks. Oligoclonal bands are not specific for MS and only denote intrathecal inflammation. These can appear in other disorders, which should be excluded by examination and other investigations. It is important to exclude other potentially treatable conditions, such as infection, vitamin B_{12} deficiency and spinal cord compression.

26.54 Clinical features of multiple sclerosis

Common presentations of multiple sclerosis

- Optic neuritis
- Relapsing/remitting sensory symptoms
- Subacute painless spinal cord lesion
- Acute brainstem syndrome
- Subacute loss of function of upper limb (dorsal column deficit)
- 6th cranial nerve palsy

Other symptoms and syndromes suggestive of CNS demyelination

- Afferent pupillary defect and optic atrophy (previous optic neuritis)
- Lhermitte's symptom (tingling in spine or limbs on neck flexion)
- Progressive non-compressive paraparesis
- Partial Brown–Séquard syndrome (p. 1221)
- Internuclear ophthalmoplegia with ataxia
- Postural ('rubral', 'Holmes') tremor
- Trigeminal neuralgia (p. 1178) under the age of 50
- Recurrent facial palsy

26.55 Investigations in a patient suspected of having multiple sclerosis

Exclude other structural disease and identify plaques of demyelination

- Image area of clinical involvement (MRI, myelography)

Demonstrate other sites of involvement

- Imaging (MRI)
- Visual evoked potentials
- Other evoked potentials

Demonstrate inflammatory nature of lesion(s)

- CSF examination
  - Cell count
  - Protein electrophoresis (oligoclonal bands)

Exclude other conditions

- Chest X-ray
- Serum angiotensin-converting enzyme (ACE) – sarcoidosis
- Serum B_{12}
- Antinuclear antibodies – SLE
- Antiphospholipid antibodies

Management

The management of MS involves four different strands: treatment of the acute episode, prevention of future relapses, treatment of complications and management of the patient's disability.

The acute episode

In a function-threatening exacerbation of MS, pulses of high-dose steroid, given either intravenously or orally over 3–5 days, will shorten the duration of the acute episode (Box 26.56). Prolonged administration of steroids does not alter the long-term outcome and causes severe adverse effects and should therefore be avoided. Pulses of steroids can be given up to three times in a year but use should be restricted to those individuals with significant function-threatening deficits. Prophylaxis to prevent the occurrence of steroid-induced osteoporosis (p. 1120) should be considered in patients requiring multiple courses of corticosteroids.

Disease-modifying treatment

Despite its immune basis, the administration of long-term steroids, standard chemotherapies and immunoglobulin is not practical or helpful in established MS. This motivated the search for innovative immuno-active treatments.

In relapsing and remitting MS, an increasing number of beta-interferons have been used to reduce relapse rates and improve long-term outlook. Their pharmacological properties tend to vary, but there has been no good trial evidence clinically separating the licensed compounds. Subcutaneous or intramuscular interferon-beta reduces the number of relapses by some 30%, with a small effect on long-term disability (Box 26.57). Long-term effects are usually local and development of antibodies should be sought; their development should preclude further long-term treatment. Other treatments are shown in Box 26.58.

Glatiramer acetate is a parenterally administered oligopeptide that may act as a competitor antigen, but in addition it increases numbers of regulatory CD4 T cells in relapsing–remitting MS, thereby helping to reduce relapse rates. Unlike other immunomodulatory treatments used for MS, glatiramer antibodies do not block function and actually appear to enhance efficacy.

Mitoxantrone was initially developed as a chemotherapeutic agent and has been shown to decrease the relapse rate in MS, as well as lowering the number of MRI lesions and reducing disability with long-term use. Its similarity to doxorubicin is reflected in its adverse effects, the most notable of which is cardiotoxicity.

26.58 Disease-modifying treatments in multiple sclerosis

Treatment	Mode of action	Comment
Interferon-beta	Immune modulation	In widespread use for reducing relapse rate (RCT evidence)
Glatiramer acetate	Immune modulation	Similar efficacy to interferon-beta (RCT evidence)
Fingolimod	Immune modulation	Superior efficacy to interferon-beta in RCTs
Monoclonal antibody to alpha4-integrin (natalizumab)	Immune modulation (blocks lymphocyte entry into CNS)	Recently introduced. Possibly more effective than interferon-beta and glatiramer acetate (RCT evidence)
Mitoxantrone	Immune suppression (cytotoxic)	Trials favour early use in aggressive disease

(RCT = randomised controlled clinical trial)

Natalizumab is a monoclonal antibody to an antigen expressed on activated T cells and monocytes, and has been associated with a dramatic fall in the number of lesions evident on MRI, with a corresponding decrease in the number of relapses and reduction in axonal damage. Rarely, neutralising antibodies block its efficacy and indicate that the drug should be withdrawn. Progressive multifocal leucoencephalopathy (PML) has been seen in some natalizumab-treated patients. Occasional cases of CNS lymphoma and toxoplasmosis may be related to drug use.

Other newer immunomodulatory treatments have been developed, including fingolimod, which is derived from the ascomycete metabolite ISP-1 (myriocin) and can be given orally. Further studies are needed to predict which immune treatment should be tried in which patients.

Special diets, including a gluten-free diet or linoleic acid supplements, and hyperbaric oxygen therapy are popular with patients but their efficacy has not yet been proven.

Treatment of symptoms, complications and disability

Treatments for the complications of MS are summarised in Box 26.59. It is important to provide patients with a careful explanation of the nature of the disease and its outcome. When and if disability occurs, patients and their relatives need appropriate support. Specialist nurses working in a multidisciplinary team of healthcare professionals are of great value in managing the chronic phase of the disease. Periods of physiotherapy and occupational therapy may improve functional capacity in those patients who become disabled, and guidance can be provided on the provision of aids at home, reducing handicap. Care of the bladder is particularly important. Urgency and frequency can be treated pharmacologically (see Box 26.31, p. 1175), but this may lead to a degree of retention with an attendant risk of infection. Retention can be managed initially by intermittent urinary catheterisation (performed by the patient, if possible), but an in-dwelling catheter may become necessary. Sexual dysfunction is a frequent source of distress. Sildenafil or tadalafil helps impotence in men, and skilled counselling and prosthetic aids are often beneficial.

26.59 Treatment of complications in multiple sclerosis

Spasticity

- Physiotherapy
- Baclofen (usually oral)
- Dantrolene
- Gabapentin
- Sativex®
- Tizanidine
- Intrathecal baclofen
- Local (IM) injection of botulinum toxin
- Chemical neuronectomy

Ataxia

- Isoniazid
- Clonazepam

Dysaesthesia

- Carbamazepine
- Gabapentin
- Phenytoin
- Amitriptyline

Bladder symptoms

- See Box 26.31, p. 1175

Fatigue

- Amantadine
- Modafinil
- Amitriptyline

Impotence

- Sildenafil 50–100 mg/24 hrs
- Tadalafil

26.60 Multiple sclerosis in pregnancy

- **Counselling**: provision of pre-conception counselling is best practice.
- **Relapse risk**: endocrine effects on the immune system ensure that relapse risk drops during pregnancy.
- **Disease-modifying drugs**: risk of teratogenicity means that all disease-modifying drugs should ideally be stopped 6–8 wks before conception and recommenced after breastfeeding has stopped.
- **Post-partum relapse rate**: rebound of immune system activity means that the highest risk of relapse is in the first year after delivery.

Acute disseminated encephalomyelitis

This is an acute monophasic demyelinating condition in which there are areas of perivenous demyelination

widely disseminated throughout the brain and spinal cord. The illness may apparently arise spontaneously but often occurs a week or so after a viral infection, especially measles and chickenpox, or following vaccination, suggesting that it is immunologically mediated.

Clinical features

Headache, vomiting, pyrexia, confusion and meningism may be presenting features, often with focal or multifocal brain and spinal cord signs. Seizures or coma may occur. A minority of patients who recover have further episodes.

Investigations

MRI shows multiple high-signal areas in a pattern similar to that of MS, although often with large confluent areas of abnormality. The CSF may be normal or show an increase in protein and lymphocytes (occasionally over 100×10^6 cells/L); oligoclonal bands may be found in the acute episode but, unlike in MS, will not persist beyond clinical recovery. The clinical picture may be very similar to a first relapse of MS.

Management

The disease may be fatal in the acute stages but is otherwise self-limiting. Treatment with high-dose intravenous methylprednisolone, using the same regimen as for a relapse of MS, is recommended.

Transverse myelitis

Transverse myelitis is an acute, usually monophasic, demyelinating disorder affecting the spinal cord. It is usually thought to be post-infectious in origin. It occurs at any age and presents with a subacute paraparesis with a sensory level, accompanied by severe pain in the neck or back at the onset. MRI should distinguish this from an external lesion affecting the spinal cord. CSF examination shows cellular pleocytosis, often with polymorphs at the onset. Oligoclonal bands are usually absent. Treatment is with high-dose intravenous methylprednisolone. The outcome is variable: one-third have static deficit, one-third go on to develop MS and one-third recover with no subsequent relapse. Some clinical features may predict the development of MS after transverse myelitis (Box 26.61).

26.61 Prognostic features predicting multiple sclerosis after transverse myelitis

Increased risk	
• Severe weakness • Catastrophic onset • Initial lancinating pain • Sensory disturbance at cervical level	• Spinal shock • Incontinence • Presence of 14-3-3 protein in CSF
Decreased risk	
• Subacute onset over days • Young onset • Retained posterior column function	• Retained tendon reflexes • Early recovery

Neuromyelitis optica

Neuromyelitis optica (also known as Devic's disease) is the occurrence of transverse myelitis and bilateral optic neuritis. The disease has been recognised for many years, particularly in Asia. The majority of cases are associated with an antibody to a neuronal membrane channel, aquaporin 4. If changes are seen on brain MRI (this is variable), they are typically high-signal lesions restricted to periventricular regions. Spinal MRI scans show lesions that are typically longer than three spinal segments (unlike the shorter lesions of MS). Clinical deficits tend to recover less well than in MS, and the disease may be more aggressive with more frequent relapses. Treatment with older immunosuppressive agents, such as steroids, azathioprine or cyclophosphamide, and/or plasmapheresis seems to be more effective than in MS.

PARANEOPLASTIC NEUROLOGICAL DISORDERS

Neurological disease may occur with systemic malignant tumours in the absence of cerebral metastases. It is now recognised that, in the majority of these cases, antigen production in the body of the tumour leads to development of antibodies to parts of the CNS. Paraneoplastic conditions are increasingly recognised, and the number of antibodies identified is also increasing (Boxes 26.62 and 26.63). These syndromes are particularly associated with small-cell carcinoma of lung, ovarian tumours, and lymphomas. Autoantibodies are found in the serum and/or CSF, and biopsy will show a lymphocytic infiltrate of the neural tissue affected.

Clinical presentations

These are summarised in Boxes 26.62 and 26.63. In most instances, the neurological condition progresses quite rapidly over a few months, preceding the malignant disease in around half of cases. The range of clinical patterns is so wide that paraneoplastic disease should be considered in the diagnosis of any unusual progressive neurological syndrome. The paraneoplastic disorders of the peripheral nervous system particularly affect the synaptic cleft (p. 1141).

Investigations and management

The presence of characteristic autoantibodies in the context of a suspicious clinical picture may be diagnostic. The causative tumour may be very small and therefore CT of the chest or abdomen or PET scanning may be necessary to find it. These investigations should only be pursued when paraneoplastic disease has been proven, rather than when it is suspected. The CSF often shows an increased protein and lymphocyte count with oligoclonal bands.

Treatment is directed at the primary tumour. Occasionally, successful therapy of the tumour is associated with improvement of the paraneoplastic syndrome. Some improvement may occur following administration of intravenous immunoglobulin.

26.62 Paraneoplastic disorders of the central nervous system

Clinical presentation	Associated tumour	Antibodies demonstrated
Limbic encephalitis	SCLC	Anti-Hu, anti-CV2, PCA-2, anti-VGKC, anti-Ma1, anti-amphiphysin, anti-Ri, ANNA-3, anti-VGCC, anti-Zic4, anti-GluR1/2, anti-GABAR
	Testicular, breast	Anti-Ma2, anti-GluR1/2
	Thymoma	Anti-VGKC, anti-CV2, anti-GluR1/2

Opsoclonus–myoclonus	Breast, ovarian	Anti-Ri, anti-Yo, anti-amphiphysin
	SCLC	Anti Hu, anti-Ri, anti-CV2, anti-amphiphysin, anti-VGCC
	Neuroblastoma	Anti-Hu
	Testicular	Anti-Ma1/2, anti-CV2
Extrapyramidal encephalitis	SCLC, thymoma, testicular	Anti-CV2, anti-Hu, anti-VGKC, anti-Ma
Optic neuritis	SCLC	Anti-CV2, anti-aquaporin
Retinal degeneration	SCLC	Anti-recoverin

(ANNA = anti-neuronal nucleolar antibody; GABAR = GABA receptor; GAD = glutamic acid decarboxylase; GluR = glutamate receptor; PCA = Purkinje cell antibody; SCLC = small-cell lung cancer; VGCC = voltage-gated calcium channel; VGKC = voltage-gated potassium channel)

26.63 Paraneoplastic disorders of the peripheral nervous system

Clinical presentation	Associated tumour	Antibodies demonstrated
Neuromyotonia	Thymoma, SCLC, others	Anti-VGKC
Myasthenia gravis	Thymoma	Anti-Achr, anti-MuSK
Sensorimotor polyneuropathy	Lymphoma, SCLC, others	Anti-HU, anti-CV2, ANNA-3, anti-Ma1, anti-amphiphysin
Lambert–Eaton syndrome	SCLC	Anti-VGCC
Motor neuropathy	Lymphoma, SCLC, others	Anti-Hu, anti-Yo, anti-CV2
Sensory neuropathy	Lymphoma, SCLC, others	Anti-Hu, anti-Yo, anti-CV2
Polymyositis/dermatomyositis	Lung, breast	Anti-Jo1

(MuSK = muscle-specific kinase; for other abbreviations, see Box 26.62)

NEURODEGENERATIVE DISEASES

Whilst MS is the most common cause of disability in young people in the UK, vascular and neurodegenerative diseases are increasingly important in later life. The neurodegenerative diseases are united in having a pathological process that leads to specific neuronal death, causing relentlessly progressive symptoms that increase in incidence in older age. The precise causes are not yet known. Alzheimer's disease (p. 251) and Parkinson's disease are the most common.

Movement disorders

Movement disorders present with a wide range of symptoms. They may be genetic or acquired, and the most important is Parkinson's disease. Most movement disorders are categorised clinically, with few confirmatory investigations available other than for those with a known gene abnormality.

Idiopathic Parkinson's disease

Parkinsonism is a clinical syndrome characterised primarily by bradykinesia (p. 1165), with associated increased

26.64 Causes of parkinsonism

Idiopathic Parkinson's disease (at least 80% of parkinsonism)

Cerebrovascular disease

Drugs and toxins

- Antipsychotic drugs (older and 'atypical')
- Metoclopramide, prochlorperazine
- Tetrabenazine
- Sodium valproate
- Lithium
- Manganese
- MPTP

Other degenerative diseases

- Dementia with Lewy bodies
- Progressive supranuclear palsy
- Multiple system atrophy
- Corticobasal degeneration
- Alzheimer's disease

Genetic

- Huntington's disease
- Fragile X tremor ataxia syndrome
- Dopa-responsive dystonia
- Spinocerebellar ataxias (particularly SCA 3)
- Wilson's disease

Anoxic brain injury

(MPTP = methyl-phenyl-tetrahydropyridine)

tone (rigidity), tremor and loss of postural reflexes. There are many causes (Box 26.64) but the most common is Parkinson's disease (PD). PD has an annual incidence of about 18/100 000 in the UK and a prevalence of about 180/100 000. Age has a critical influence on incidence and prevalence, the latter rising to 300–500/100 000 after 80 years of age. Average age of onset is about 60 years, and fewer than 5% of patients present under the age of 40. Genetic factors are increasingly recognised and several single genes causing parkinsonism have been identified, although they only account for a very small proportion of cases overall. Having a first-degree relative with PD confers a 2–3 times increased risk of developing PD. It is a progressive and incurable condition, with a variable prognosis. Whilst motor symptoms are the most common presenting features, non-motor symptoms (particularly cognitive impairment, depression and anxiety) become increasingly common as the disease progresses, and significantly reduce quality of life.

Pathophysiology

Although mutations in several genes have been identified in a few cases, in most patients the cause remains unknown. The discovery that methyl-phenyl-tetrahydropyridine (MPTP) caused severe parkinsonism in young drug users suggested that PD might be due to an environmental toxin but none has been convincingly identified. The pathological hallmarks of PD are depletion of the pigmented dopaminergic neurons in the substantia nigra and the presence of α-synuclein and other protein inclusions in nigral cells (Lewy bodies – Fig. 26.29). It is thought that environmental or genetic factors alter the α-synuclein protein, rendering it toxic and leading to Lewy body formation within the nigral cells. Lewy bodies are also found in the basal ganglia, brainstem and cortex, and increase with disease progression. PD is recognised as a synucleinopathy alongside multiple system atrophy and dementia with Lewy bodies. The loss of dopaminergic neurotransmission is responsible for many of the clinical features.

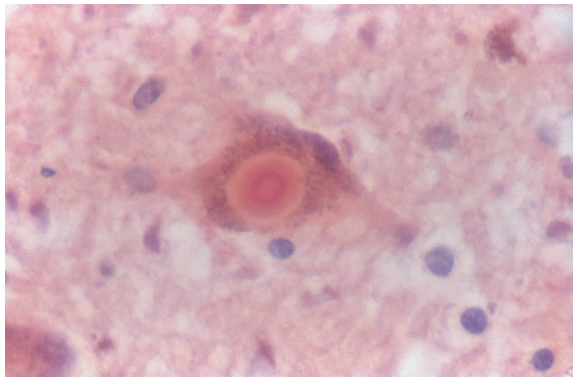

Fig. 26.29 Parkinson's disease. High power (× 400) of substantia nigra of a patient with Parkinson's disease showing classical Lewy body (haematoxylin and eosin).

Clinical features

Non-motor symptoms, including reduction in sense of smell (hyposmia), constipation and REM sleep behavioural disturbance (RBD), may precede the development of typical motor features by many years, but patients rarely present at this stage. The motor symptoms are almost always initially asymmetrical. The hallmark is bradykinesia, leading to classic symptoms such as increasingly small handwriting, difficulty with tying shoelaces or buttoning, and difficulty rolling over in bed. Tremor is an early feature but may not be apparent in at least 20% of people with PD. It is typically a unilateral rest tremor (p. 1165) affecting limbs, jaw and chin, but not the head. In some patients, tremor remains the dominant symptom for many years. Rigidity causes stiffness and a flexed posture. Although postural righting reflexes are impaired early on in the disease, falls tend not to occur until later. As the disease advances, speech becomes softer and indistinct. There are a number of abnormalities on neurological examination (Box 26.65).

Although the features are initially unilateral, gradual bilateral involvement evolves with time. Cognition is spared in early disease; if impaired, it should trigger consideration of alternative diagnoses, such as dementia with Lewy bodies.

Non-motor symptoms

Some non-motor symptoms (NMS) precede the onset of more typical symptoms by many years (see above). Depression or anxiety may also be presenting features of PD. For most patients, however, NMS become increasingly common and disabling as PD progresses. Cognitive impairment, including dementia, is the symptom most likely to impair quality of life for patients and their carers. Estimates of dementia frequency range from 30 to 80%, depending on definitions and length of follow-up. Other distressing NMS include other neuropsychiatric features (anxiety, depression, apathy, hallucinosis/psychosis), sleep disturbance and hypersomnolence, fatigue, pain, sphincter disturbance and constipation, sexual problems (erectile failure, loss of libido or hypersexuality) and drooling.

Investigations

The diagnosis is clinical. Structural imaging (CT or MRI) is usually normal for age and thus rarely helpful,

26.65 Physical signs in Parkinson's disease

General

- Expressionless face (hypomimia)
- Soft, rapid, indistinct speech (dysphonia)
- Flexed (stooped) posture
- Impaired postural reflexes

Gait

- Slow to start walking (failure of gait ignition)
- Rapid, short stride length, tendency to shorten (festination)
- Reduction of arm swing
- Impaired balance on turning

Tremor

Resting (3–4 Hz, moderate amplitude): most common
- Asymmetric, usually first in arm/hand ('pill rolling')
- May affect legs, jaw and chin, but not head
- Intermittent, present at rest, often briefly abolished by movement of the limb, exacerbated by walking

Postural (6–8 Hz, moderate amplitude)
- Present immediately on stretching out arms

Re-emergent tremor (3–4 Hz, moderate amplitude)
- Initially no tremor on stretching arms out, rest tremor re-emerges after a few seconds

Rigidity

- Cogwheel type, mostly upper limbs (due to tremor superimposed upon rigidity)
- Lead pipe type

Akinesia (fundamental feature)

- Slowness of movement
- Fatiguing and decrease in size of repetitive movements

Normal findings (if abnormal, consider other causes)

- Power, deep tendon reflexes, plantar responses
- Eye movements
- Sensory and cerebellar examination

although it may support a suspected vascular cause. Functional dopaminergic imaging (SPECT or PET) is abnormal, even at early stages (Fig. 26.30), but does not differentiate between the different forms of degenerative parkinsonism (see Box 26.64) and so is not specific for PD. In younger patients, specific investigations may be appropriate (e.g. exclusion of Huntington's and Wilson's diseases). Some patients with family histories may wish to consider genetic testing, although the role of genetic counselling is uncertain at present.

Management

Drug therapy

Drug treatment for PD remains symptomatic rather than curative, and there is no evidence that any of the currently available drugs are neuroprotective. Levodopa (LD) remains the most effective treatment available, but other agents include dopamine agonists, anticholinergics, inhibitors of monoamine oxidase (MAOI)-B and catechol-O-methyl-transferase (COMT), and amantadine. Debate continues about when to start treatment, and with which drug. In general, most specialists recommend initiating treatment when symptoms are impacting on everyday life; whether it is best to start with LD, a dopamine agonist or MAOI-B remains unclear, but most accept that the most effective, best-tolerated and cheapest drug is LD. Many motor symptoms, such as tremor, freezing, falling, head-drop and abnormal flexion, are quite resistant to treatment. Some NMS, such as anxiety or depression, may respond to drug or non-drug treatments. In the UK, rivastigmine is licensed for use in PD-associated dementia, although its effect is modest at best. Many other NMS are resistant to treatment. Evidence-based statements regarding diagnosis and drug management of PD are listed in Box 26.66.

Levodopa. LD is the precursor to dopamine. When administered orally, more than 90% is decarboxylated to dopamine peripherally in the gastrointestinal tract and blood vessels, and only a small proportion reaches the brain. This peripheral conversion is responsible for the high frequency of adverse effects, and to avoid this, LD is combined with a dopa decarboxylase inhibitor (DDI); the inhibitor does not cross the blood–brain barrier, thus avoiding unwanted decarboxylation-blocking in the brain. Two DDIs, carbidopa and benserazide, are available as combination preparations with LD, as Sinemet® and Madopar®, respectively.

LD is most effective at relieving the akinesia and rigidity; tremor response is often less satisfactory, and it has no effect on many motor (posture, freezing) and non-motor symptoms. Failure of akinesia/rigidity to respond to LD 1000 mg/day should prompt reconsideration of the diagnosis. Although controlled-release versions of LD exist, these are usually best reserved for use overnight, as their variable bioavailability makes them difficult to use throughout the day. Madopar® is also available as a dispersible tablet for more rapid-onset effect.

Adverse effects include postural hypotension, nausea and vomiting, which may be offset by domperidone. LD may exacerbate or trigger hallucinations, and abnormal LD-seeking behaviour may occur uncommonly

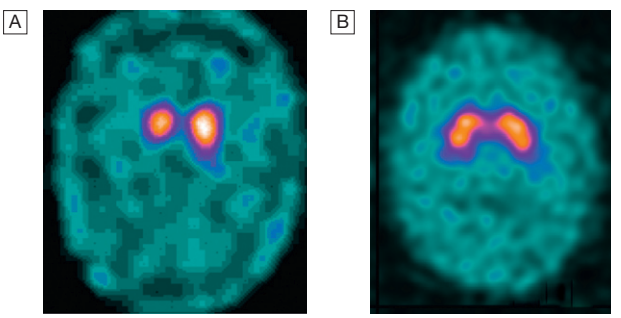

Fig. 26.30 Imaging in Parkinson's disease. A SPECT scan in Parkinson's disease showing reduced dopamine activity in the basal ganglia. B Normal.

EBM 26.66 Management of Parkinson's disease

Early treatment

'Patients with early PD may be considered for treatment with:
- levodopa plus dopa decarboxylase inhibitor *or*
- oral or transdermal dopamine agonists *or*
- monoamine oxidase B inhibitors.'

'Ergot-derived dopamine agonists should not be used as first-line treatment.'

'Anticholinergic drugs should not be used as first-line treatment.'

Motor fluctuations

'Motor fluctuations may be treated with either monoamine oxidase B inhibitors or dopamine agonists.'

'Dopamine agonists may be used to manage motor complications in patients with advanced PD. The non-ergot agonists are preferable to the ergot agonists.'

'Intermittent or infusions of subcutaneous apomorphine may be used to manage advanced PD.'

'Catechol-O-methyl-transferase (COMT) inhibitors may be used to reduce off-time in patients with advanced PD.'

- SIGN 113. Diagnosis and pharmacological management of Parkinson's disease, 2010.

For further information: www.sign.ac.uk

26.67 Dopamine agonists*

Ergot-derived

- Bromocriptine
- Lisuride
- Pergolide
- Cabergoline

Non-ergot-derived

- Ropinirole
- Pramipexole
- Rotigotine (transdermal patch)
- Apomorphine (subcutaneous)

*Oral unless otherwise stated.

(dopamine dysregulation syndrome) in which the patient takes excessive doses of LD.

As PD progresses, the response to LD becomes less predictable in many patients, leading to motor fluctuations. This end-of-dose deterioration is due to progressive loss of dopamine storage capacity by dwindling numbers of striatonigral neurons. LD-induced involuntary movements (dyskinesia) may occur as a peak-dose phenomenon or as a biphasic phenomenon (occurring during both the build-up and wearing-off phases). More complex fluctuations present as sudden, unpredictable changes in response, in which periods of parkinsonism ('off' phases) alternate with improved mobility but with dyskinesias ('on' phases). Motor complication management is difficult; wearing-off effects may respond to increased dose or frequency of LD or the addition of a COMT inhibitor (see below). More complex fluctuations may be improved by the addition of dopamine agonists (including continuous infusion of apomorphine), use of intrajejunal LD via a percutaneous endoscopic jejunostomy, or deep brain stimulator implantation.

Dopamine receptor agonists. Originally introduced in the hope of delaying the initiation of LD, and thus delaying motor complications, several dopamine agonists are available, and may be delivered orally, transdermally or subcutaneously (Box 26.67).

The ergot-derived agonists are no longer recommended because of rare but serious fibrotic effects. With the exception of apomorphine, all the agonists are considerably less powerful than LD in relieving parkinsonism, have more adverse effects (nausea, vomiting, confusion and hallucinations, impulse control disorders) and are more expensive. Their role in the management of PD (monotherapy or adjunctive) remains uncertain, and evidence is accruing to suggest that their usefulness as initial monotherapy is short-lasting.

MAOI-B inhibitors. Monoamine oxidase type B facilitates breakdown of excess dopamine in the synapse. Two inhibitors are used in PD: selegiline and rasagiline. The effects of both are modest, although usually well tolerated. Neither is neuroprotective, despite initial hopes.

COMT inhibitors. Catechol-O-methyl-transferase (along with dopa decarboxylase) is involved in peripheral breakdown of LD. Two inhibitors are available: entacapone and tolcapone (which also inhibits central COMT). Entacapone has a modest effect and is most useful for early wearing-off. It is available either as a single tablet taken with each LD/DDI dose, or as a combination tablet with LD and DDI. The more potent tolcapone is less used because of rare but serious hepatotoxicity.

Amantadine. This has a mild, usually short-lived effect on bradykinesia and is rarely used unless patients are unable to tolerate other drugs. It is more commonly employed as a treatment for LD-induced dyskinesias, although again benefit is modest and short-lived. Adverse effects include livedo reticularis, peripheral oedema, confusion and other anticholinergic effects.

Anticholinergic drugs. These were the main treatment for PD prior to the introduction of LD. Their role now is limited by lack of efficacy (apart from an effect on tremor sometimes) and adverse effects, including dry mouth, blurred vision, constipation, urinary retention, confusion and hallucinosis. Several anticholinergics are available, including trihexyphenidyl (benzhexol) and orphenadrine.

Surgery

Destructive neurosurgery was commonly used before the introduction of LD. In the last 20 years, stereotactic surgery has emerged and most commonly involves deep brain stimulation (DBS), rather than the destructive approach of previous eras. Various targets have been identified, including the thalamus (though this is only effective for tremor), globus pallidus and subthalamic nucleus. DBS is usually reserved for patients with medically refractory tremor or motor fluctuations, and careful patient selection is vital to success. Intracranial delivery of fetal grafts or specific growth factors remains experimental.

Physiotherapy, occupational therapy and speech therapy

Patients at all stages of PD benefit from physiotherapy, which helps reduce rigidity and corrects abnormal posture. Occupational therapists can provide equipment to help overcome functional limitations, such as rails for stairs and the toilet, and bathing equipment. Speech therapy can help where dysarthria and dysphonia interfere with communication, and advice may also be provided to those with dysphagia on the use of altered-texture diets. As with many complex neurological disorders, patients with PD should ideally be managed by a multidisciplinary team, including PD specialist nurses.

Other parkinsonian syndromes

Cerebrovascular disease and drug-induced parkinsonism are the most common alternative causes of parkinsonism (see Box 26.64). There are several degenerative conditions that cause parkinsonism, including multiple system atrophy, progressive supranuclear palsy and corticobasal degeneration. They typically have a more rapid progression than PD and tend to be resistant to treatment with LD. They are defined pathologically and identification during life is difficult. There are other conditions that may rarely manifest as parkinsonism, including Huntington's and Wilson's diseases.

Multiple system atrophy

Multiple system atrophy (MSA) is characterised by parkinsonism, autonomic failure and cerebellar symptoms, with either parkinsonism (MSA-P) or cerebellar features (MSA-C) predominating. It is much less common than PD, with a prevalence of about 4/100 000. Although early distinction between PD and MSA-P may be difficult, early falls, postural instability and lack of response to LD are clues. The pathological hallmark is α-synuclein-containing glial cytoplasmic inclusions found in the basal ganglia, cerebellum and motor cortex. Management is symptomatic and the prognosis is less good than for PD, with mean survival from symptom onset of fewer than 10 years, and early disability. Cognition is preserved.

Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) presents with symmetrical parkinsonism, cognitive impairment, early falls and bulbar symptoms. The characteristic eye movement disorder, with slowed vertical saccades leading to impairment of up and down gaze, may take years to emerge. PSP has different pathological features, being associated with abnormal accumulation of tau (τ) proteins and degeneration of the substantia nigra, subthalamic nucleus and mid-brain. It is therefore a tauopathy rather than synucleinopathy. The prevalence is about 5/100 000, with average survival similar to that in MSA. There is no treatment, and the parkinsonism usually does not respond to LD.

Corticobasal degeneration

Corticobasal degeneration (CBD) is less common than MSA or PSP, and the clinical manifestations are variable, including parkinsonism, dystonia, myoclonus and 'alien limb' phenomenon, whereby a limb (usually upper) moves about or interferes with the other limb without apparent conscious control. Cortical symptoms, especially apraxia, are common and may be the only features in some cases, including dementia. A number of other diseases may present with a corticobasal syndrome, including other dementias. CBD is a tauopathy with widespread deposition throughout the brain, and has similar survival rates to MSA and PSP.

Wilson's disease

This is an autosomal recessive disorder causing a defect of copper metabolism (p. 973). It is a treatable cause of various movement disorders, including tremor, dystonia, parkinsonism and ataxia; psychiatric symptoms may also occur. Wilson's should always be excluded in younger patients presenting with any movement disorder.

Huntington's disease

Huntington's disease (HD) is an autosomal dominant disorder, usually presenting in adults but occasionally children. It is due to expansion of a trinucleotide CAG repeat in the *Huntingtin* gene on chromosome 4 (p. 65). The disease frequently demonstrates the phenomenon of anticipation, in which there is a younger age at onset as the disease is passed through generations, due to progressive expansion of the repeat. The prevalence is about 4–8/100 000.

Clinical features

HD typically presents with a progressive behavioural disturbance, abnormal movements (usually chorea), and cognitive impairment leading to dementia. Onset under 18 years is rare, but patients may then present with parkinsonism rather than chorea (the 'Westphal variant'). There is always a family history, although this may be concealed.

Investigations and management

The diagnosis is confirmed by genetic testing; presymptomatic testing for other family members is available but must be preceded by appropriate counselling (p. 67). Brain imaging may show caudate atrophy but is not a reliable test. There are a number of HD mimics.

Management is symptomatic. The chorea may respond to neuroleptics such as risperidone or sulpiride, or other drugs such as tetrabenazine. Depression and anxiety are common, and may be helped by medication.

Ataxias

The ataxias are a heterogeneous group of inherited and acquired disorders, presenting either with pure ataxia or in association with other neurological and non-neurological features. The differential is wide (Boxes 26.68 and 26.69), and diagnosis is guided by age of onset, evolution and clinical features. A significant proportion of cases remain idiopathic despite investigation.

The hereditary ataxias are a group of inherited disorders in which degenerative changes occur to varying

26.68 Causes of acquired ataxia

Structural lesions	
• Brain tumour	• Brain abscess
Toxic	
• Drugs: lithium, phenytoin, amiodarone, toluene, 5-fluorouracil, cytosine arabinoside • Alcohol • Heavy metals/chemicals: mercury, lead, thallium	
Infection/post-infectious	
• HIV • Varicella zoster • Whipple's disease	• Miller Fisher syndrome (p. 1224)
Degenerative	
• Multiple system atrophy • Sporadic Creutzfeldt–Jakob disease	• Idiopathic (or sporadic) late-onset cerebellar ataxia
Inflammatory/immune-mediated	
• Multiple sclerosis • Gluten ataxia (coeliac disease)	• Paraneoplastic ataxia • Hashimoto encephalopathy
Metabolic	
• Vitamin B_1 or E deficiency • Hypothyroidism	• Hypoparathyroidism
Vascular	
• Stroke (ischaemic or haemorrhagic)	• Vascular malformations • Superficial siderosis

extents in the cerebellum, brainstem, pyramidal tracts, spinocerebellar tracts, and optic and peripheral nerves, and which influence the clinical manifestations. Onset ranges from infancy to adulthood, with recessive, sex-linked or dominant inheritance (see Box 26.69). Whilst the genetic abnormality has been identified for some, allowing diagnostic testing, this is not currently the case for many of the hereditary ataxias.

Tremor disorders

Tremor (p. 1165) is a feature of many disorders, but the most important clinical syndromes are PD, essential tremor, drug-induced tremors (Box 26.70) and functional (psychogenic) tremors.

Essential tremor

This has a prevalence of about 300/100 000 and may display a dominant pattern of inheritance, although no genes have thus far been identified. It may present at any age with a bilateral arm tremor (8–10 Hz), rarely at rest but typical with movement. The head and voice may be involved. The tremor improves in about 50% of patients with small amounts of alcohol. There are no specific tests, and it should be distinguished from other tremor syndromes, including dystonic tremor. Beta-blockers and primidone are sometimes helpful, and DBS of the thalamus is an effective treatment for severe cases.

26.69 Inherited ataxias

Inheritance pattern	Age of onset	Clinical features
Autosomal dominant		
Episodic ataxias	Childhood and early adulthood	Brief episodes of ataxia, sometimes induced by stress or startle. May develop progressive ataxia
Spinocerebellar ataxias (SCA)	Childhood to middle age	Over 30 subtypes identified thus far. Progressive ataxia, sometimes associated with other features, including retinitis pigmentosa, pyramidal tract abnormalities, peripheral neuropathy and cognitive deficits
Dentato-rubro-pallidoluysian atrophy (DRPLA)	Childhood to middle age	Children present with myoclonic epilepsy and progressive ataxia. Adults have progressive ataxia with psychiatric features, dementia and choreoathetosis
Autosomal recessive		
Friedreich's ataxia	Childhood/adolescence (late onset possible)	Ataxia, nystagmus, dysarthria, spasticity, areflexia, proprioceptive impairment, diabetes mellitus, optic atrophy, cardiac abnormalities. Usually chair-bound
Ataxia telangiectasia	Childhood	Progressive ataxia, athetosis, telangiectasia on conjunctivae, impaired DNA repair, immune deficiency, tendency to malignancies
Abetalipoproteinaemia	Childhood	Steatorrhoea, sensorimotor neuropathy, retinitis pigmentosa, malabsorption of vitamins A, D, E, K
Hereditary ataxia with vitamin E deficiency	< 20 yrs	Similar to Friedreich's ataxia, visual loss or retinitis pigmentosa, chorea
Others	Usually young onset	Numerous, with genes only identified in some
X-linked		
Fragile X tremor ataxia syndrome	> 50 yrs	Tremor, ataxia, parkinsonism, autonomic failure, cognitive impairment and dementia
Adrenoleucodystrophy	Childhood to adult	Impaired adrenal and cognitive function, sometimes spastic paraparesis
Mitochondrial disease	Various	Ataxia features in several mitochondrial diseases, including Kearns–Sayre syndrome, MELAS, MERRF, Leigh's syndrome (p. 46)

(MELAS = mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MERRF = myoclonic epilepsy with ragged red fibres)

26.70 Drug-induced tremor (usually postural)*

- β-agonists (e.g. salbutamol)
- Theophylline
- Sodium valproate
- Thyroxine
- Lithium
- Tricyclic antidepressants
- Recreational drugs (e.g. amphetamines)
- Alcohol
- Caffeine

*Drugs causing parkinsonism and associated tremor are listed in Box 26.64.

Dystonia

Dystonia is characterised by a focal increase in tone affecting muscles in the limbs or trunk. It may be a feature of a number of neurological conditions (PD, Wilson's disease), or occur secondary to brain damage (trauma, stroke) or drugs (tardive syndromes). Dystonia also occurs as a primary disorder. In childhood onset, the cause is usually genetic and dystonia is generalised but adult onset is usually focal; examples include a twisted neck (torticollis), repetitive blinking (blepharospasm) or tremor. Task-specific symptoms (e.g. writer's cramp, musician's dystonia) are often dystonic. Treatment is difficult but botulinum toxin injections or DBS may be useful.

Hemifacial spasm

This usually presents after middle age with intermittent twitching around one eye, spreading ipsilaterally to other facial muscles. The spasms are exacerbated by talking, eating and stress. Hemifacial spasm is usually idiopathic (similarly to trigeminal neuralgia, it has been suggested that it is due to an aberrant arterial loop irritating the 7th nerve just outside the pons), but may be symptomatic and secondary to structural lesions or MS. Drug treatment is not effective but injections of botulinum toxin into affected muscles help, although these usually have to be repeated every 3 months or so. In refractory cases, microvascular decompression may be considered.

Motor neuron disease

Motor neuron disease (MND) is a neurodegenerative condition caused by loss of upper and lower motor neurons in the spinal cord, cranial nerve nuclei and motor cortex. Annual incidence is about 2/100 000, with a prevalence of about 7/100 000. Most cases are sporadic but between 5 and 10% of cases are familial. Abnormalities in the superoxide dismutase (*SOD1*) gene account for about 20% of such cases, and recently an expanded repeat sequence in the *C9ORF72* gene on chromosome 9 has been associated with MND and frontotemporal dementia. The most common form of MND is amyotrophic sclerosis (ALS), and many use the terms MND and ALS interchangeably. ALS is characterised by a combination of upper and lower motor neuron signs; there are rarer, pure lower (progressive muscular atrophy) or upper (progressive lateral sclerosis) motor neuron variants of MND. The average age of onset is 65, with 10% presenting before 45 years.

26.71 Clinical features of motor neuron disease

Onset
- Usually after the age of 50 yrs
- Very uncommon before the age of 30 yrs
- Affects males more commonly than females

Symptoms
- Limb muscle weakness, cramps, occasionally fasciculation
- Disturbance of speech/swallowing (dysarthria/dysphagia)

Signs
- Wasting and fasciculation of muscles
- Weakness of muscles of limbs, tongue, face and palate
- Pyramidal tract involvement, causing spasticity, exaggerated tendon reflexes, extensor plantar responses
- External ocular muscles and sphincters usually remain intact
- No objective sensory deficit

Course
- Symptoms often begin focally in one part and spread gradually but relentlessly to become widespread

26.72 Patterns of involvement in motor neuron disease

Progressive muscular atrophy
- Predominantly spinal motor neurons affected
- Weakness and wasting of distal limb muscles at first
- Fasciculation in muscles
- Tendon reflexes may be absent

Progressive bulbar palsy
- Early involvement of tongue, palate and pharyngeal muscles
- Dysarthria/dysphagia
- Wasting and fasciculation of tongue
- Pyramidal signs may also be present

Amyotrophic lateral sclerosis (ALS)
- Combination of distal and proximal muscle-wasting and weakness, fasciculation
- Spasticity, exaggerated reflexes, extensor plantars
- Bulbar and pseudobulbar palsy follow eventually
- Pyramidal tract features may predominate

Clinical features

MND typically presents focally, either with limb onset (e.g. foot drop) or with bulbar symptoms; respiratory onset is rare but respiratory failure is a common terminal event. Sensory, autonomic and visual symptoms do not occur, although cramp is common (Box 26.71). Examination reveals a combination of lower and upper motor neuron signs (e.g. brisk reflexes in wasted, fasciculating muscles) without sensory involvement (Box 26.72). Cognitive impairment is under-recognised in MND: up to 50% will have a mainly executive impairment on formal testing, and around 10% develop a frontotemporal dementia (FTD). About 10% of patients presenting with FTD will develop ALS within a few years of dementia onset. MND is relentlessly progressive and up to 50% die within 2 years of diagnosis.

Investigations

Clinical features are often typical but alternative diagnoses should be excluded. Exclusion of treatable causes, such as immune-mediated multifocal motor neuropathy with conduction block (p. 1224) and cervical myeloradiculopathy, is essential. Blood tests are usually normal, other than a mildly raised creatine kinase. Sensory and motor nerve conduction studies are normal but there may be reduction in amplitude of motor action potentials due to axonal loss. Electromyography will usually confirm the typical features of widespread denervation and re-innervation. Spinal fluid analysis is not usually necessary. DNA testing may become more important as genetic factors become clearer.

Management

Patients should be managed within a multidisciplinary service, including physiotherapists, speech and occupational therapists, dietitians, ventilatory and feeding support, and palliative care teams, with neurological and respiratory input. Riluzole is licensed for ALS but has only a modest effect (Box 26.73). Non-invasive ventilatory support and/or feeding by percutaneous gastrostomy may improve quality of life in selected patients. Rapid access to palliative care teams is essential for patients as they enter the terminal stages of MND.

EBM 26.73 Effective treatments for amyotrophic lateral sclerosis/motor neuron disease

'Riluzole 100 mg daily is reasonably safe and may prolong median survival by about 2–3 months in patients with ALS.'

'Non-invasive ventilation significantly prolongs survival and improves or maintains quality of life in people with ALS. Survival and some measures of quality of life were significantly improved in the subgroup of people with better bulbar function, but not in those with severe bulbar impairment.'

- Miller RG, et al. Riluzole for amyotrophic lateral sclerosis (ALS)/motor neuron disease (MND). Cochrane Database of Systematic Reviews, 2012, issue 3. Art. no.: CD001447.

For further information: www.cochrane.org/cochrane-reviews

Spinal muscular atrophy

This is a group of genetically determined disorders affecting spinal and cranial lower motor neurons, characterised by proximal and distal wasting, fasciculation and weakness of muscles. Involvement is usually symmetrical but occasional localised forms occur. With the exception of the infantile form, progression is slow and the prognosis better than for MND.

INFECTIONS OF THE NERVOUS SYSTEM

The clinical features of nervous system infections depend on the location of the infection (the meninges or the parenchyma of the brain and spinal cord), the causative organism (virus, bacterium, fungus or parasite), and whether the infection is acute or chronic.

26.74 Infections of the nervous system

Bacterial infections	
• Meningitis	• Neurosyphilis
• Suppurative encephalitis	• Leprosy (peripheral nerves)*
• Brain abscess	• Diphtheria (peripheral nerves)*
• Paravertebral (epidural) abscess	• Tetanus (motor cells)
• Tuberculosis (Ch. 19)	
Viral infections	
• Meningitis	• Subacute sclerosing panencephalitis (late sequel)
• Encephalitis	• Rabies
• Transverse myelitis	• HIV infection (Ch. 14)
• Progressive multifocal leucoencephalopathy	
• Poliomyelitis	
Prion diseases	
• Creutzfeldt–Jakob disease	• Kuru
Protozoal infections	
• Malaria*	• Trypanosomiasis*
• Toxoplasmosis (in immune-suppressed)*	• Amoebic abscess*
Helminthic infections	
• Schistosomiasis (spinal cord)*	• Hydatid disease*
• Cysticercosis*	• Strongyloidiasis*
Fungal infections	
• *Candida* meningitis or brain abscess	• Cryptococcal meningitis

*These infections are discussed in Chapter 13.

The major infections of the nervous system are listed in Box 26.74. The frequency of these varies geographically. Helminthic infections, such as cysticercosis and hydatid disease, and protozoal infections are described in Chapter 13.

Meningitis

Acute infection of the meninges presents with a characteristic combination of pyrexia, headache and meningism. Meningism consists of headache, photophobia and stiffness of the neck, often accompanied by other signs of meningeal irritation, including Kernig's sign (extension at the knee with the hip joint flexed causes spasm in the hamstring muscles) and Brudzinski's sign (passive flexion of the neck causes flexion of the hips and knees). Meningism is not specific to meningitis and can occur in patients with subarachnoid haemorrhage. The severity of clinical features varies with the causative organism, as does the presence of other features such as a rash. Abnormalities in the CSF (see Box 26.5, p. 1154) are important in distinguishing the cause of meningitis. Causes of meningitis are listed in Box 26.75.

Viral meningitis

Viruses are the most common cause of meningitis, usually resulting in a benign and self-limiting illness requiring no specific therapy. It is much less serious

26.75 Causes of meningitis

Infective

Bacteria (see Box 26.76)

Viruses
- Enteroviruses (echo, Coxsackie, polio)
- Mumps
- Influenza
- Herpes simplex
- Varicella zoster
- Epstein–Barr
- HIV
- Lymphocytic choriomeningitis
- Mollaret's meningitis (herpes simplex virus type 2)

Protozoa and parasites
- Cysticerci
- Amoeba

Fungi
- *Cryptococcus neoformans*
- *Candida*
- *Histoplasma*
- *Blastomyces*
- *Coccidioides*
- *Sporothrix*

Non-infective ('sterile')

Malignant disease
- Breast cancer
- Bronchial cancer
- Leukaemia
- Lymphoma

Inflammatory disease (may be recurrent)
- Sarcoidosis
- SLE
- Behçet's disease

than bacterial meningitis unless there is associated encephalitis (which is rare). A number of viruses can cause meningitis (see Box 26.75), the most common being enteroviruses. Where specific immunisation is not employed, the mumps virus is a common cause.

Clinical features

Viral meningitis occurs mainly in children or young adults, with acute onset of headache and irritability and the rapid development of meningism. The headache is usually the most severe feature. There may be a high pyrexia but focal neurological signs are rare.

Investigations

The diagnosis is made by lumbar puncture. The CSF usually contains an excess of lymphocytes but glucose and protein levels are commonly normal; the protein level may be raised. It is extremely important to verify that the patient has not received antibiotics (for whatever cause) prior to the lumbar puncture, as this picture can also be found in partially treated bacterial meningitis.

Management

There is no specific treatment and the condition is usually benign and self-limiting. The patient should be treated symptomatically in a quiet environment. Recovery usually occurs within days, although a lymphocytic pleocytosis may persist in the CSF. Meningitis may also occur as a complication of a systemic viral infection such as mumps, measles, infectious mononucleosis, herpes zoster and hepatitis. Whatever the virus, complete recovery without specific therapy is the rule.

Bacterial meningitis

Many bacteria can cause meningitis but geographical patterns vary, as does age-related sensitivity (Box 26.76).

26.76 Bacterial causes of meningitis

Age of onset	Common	Less common
Neonate	Gram-negative bacilli (*Escherichia coli*, *Proteus*) Group B streptococci	*Listeria monocytogenes*
Pre-school child	*Haemophilus influenzae* *Neisseria meningitidis* *Streptococcus pneumoniae*	*Mycobacterium tuberculosis*
Older child and adult	*Neisseria meningitidis* *Streptococcus pneumoniae*	*Listeria monocytogenes* *Mycobacterium tuberculosis* *Staphylococcus aureus* (skull fracture) *Haemophilus influenzae*

Bacterial meningitis is usually part of a bacteraemic illness, although direct spread from an adjacent focus of infection in the ear, skull fracture or sinus can be causative. Antibiotics have rendered this less common but mortality and morbidity remain significant. An important factor in determining prognosis is early diagnosis and the prompt initiation of appropriate therapy. The meningococcus and other common causes of meningitis are normal commensals of the upper respiratory tract. New and potentially pathogenic strains are acquired by the air-borne route but close contact is necessary. Epidemics of meningococcal meningitis occur particularly in cramped living conditions or where the climate is hot and dry. The organism invades through the nasopharynx, producing septicaemia and leading to meningitis.

Pathophysiology

The meningococcus (*Neisseria meningitidis*) is now the most common cause of bacterial meningitis in Western Europe after *Streptococcus pneumoniae*, whilst in the USA *Haemophilus influenzae* remains common. In India, *H. influenzae* B and *Strep. pneumoniae* are probably the most common causes of bacterial meningitis, especially in children. *Strep. suis* is a rare zoonotic cause of meningitis associated with contact with pigs. The infection stimulates an immune response, causing the pia–arachnoid membrane to become congested and infiltrated with inflammatory cells. Pus then forms in layers, which may later organise to form adhesions. These may obstruct the free flow of CSF, leading to hydrocephalus, or they may damage the cranial nerves at the base of the brain. Hearing loss is a frequent complication. The CSF pressure rises rapidly, the protein content increases, and there is a cellular reaction that varies in type and severity according to the nature of the inflammation and the causative organism. An obliterative endarteritis of the leptomeningeal arteries passing through the meningeal exudate may produce secondary cerebral infarction. Pneumococcal meningitis is often associated with a very purulent CSF and a high mortality, especially in older adults.

26.77 Complications of meningococcal septicaemia

- Meningitis
- Rash (morbilliform, petechial or purpuric)
- Shock
- Intravascular coagulation
- Renal failure
- Peripheral gangrene
- Arthritis (septic or reactive)
- Pericarditis (septic or reactive)

Clinical features

Headache, drowsiness, fever and neck stiffness are the usual presenting features. In severe bacterial meningitis the patient may be comatose and later there may be focal neurological signs. Ninety percent of patients with meningococcal meningitis will have two of the following: fever, neck stiffness, altered consciousness and rash. When accompanied by septicaemia, it may present very rapidly, with abrupt onset of obtundation due to cerebral oedema. Complications of meningococcal septicaemia are listed in Box 26.77. Chronic meningococcaemia is a rare condition in which the patient can be unwell for weeks or even months with recurrent fever, sweating, joint pains and transient rash. It usually occurs in the middle-aged and elderly, and in those who have previously had a splenectomy. In pneumococcal and *Haemophilus* infections there may be an associated otitis media. Pneumococcal meningitis may be associated with pneumonia and occurs especially in older patients and alcoholics, as well as those without functioning spleens. *Listeria monocytogenes* is an increasing cause of meningitis and rhombencephalitis (brainstem encephalitis) in the immunosuppressed, people with diabetes, alcoholics and pregnant women (p. 339). It can also cause meningitis in neonates.

Investigations

Lumbar puncture is mandatory unless there are contraindications (p. 1154). If the patient is drowsy and has focal neurological signs or seizures, is immunosuppressed, has undergone recent neurosurgery or has suffered a head injury, it is wise to obtain a CT to exclude a mass lesion (such as a cerebral abscess) before lumbar puncture because of the risk of coning. This should not, however, delay treatment of a presumptive meningitis. If lumbar puncture is deferred or omitted, it is essential to take blood cultures and to start empirical treatment (Fig. 26.31). Lumbar puncture will help differentiate the causative organism: in bacterial meningitis the CSF is cloudy (turbid) due to the presence of many neutrophils (often $> 1000 \times 10^6$ cells/L), the protein content is significantly elevated and the glucose reduced. Gram film and culture may allow identification of the organism. Blood cultures may be positive. PCR techniques can be used on both blood and CSF to identify bacterial DNA. These methods are useful in detecting meningococcal infection and in typing the organism.

Management

There is an untreated mortality rate of around 80%, so action must be swift. If bacterial meningitis is suspected, the patient should be given parenteral benzylpenicillin immediately (intravenous is preferable) and prompt hospital admission should be arranged. The only contraindication is a history of penicillin anaphylaxis.

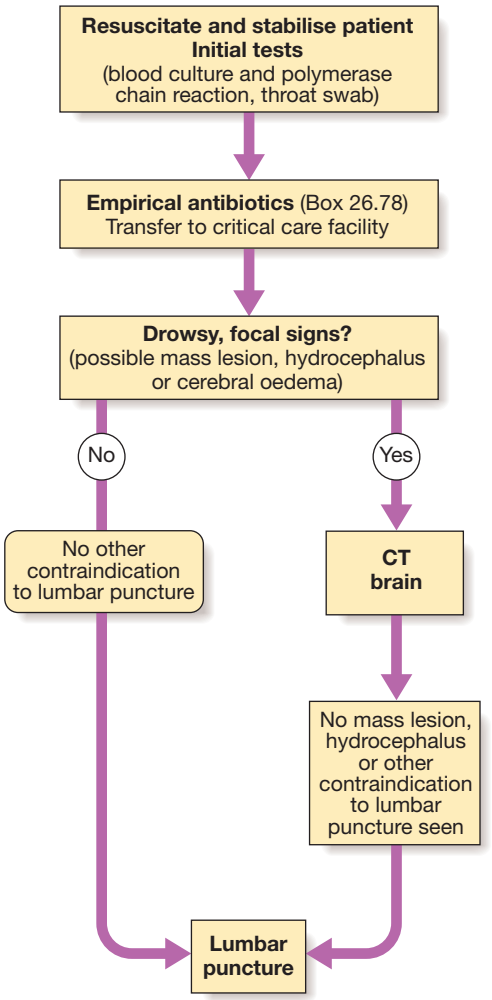

Fig. 26.31 The investigation of meningitis.

Recommended empirical therapy before the cause of meningitis is known is given in Box 26.78, and the preferred antibiotic when the organism is known after CSF examination is stipulated in Box 26.79. Adjunctive corticosteroid therapy is useful in both children and adults (Box 26.80) in developed countries where the incidence of penicillin resistance is low, but its role in settings where there are high rates of resistance or in under-developed countries where there are high rates of untreated HIV is unclear.

In meningococcal disease, mortality is doubled if the patient presents with features of septicaemia rather than meningitis. Individuals likely to require intensive care facilities and expertise include those with cardiac, respiratory or renal involvement, and those with CNS depression prejudicing the airway. Early endotracheal intubation and mechanical ventilation protect the airway and may prevent the development of the acute respiratory distress syndrome (ARDS, p. 192). Adverse prognostic features include hypotensive shock, a rapidly developing rash, a haemorrhagic diathesis, multisystem failure and age over 60 years.

Prevention of meningococcal infection

Close contacts of patients with meningococcal infection (Box 26.81) should be given 2 days of oral rifampicin. In

26.78 Treatment of pyogenic meningitis of unknown cause

1. Adults aged 18–50 yrs with or without a typical meningococcal rash

- Cefotaxime 2 g IV 4 times daily *or*
- Ceftriaxone 2 g IV twice daily

2. Patients in whom penicillin-resistant pneumococcal infection is suspected, or in areas with a significant incidence of penicillin resistance in the community

As for (1) but add:
- Vancomycin 1 g IV twice daily *or*
- Rifampicin 600 mg IV twice daily

3. Adults aged > 50 yrs and those in whom *Listeria monocytogenes* infection is suspected (brainstem signs, immunosuppression, diabetic, alcoholic)

As for (1) but add:
- Ampicillin 2 g IV 6 times daily *or*
- Co-trimoxazole 50 mg/kg IV daily in two divided doses

4. Patients with a clear history of anaphylaxis to β-lactams

- Chloramphenicol 25 mg/kg IV 4 times daily *plus*
- Vancomycin 1 g IV twice daily

5. Adjunctive treatment (see text)

- Dexamethasone 0.15 mg/kg 4 times daily for 2–4 days

26.79 Chemotherapy of bacterial meningitis when the cause is known

Pathogen	Regimen of choice	Alternative agents
N. meningitidis	Benzylpenicillin 2.4 g IV 6 times daily for 5–7 days	Cefuroxime, ampicillin Chloramphenicol*
Strep. pneumoniae (sensitive to β-lactams, MIC < 1 mg/L)	Cefotaxime 2 g IV 4 times daily *or* ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol*
Strep. pneumoniae (resistant to β-lactams)	As for sensitive strains but add vancomycin 1 g IV twice daily *or* rifampicin 600 mg IV twice daily	Vancomycin *plus* rifampicin* Moxifloxacin Gatifloxacin
H. influenzae	Cefotaxime 2 g IV 4 times daily *or* ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol*
L. monocytogenes	Ampicillin 2 g IV 6 times daily *plus* gentamicin 5 mg/kg IV daily	Ampicillin 2 g IV 4-hourly *plus* co-trimoxazole 50 mg/kg daily in two divided doses
Strep. suis	Cefotaxime 2 g IV 4 times daily *or* ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol*

*For patients with a history of anaphylaxis to β-lactam antibiotics.
(MIC = minimum inhibitory concentration)

EBM 26.80 Adjunctive dexamethasone for bacterial meningitis

Corticosteroids significantly reduce hearing loss and neurological sequelae, but do not reduce overall mortality.

- Brouwer MC, et al. Corticosteroids for acute bacterial meningitis. Cochrane Database of Systematic Reviews, 2010, issue 9. Art. no.: CD004405.

For further information: www.cochrane.org/cochrane-reviews

26.81 Chemoprophylaxis following meningococcal exposure

Close contacts warranting chemoprophylaxis

- Household contacts (including persons who ate or slept in the same dwelling as the patient during the 7 days prior to disease onset)
- Child-care and nursery-school contacts
- Persons having contact with patient's oral secretions during the 7 days prior to disease onset
  - Kissing
  - Sharing of toothbrushes
  - Sharing of eating utensils
  - Mouth-to-mouth resuscitation
  - Unprotected contact during endotracheal intubation
- Aircraft contacts for persons seated next to the patient for > 8 hrs

Persons at low risk in whom chemoprophylaxis is not recommended

- Casual contact (e.g. at school or work) without direct exposure to patient's oral secretions
- Indirect contact only (contact with a high-risk contact and not a case)
- Health-care worker without direct exposure to patient's oral secretions

adults, a single dose of ciprofloxacin is an alternative. If not treated with ceftriaxone, the index case should be given similar treatment to clear infection from the nasopharynx before hospital discharge. Vaccines are available for most meningococcal subgroups but not group B, which is among the most common serogroup isolated in many countries.

Tuberculous meningitis

Tuberculous meningitis is now uncommon in developed countries in previously healthy individuals, although it is still seen in those born in endemic areas and in the immunocompromised. It remains common in developing countries and is seen more frequently as a secondary infection in patients with the acquired immunodeficiency syndrome (AIDS).

Pathophysiology

Tuberculous meningitis most commonly occurs shortly after a primary infection in childhood or as part of miliary tuberculosis (p. 689). The usual local source of infection is a caseous focus in the meninges or brain substance adjacent to the CSF pathway. The brain is covered by a greenish, gelatinous exudate, especially around the base, and numerous scattered tubercles are found on the meninges.

26.82 Clinical features and staging of tuberculous meningitis

Symptoms

- Headache
- Vomiting
- Low-grade fever
- Lassitude
- Depression
- Confusion
- Behaviour changes

Signs

- Meningism (may be absent)
- Oculomotor palsies
- Papilloedema
- Depression of conscious level
- Focal hemisphere signs

Staging of severity

- Stage I (early): non-specific symptoms and signs without alteration of consciousness
- Stage II (intermediate): altered consciousness without coma or delirium + minor focal neurological signs
- Stage III (advanced): stupor or coma, severe neurological deficits, seizures or abnormal movements

Clinical features

The clinical features and staging criteria are listed in Box 26.82. Onset is much slower than in other bacterial meningitis – over 2–8 weeks. If untreated, it is fatal in a few weeks but complete recovery is usual if treatment is started at stage I (see Box 26.82). When treatment is initiated later, the rate of death or serious neurological deficit may be as high as 30%.

Investigations

Lumbar puncture should be performed if the diagnosis is suspected. The CSF is under increased pressure. It is usually clear but, when allowed to stand, a fine clot ('spider web') may form. The fluid contains up to 500×10^6 cells/L, predominantly lymphocytes, but can contain neutrophils. There is a rise in protein and a marked fall in glucose. The tubercle bacillus may be detected in a smear of the centrifuged deposit from the CSF but a negative result does not exclude the diagnosis. The CSF should be cultured but, as this result will not be known for up to 6 weeks, treatment must be started without waiting for confirmation. Brain imaging may show hydrocephalus, brisk meningeal enhancement on enhanced CT or MRI, and/or an intracranial tuberculoma.

Management

As soon as the diagnosis is made or strongly suspected, chemotherapy should be started using one of the regimens that include pyrazinamide, described on page 693. The use of corticosteroids in addition to anti-tuberculous therapy has been controversial. Recent evidence suggests that it improves mortality, especially if given early, but not focal neurological damage. Surgical ventricular drainage may be needed if obstructive hydrocephalus develops. Skilled nursing is essential during the acute phase of the illness, and adequate hydration and nutrition must be maintained.

Other forms of meningitis

Fungal meningitis (especially cryptococcosis – p. 384) usually occurs in patients who are immunosuppressed and is a recognised complication of HIV infection (p. 401). The CSF findings are similar to those of tuberculous meningitis, but the diagnosis can be confirmed by microscopy or specific serological tests.

In some areas, meningitis may be caused by spirochaetes (leptospirosis, Lyme disease and syphilis – pp. 336, 334 and 419), rickettsiae (typhus fever – p. 350) or protozoa (amoebiasis – p. 367).

Meningitis can also be due to non-infective pathologies. This is seen in recurrent aseptic meningitis due to SLE, Behçet's disease or sarcoidosis, as well as a condition of previously unknown origin known as Mollaret's syndrome, in which the recurrent meningitis is associated with epithelioid cells in the spinal fluid ('Mollaret' cells). Recent evidence suggests that this condition may be due to human herpes virus type 2, and is therefore infective after all. Meningitis can also be seen due to direct invasion of the meninges by neoplastic cells ('malignant meningitis' – see Box 26.75, p. 1202).

Parenchymal viral infections

Infection of the substance of the nervous system will produce symptoms of focal dysfunction (deficits and/or seizures) with general signs of infection, depending on the acuteness of the infection and the type of organism.

Viral encephalitis

A range of viruses can cause encephalitis but only a minority of patients have a history of recent viral infection. In Europe, the most serious cause of viral encephalitis is herpes simplex (p. 325), which probably reaches the brain via the olfactory nerves. Varicella zoster is also an important cause. The development of effective therapy for some forms of encephalitis has increased the importance of clinical diagnosis and virological examination of the CSF. In some parts of the world, viruses transmitted by mosquitoes and ticks (arboviruses) are an important cause of encephalitis. The epidemiology of some of these infections is changing. Japanese encephalitis (p. 328) has spread relentlessly across Asia to Australia, and there have been outbreaks of West Nile encephalitis in Romania, Israel and New York. HIV may cause encephalitis with a subacute or chronic presentation, but occasionally has an acute presentation with seroconversion.

Pathophysiology

The infection provokes an inflammatory response that involves the cortex, white matter, basal ganglia and brainstem. The distribution of lesions varies with the type of virus. For example, in herpes simplex encephalitis, the temporal lobes are usually primarily affected, whereas cytomegalovirus can involve the areas adjacent to the ventricles (ventriculitis). Inclusion bodies may be present in the neurons and glial cells and there is an infiltration of polymorphonuclear cells in the perivascular space. There is neuronal degeneration and diffuse glial proliferation, often associated with cerebral oedema.

Clinical features

Viral encephalitis presents with acute onset of headache, fever, focal neurological signs (aphasia and/or

hemiplegia, visual field defects) and seizures. Disturbance of consciousness ranging from drowsiness to deep coma supervenes early and may advance dramatically. Meningism occurs in many patients. Rabies presents a distinct clinical picture and is described below.

Investigations

Imaging by CT scan may show low-density lesions in the temporal lobes but MRI is more sensitive in detecting early abnormalities. Lumbar puncture should be performed once imaging has excluded a mass lesion. The CSF usually contains excess lymphocytes but polymorphonuclear cells may predominate in the early stages. The CSF may be normal in up to 10% of cases. Some viruses, including the West Nile virus, may cause a sustained neutrophilic CSF. The protein content may be elevated but the glucose is normal. The EEG is usually abnormal in the early stages, especially in herpes simplex encephalitis, with characteristic periodic slow-wave activity in the temporal lobes. Virological investigations of the CSF, including PCR for viral DNA, may reveal the causative organism but treatment initiation should not await this.

Management

Optimum treatment for herpes simplex encephalitis (aciclovir 10 mg/kg IV 3 times daily for 2–3 weeks) has reduced mortality from 70% to around 10%. This should be given early to all patients suspected of suffering from viral encephalitis.

Some survivors will have residual epilepsy or cognitive impairment. For details of post-infectious encephalomyelitis, see page 1192. Anticonvulsant treatment may be needed (p. 1183) and raised intracranial pressure may indicate the need for dexamethasone.

Brainstem encephalitis

This presents with ataxia, dysarthria, diplopia or other cranial nerve palsies. The CSF is lymphocytic, with a normal glucose. The causative agent is presumed to be viral. However, *Listeria monocytogenes* may cause a similar syndrome with meningitis (and often a polymorphonuclear CSF pleocytosis) and requires specific treatment with ampicillin 500 mg 4 times daily (see Box 26.79).

Rabies

Rabies is caused by a rhabdovirus that infects the central nervous tissue and salivary glands of a wide range of mammals, and is usually conveyed by saliva through bites or licks on abrasions or on intact mucous membranes. Humans are most frequently infected from dogs and bats. In Europe, the maintenance host is the fox. The incubation period varies in humans from a minimum of 9 days to many months but is usually between 4 and 8 weeks. Severe bites, especially if on the head or neck, are associated with shorter incubation periods. Human rabies is a rare disease, even in endemic areas. However, because it is usually fatal, major efforts are directed at limiting its spread and preventing its importation into uninfected countries, such as the UK.

Clinical features

At the onset there may be fever, and paraesthesia at the site of the bite. A prodromal period of 1–10 days, during which the patient becomes increasingly anxious, leads to the characteristic 'hydrophobia'. Although the patient is thirsty, attempts at drinking provoke violent contractions of the diaphragm and other inspiratory muscles. Delusions and hallucinations may develop, accompanied by spitting, biting and mania, with lucid intervals in which the patient is markedly anxious. Cranial nerve lesions develop and terminal hyperpyrexia is common. Death ensues, usually within a week of the onset of symptoms.

Investigations

During life, the diagnosis is usually made on clinical grounds but rapid immunofluorescent techniques can detect antigen in corneal impression smears or skin biopsies.

Management

Established disease

Only a few patients with established rabies have survived. All received some post-exposure prophylaxis (see below) and needed intensive care facilities to control cardiac and respiratory failure. Otherwise, only palliative treatment is possible once symptoms have appeared. The patient should be heavily sedated with diazepam, supplemented by chlorpromazine if needed. Nutrition and fluids should be given intravenously or through a gastrostomy.

Pre-exposure prophylaxis

Pre-exposure prophylaxis is required by those who handle potentially infected animals professionally, those who work with rabies virus in laboratories and those who live at special risk in rabies-endemic areas. Protection is afforded by intradermal injections of human diploid cell strain vaccine, or two intramuscular injections given 4 weeks apart, followed by yearly boosters.

Post-exposure prophylaxis

The wounds should be thoroughly cleaned, preferably with a quaternary ammonium detergent or soap; damaged tissues should be excised and the wound left unsutured. Rabies can usually be prevented if treatment is started within a day or two of biting. Delayed treatment may still be of value. For maximum protection, hyperimmune serum and vaccine are required.

The safest antirabies antiserum is human rabies immunoglobulin. The dose is 20 U/kg body weight; half is infiltrated around the bite and half is given intramuscularly at a different site from the vaccine. Hyperimmune animal serum may be used but hypersensitivity reactions, including anaphylaxis, are common.

The safest vaccine, free of complications, is human diploid cell strain vaccine; 1.0 mL is given intramuscularly on days 0, 3, 7, 14, 30 and 90. In developing countries, where human rabies globulin may not be obtainable, 0.1 mL of vaccine may be given intradermally into eight sites on day 1, with single boosters on days 7 and 28. Where human products are not available and when risk of rabies is slight (licks on the skin, or minor bites of covered arms or legs), it may be justifiable to delay starting treatment while observing the biting animal or awaiting examination of its brain, rather than use the older vaccine.

Poliomyelitis

Pathophysiology

Disease is caused by one of three polioviruses, which constitutes a subgroup of the enteroviruses. Poliomyelitis has become much less common in developed countries following the widespread use of oral vaccines but is still a problem in the developing world, especially parts of Africa. Infection usually occurs through the nasopharynx.

The virus causes a lymphocytic meningitis and infects the grey matter of the spinal cord, brainstem and cortex. There is a particular propensity to damage anterior horn cells, especially in the lumbar segments.

Clinical features

The incubation period is 7–14 days. Figure 26.32 illustrates the various features of the infection. Many patients recover fully after the initial phase of a few days of mild fever and headache. In other individuals, after a week of well-being, there is a recurrence of pyrexia, headache and meningism. Weakness may start later in one muscle group and can progress to widespread paresis. Respiratory failure may supervene if intercostal muscles are paralysed or the medullary motor nuclei are involved. Epidemics vary widely in terms of the incidence of non-paralytic cases and in mortality rate. Death occurs from respiratory paralysis. Muscle weakness is maximal at the end of the first week and gradual recovery may then take place over several months. Muscles showing no signs of recovery after a month will probably not regain useful function. Second attacks are very rare but occasionally patients show late deterioration in muscle bulk and power many years after the initial infection (this is termed the 'post-polio syndrome').

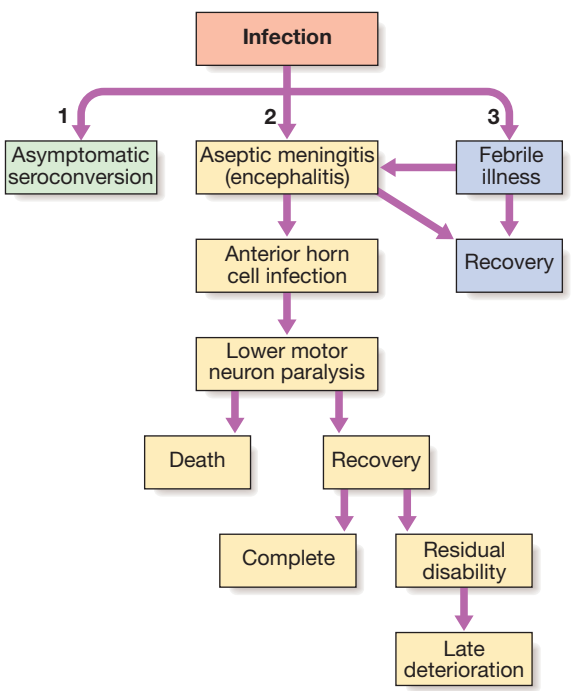

Fig. 26.32 Poliomyelitis. Possible consequences of infection.

Investigations

The CSF shows a lymphocytic pleocytosis, a rise in protein and a normal sugar content. Poliomyelitis virus may be cultured from CSF and stool.

Management

Established disease

In the early stages, bed rest is imperative because exercise appears to worsen the paralysis or precipitate it. At the onset of respiratory difficulties, a tracheostomy and ventilation are required. Subsequent treatment is by physiotherapy and orthopaedic measures.

Prophylaxis

Prevention of poliomyelitis is by immunisation with live (Sabin) vaccine. In developed countries where polio is now very rare, the live vaccine has been replaced by the killed vaccine in childhood immunisation schedules.

Herpes zoster (shingles)

Herpes zoster is the result of reactivation of the varicella zoster virus that has lain dormant in a nerve root ganglion following chickenpox earlier in life. Reactivation may be spontaneous (as usually occurs in the middle-aged or elderly) or due to immunosuppression (as in patients with diabetes, malignant disease or AIDS). Full details are given on page 318.

Subacute sclerosing panencephalitis

This is a rare, chronic, progressive and eventually fatal complication of measles, presumably a result of an inability of the nervous system to eradicate the virus. It occurs in children and adolescents, usually many years after the primary virus infection. There is generalised neurological deterioration and onset is insidious, with intellectual deterioration, apathy and clumsiness, followed by myoclonic jerks, rigidity and dementia.

The CSF may show a mild lymphocytic pleocytosis and the EEG demonstrates characteristic periodic bursts of triphasic waves. Although there is persistent measles-specific IgG in serum and CSF, antiviral therapy is ineffective and death ensues within a few years.

Progressive multifocal leucoencephalopathy

This was originally described as a rare complication of lymphoma, leukaemia or carcinomatosis, but has become more frequent as a feature of AIDS (p. 402). It is an infection of oligodendrocytes by human polyomavirus JC, which causes widespread demyelination of the white matter of the cerebral hemispheres. Clinical signs include dementia, hemiparesis and aphasia, which progress rapidly, usually leading to death within weeks or months. Areas of low density in the white matter are seen on CT but MRI is more sensitive, showing diffuse high signal in the cerebral white matter on T2-weighted images. The only treatment available is to restore the immune response (by treating AIDS or any other cause of immunosuppression).

Parenchymal bacterial infections

Cerebral abscess

Bacteria may enter the cerebral substance through penetrating injury, by direct spread from paranasal sinuses or the middle ear, or secondary to septicaemia. The site of abscess formation and the likely causative organism are both related to the source of infection (Box 26.83). Initial infection leads to local suppuration followed by loculation of pus within a surrounding wall of gliosis, which in a chronic abscess may form a tough capsule. Haematogenous spread may lead to multiple abscesses.

Clinical features

A cerebral abscess may present acutely with fever, headache, meningism and drowsiness, but more commonly presents over days or weeks as a cerebral mass lesion with little or no evidence of infection. Seizures, raised intracranial pressure and focal hemisphere signs occur alone or in combination. Distinction from a cerebral tumour may be impossible on clinical grounds.

Investigations

Lumbar puncture is potentially hazardous in the presence of raised intracranial pressure and CT should always precede it. CT reveals single or multiple low-density areas, which show ring enhancement with contrast and surrounding cerebral oedema (Fig. 26.33). There may be an elevated white blood cell count and ESR in patients with active local infection. The possibility of cerebral toxoplasmosis or tuberculous disease secondary to HIV infection (p. 402) should always be considered.

Management and prognosis

Antimicrobial therapy is indicated once the diagnosis is made. The likely source of infection should guide the choice of antibiotic (see Box 26.83). In neurosurgical patients, the addition of vancomycin should be considered. Surgical drainage by burr-hole aspiration or excision may be necessary, especially where the presence of a capsule may lead to a persistent focus of infection.

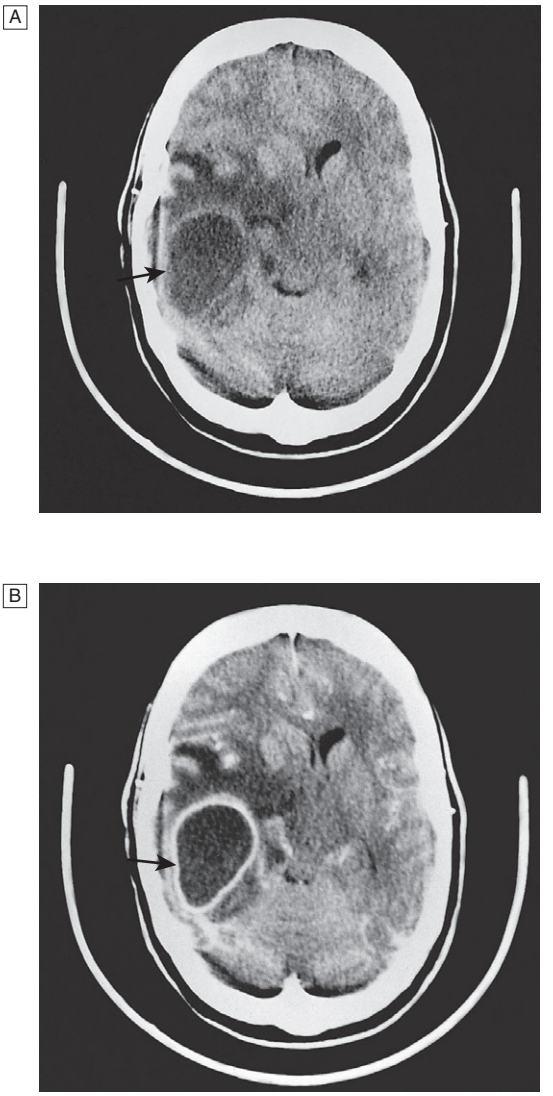

Fig. 26.33 Right temporal cerebral abscess (arrows), with surrounding oedema and midline shift to the left. A Unenhanced CT image. B Contrast-enhanced CT image.

26.83 Aetiology and treatment of bacterial cerebral abscess

Site of abscess	Source of infection	Likely organisms	Recommended treatment
Frontal lobe	Paranasal sinuses Teeth	Streptococci Anaerobes	Cefotaxime 2–3 g IV 4 times daily *plus* Metronidazole 500 mg IV 3 times daily
Temporal lobe **Cerebellum**	Middle ear Sphenoid sinus Mastoid/middle ear	Streptococci Enterobacteriaceae *Pseudomonas* spp. Anaerobes	Ampicillin 2–3 g IV 3 times daily *plus* Metronidazole 500 mg IV 3 times daily *plus either* Ceftazidime 2 g IV 3 times daily *or* Gentamicin* 5 mg/kg IV daily
Any site	Penetrating trauma	Staphylococci	Flucloxacillin 2–3 g IV 4 times daily *or* Cefuroxime 1.5 g IV 3 times daily
Multiple	Metastatic and cryptogenic	Streptococci Anaerobes	Benzylpenicillin 1.8–2.4 g IV 4 times daily if endocarditis or cyanotic heart disease Otherwise cefotaxime 2–3 g IV 4 times daily *plus* Metronidazole 500 mg IV 3 times daily

*Monitor gentamicin levels.

Epilepsy frequently develops and is often resistant to treatment.

Despite advances in therapy, the mortality rate remains at 10–20% and this may partly relate to delay in diagnosis and initiation of treatment.

Subdural empyema

This is a rare complication of frontal sinusitis, osteomyelitis of the skull vault or middle ear disease. A collection of pus in the subdural space spreads over the surface of the hemisphere, causing underlying cortical oedema or thrombophlebitis. Patients present with severe pain in the face or head and pyrexia, often with a history of preceding paranasal sinus or ear infection. The patient then becomes drowsy, with seizures and focal signs such as a progressive hemiparesis.

The diagnosis rests on a strong clinical suspicion in patients with a local focus of infection. Careful assessment with contrast-enhanced CT or MRI may show a subdural collection with underlying cerebral oedema. Management requires aspiration of pus via a burr-hole and appropriate parenteral antibiotics. Any local source of infection must be treated to prevent re-infection.

Spinal epidural abscess

The characteristic clinical features are pain in a root distribution and progressive transverse spinal cord syndrome with paraparesis, sensory impairment and sphincter dysfunction. Features of the primary focus of infection may be less obvious and thus can be overlooked. The resurgence of resistant staphylococcal infection and intravenous drug misuse has contributed to a recent marked rise in incidence.

X-ray changes occur late if present, so MRI or myelography should precede urgent neurosurgical intervention. Decompressive laminectomy with draining of the abscess relieves the pressure on the dura. Organisms may be grown from the pus or blood. Surgery, together with appropriate antibiotics, may prevent complete and irreversible paraplegia.

Lyme disease

This can cause numerous neurological problems, including polyradiculopathy, meningitis, encephalitis and mononeuritis multiplex (p. 334).

Neurosyphilis

Neurosyphilis may present as an acute or chronic process and may involve the meninges, blood vessels and/or parenchyma of the brain and spinal cord. The decade to 2008 saw a ten-fold increase in the incidence of syphilis, mostly as a result of misguided relaxation of safe sex measures with the advent of effective antiretroviral treatments for AIDS. Parallel increases in neurosyphilis are inevitable. The clinical manifestations are diverse and early diagnosis and treatment remain important.

Clinical features

The clinical and pathological features of the three most common presentations are summarised in Box 26.84. Neurological examination reveals signs indicative of the anatomical localisation of lesions. Delusions of grandeur suggest general paresis of the insane, but more commonly there is simply progressive dementia. Small and irregular pupils that react to convergence but not light, as described by Argyll Robertson (see Box 26.28, p. 1172), may accompany any neurosyphilitic syndrome, but most commonly tabes dorsalis.

26.84 Clinical and pathological features of neurosyphilis

Type	Pathology	Clinical features
Meningovascular (5 yrs)*	Endarteritis obliterans Meningeal exudate Granuloma (gumma)	Stroke Cranial nerve palsies Seizures/mass lesion
General paralysis of the insane (5–15 yrs)*	Degeneration in cerebral cortex/ cerebral atrophy Thickened meninges	Dementia Tremor Bilateral upper motor signs
Tabes dorsalis (5–20 yrs)*	Degeneration of sensory neurons Wasting of dorsal columns Optic atrophy	Lightning pains Sensory ataxia Visual failure Abdominal crises Incontinence Trophic changes
Any of the above		Argyll Robertson pupils (p. 1172)

*Interval from primary infection.

Investigations

Routine screening for syphilis is warranted in many neurological patients. Serological tests (p. 420) are positive in the serum in most patients, but CSF examination is essential if neurological involvement is suspected. Active disease is suggested by an elevated cell count, usually lymphocytic, and the protein content may be elevated to 0.5–1.0 g/L with an increased gamma globulin fraction. Serological tests in the CSF are usually positive, but progressive disease can occur with negative CSF serology.

Management

The injection of procaine benzylpenicillin (procaine penicillin) and probenecid for 17 days is essential in the treatment of neurosyphilis of all types (p. 421). Further courses of penicillin must be given if symptoms are not relieved, if the condition continues to advance or if the CSF continues to show signs of active disease. The cell count returns to normal within 3 months of completion of treatment, but the elevated protein takes longer to subside and some serological tests may never revert to normal. Evidence of clinical progression at any time is an indication for renewed treatment.

Diseases caused by bacterial toxins

Tetanus

This disease results from infection with *Clostridium tetani*, a commensal in the gut of humans and domestic animals that is found in soil. Infection enters the body through wounds, which may be trivial. It is rare in the

UK, occurring mostly in gardeners and farmers, but a recent increase has been seen in intravenous drug misusers. By contrast, the disease is common in many developing countries, where dust contains spores derived from animal and human excreta. Unhygienic practices soon after birth may lead to infection of the umbilical stump or site of circumcision, causing tetanus neonatorum. Tetanus is still one of the major killers of adults, children and neonates in developing countries, where the mortality rate can be nearly 100% in the newborn and around 40% in others.

In circumstances unfavourable to the growth of the organism, spores are formed and these may remain dormant for years in the soil. Spores germinate and bacilli multiply only in the anaerobic conditions that occur in areas of tissue necrosis or if the oxygen tension is lowered by the presence of other organisms, particularly if aerobic. The bacilli remain localised but produce an exotoxin with an affinity for motor nerve endings and motor nerve cells.

The anterior horn cells are affected after the exotoxin has passed into the blood stream and their involvement results in rigidity and convulsions. Symptoms first appear from 2 days to several weeks after injury – the shorter the incubation period, the more severe the attack and the worse the prognosis.

Clinical features

By far the most important early symptom is trismus – spasm of the masseter muscles, which causes difficulty in opening the mouth and in masticating; hence the name 'lockjaw'. Lockjaw in tetanus is painless, unlike the spasm of the masseters due to dental abscess, septic throat or other causes. Conditions that can mimic tetanus include hysteria and phenothiazine overdosage, or overdose in intravenous drug misusers.

In tetanus, the tonic rigidity spreads to involve the muscles of the face, neck and trunk. Contraction of the frontalis and the muscles at the angles of the mouth leads to the so-called 'risus sardonicus'. There is rigidity of the muscles at the neck and trunk of varying degree. The back is usually slightly arched ('opisthotonus') and there is a board-like abdominal wall.

In the more severe cases, violent spasms lasting for a few seconds to 3–4 minutes occur spontaneously, or may be induced by stimuli such as movement or noise. These convulsions are painful, exhausting and of very serious significance, especially if they appear soon after the onset of symptoms. They gradually increase in frequency and severity for about 1 week and the patient may die from exhaustion, asphyxia or aspiration pneumonia. In less severe illness, convulsions may not commence until a week or so after the first sign of rigidity, and in very mild infections they may never appear. Autonomic involvement may cause cardiovascular complications, such as hypertension. Rarely, the only manifestation of the disease may be 'local tetanus' – stiffness or spasm of the muscles near the infected wound – and the prognosis is good if treatment is commenced at this stage.

Investigations

The diagnosis is made on clinical grounds. It is rarely possible to isolate the infecting organism from the original locus of entry.

26.85 Treatment of tetanus

Neutralise absorbed toxin
• IV injection of 3000 U of human tetanus antitoxin
Prevent further toxin production
• Débridement of wound • Benzylpenicillin 600 mg IV 4 times daily (metronidazole if patient is allergic to penicillin)
Control spasms
• Nurse in a quiet room • Avoid unnecessary stimuli • IV diazepam • If spasms continue, paralyse patient and ventilate
General measures
• Maintain hydration and nutrition • Treat secondary infections

Management

Established disease

Management of established disease should begin as soon as possible, as shown in Box 26.85.

Prevention

Tetanus can be prevented by immunisation and prompt treatment of contaminated wounds by débridement and antibiotics. In patients with a contaminated wound, the immediate danger of tetanus can be greatly reduced by the injection of 1200 mg of penicillin followed by a 7-day course of oral penicillin. For those allergic to penicillin, erythromycin should be used. When the risk of tetanus is judged to be present, an intramuscular injection of 250 U of human tetanus antitoxin should be given, along with toxoid which should be repeated 1 month and 6 months later. For those already immunised, only a booster dose of toxoid is required.

Botulism

Botulism is caused by the neurotoxins of *Clostridium botulinum*, which are extremely potent and cause disease after ingestion of even picogram amounts. Its classical form is an acute onset of bilateral cranial neuropathies associated with symmetric descending weakness.

Anaerobic conditions are necessary for the organism's growth. It may contaminate and thrive in many foodstuffs, where sealing and preserving provide the requisite conditions. Contaminated honey has been implicated in infant botulism, in which the organism colonises the gastrointestinal tract. Wound botulism is a growing problem in injection drug-users.

The toxin causes predominantly bulbar and ocular palsies (difficulty in swallowing, blurred or double vision, ptosis), progressing to limb weakness and respiratory paralysis. Criteria for the clinical diagnosis are shown in Box 26.86.

Management includes assisted ventilation and general supportive measures until the toxin eventually dissociates from nerve endings 6–8 weeks following ingestion. A polyvalent antitoxin is available for post-exposure prophylaxis and for the treatment of suspected botulism. It specifically neutralises toxin types A, B and E and is not effective against infantile botulism (in which

26.86 The US Centers for Disease Control (CDC) definition of botulism

Three main syndromes

1. Infantile
2. Food-borne
3. Wound infection

Clinical features

- Absence of fever
- Symmetrical neurological deficits
- Patient remains responsive
- Normal or slow heart rate and normal blood pressure
- No sensory deficits with the exception of blurred vision

active growth of the organism allows continued toxin production).

Transmissible spongiform encephalopathies

Transmissible spongiform encephalopathies (TSEs) include a number of veterinary and medical conditions that are characterised by the histopathological triad of cortical spongiform change, neuronal cell loss and gliosis. Associated with these changes, there is deposition of amyloid made up of an altered form of a normally occurring protein, the prion protein.

The precise nature of the infective agent is not yet clear but almost certainly involves the cascade formation of an abnormal prion protein. TSEs may also occur spontaneously or as an inherited disorder. Diseases affecting animals include bovine and feline spongiform encephalopathies (BSE and FSE). These diseases achieved media prominence in the 1990s, when a form of Creutzfeldt–Jakob disease emerged that was associated with prion protein ingestion.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is the best-characterised human TSE. Some 10% of cases arise due to a mutation in the gene coding for the prion protein. The sporadic form is the most common, occurring in middle-aged to elderly patients. Clinical features usually involve a rapidly progressive dementia, with myoclonus and a characteristic EEG pattern (repetitive slow-wave complexes), although a number of other features, such as visual disturbance or ataxia, may also be seen. These are particularly common in CJD transmitted by inoculation (e.g. by infected dura mater grafts). Death occurs after a mean of 4–6 months. There is no effective treatment.

Variant Creutzfeldt–Jakob disease

A variant of CJD (vCJD) emerged in the late 1990s, affecting a small number of patients in the UK. The causative agent appears to be identical to that causing BSE in cows, and the disease may have been a result of the epidemic of BSE in the UK a decade earlier. Patients affected by vCJD are typically younger than those with sporadic CJD and present with neuropsychiatric changes and sensory symptoms in the limbs, followed by ataxia, dementia and death. Progression is slightly slower than in patients with sporadic CJD (mean time to death is over a year). Characteristic EEG changes are not present, but MRI brain scans show characteristic high-signal changes in the pulvinar in a high proportion of cases (Fig. 26.34). Brain histology is distinct, with very florid plaques containing the prion proteins. Abnormal prion protein has been identified in tonsil specimens from sufferers of vCJD, leading to the suggestion that the disease could be transmitted by reticulo-endothelial tissue (like TSEs in animals but unlike sporadic CJD in humans). This has caused great concern in the UK, leading to precautionary measures such as leucodepletion of all blood used for transfusion, and the mandatory use of disposable surgical instruments wherever possible for tonsillectomy, appendicectomy and ophthalmological procedures. The incidence of vCJD has now declined dramatically but surveillance and research continue.

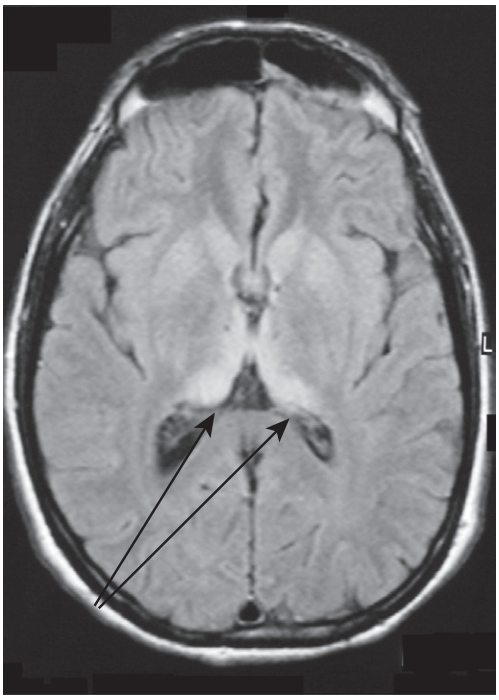

Fig. 26.34 MRI in variant Creutzfeldt–Jakob disease. Arrows indicate bilateral pulvinar hyperintensity.

Other TSE syndromes

Other extremely rare, inherited human TSEs include Gerstmann–Sträussler–Scheinker disease, fatal familial insomnia and kuru. Kuru occurred only in members of a cannibalistic New Guinea tribe and was probably transmitted by people eating the brains of dead tribal members. Clinical features include progressive ataxia and dementia.

INTRACRANIAL MASS LESIONS AND RAISED INTRACRANIAL PRESSURE

Many different types of mass lesion may arise within the intracranial cavity (Box 26.87). In developing countries, tuberculoma and other infections are frequent causes, but in the West, intracranial haemorrhage and brain

26.87 Common causes of raised intracranial pressure

Mass lesions

- Intracranial haemorrhage (traumatic or spontaneous)
  - Extradural haematoma
  - Subdural haematoma
  - Intracerebral haemorrhage
- Cerebral tumour (particularly posterior fossa lesions or high-grade gliomas: see Box 26.89)
- Infective
  - Cerebral abscess
  - Tuberculoma
  - Cysticercosis (p. 380)
  - Hydatid cyst (p. 380)
- Colloid cyst (in ventricles)

Disturbance of CSF circulation

- Obstructive (non-communicating) hydrocephalus: obstruction within ventricular system
- Communicating hydrocephalus: site of obstruction outside ventricular system

Obstruction to venous sinuses

- Cerebral venous thrombosis
- Trauma (depressed fractures overlying sinuses)

Diffuse brain oedema or swelling

- Meningo-encephalitis
- Trauma (diffuse head injury, near-drowning)
- Subarachnoid haemorrhage
- Metabolic (e.g. water intoxication)
- Idiopathic intracranial hypertension

tumours are more common. The clinical features depend on the site of the mass, its nature and its rate of expansion. Symptoms and signs (see Box 26.88) are produced by a number of mechanisms.

Raised intracranial pressure

Raised intracranial pressure (RIP) may be caused by mass lesions, cerebral oedema, obstruction to CSF circulation causing hydrocephalus, impaired CSF absorption and cerebral venous obstruction (see Box 26.87).

Clinical features

In adults, intracranial pressure is less than 10–15 mmHg. The features of RIP are listed in Box 26.88. The speed of pressure increase influences presentation. If slow, compensatory mechanisms may occur, including alteration in the volume of fluid in CSF spaces and venous sinuses, which minimise symptoms. Rapid pressure increase (as in aggressive tumours) does not permit these compensatory mechanisms to occur, leading to early symptoms, including sudden death. Papilloedema is not always present, either because the pressure rise has been too rapid or because of anatomical anomalies of the meningeal sheath of the optic nerve.

A false localising sign is one in which the pathology is remote from the site of the expected lesion; in RIP, the 6th cranial nerve (unilateral or bilateral) is most commonly affected, but the 3rd, 5th and 7th nerves may also be involved. Sixth nerve palsies are thought to be due either to stretching of the long slender nerve or to compression against the petrous temporal bone ridge.

26.88 Clinical features of intracranial mass lesions

Presentation	Features
Seizures	Focal onset ± generalised spread
Focal symptoms	Progressive loss of function Weakness Numbness Dysphasia Cranial neuropathy
False localising signs	Unilateral/bilateral 6th nerve palsies Contralateral 3rd nerve (usually pupil first)
Raised intracranial pressure (usually aggressive tumours causing vasogenic oedema or obstructive hydrocephalus)	Headache worse on lying/straining Vomiting Diplopia (6th nerve involvement) Papilloedema Bradycardia, raised blood pressure Impaired conscious level
Stroke/TIA-like symptoms	Acute haemorrhage into tumour Paroxysmal 'tumour attacks'
Cognitive/behavioural change	Usually frontal mass lesions
Endocrine abnormalities	Pituitary tumours
Incidental finding	Asymptomatic but identified on imaging (meningiomas commonly)

(TIA = transient ischaemic attack)

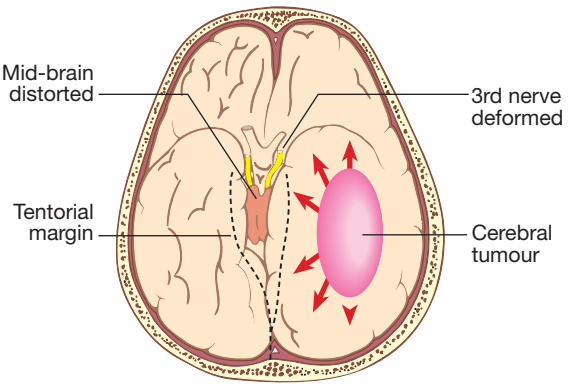

Fig. 26.35 Cerebral tumour displacing medial temporal lobe and causing pressure on the mid-brain and 3rd cranial nerve.

Trans-tentorial herniation of the uncus may compress the ipsilateral 3rd nerve and usually involves the pupillary fibres first, causing a dilated pupil; however, a false localising contralateral 3rd nerve palsy may also occur, perhaps due to extrinsic compression by the tentorial margin. Vomiting, coma, bradycardia and arterial hypertension are later features of RIP.

The rise in intracranial pressure from a mass lesion may cause displacement of the brain. Downward displacement of the medial temporal lobe (uncus) through the tentorium due to a large hemisphere mass may cause 'temporal coning' (Fig. 26.35). This may stretch the 3rd and/or 6th cranial nerves, or cause pressure on the contralateral cerebral peduncle (causing ipsilateral upper motor neuron signs), and is usually accompanied by progressive coma. Downward movement of the

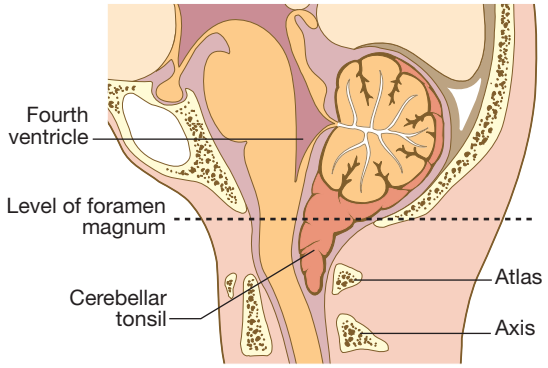

Fig. 26.36 Tonsillar cone. Downward displacement of the cerebellar tonsils below the level of the foramen magnum.

cerebellar tonsils through the foramen magnum may compress the medulla – 'tonsillar coning' (Fig. 26.36). This may result in brainstem haemorrhage and/or acute obstruction of the CSF pathways. As coning progresses, coma and death occur unless the condition is rapidly treated.

Management

Primary management of RIP should be targeted at relieving the cause (e.g. surgical decompression of mass lesion, steroids to reduce vasogenic oedema or shunt procedure to relieve hydrocephalus). Supportive treatment includes maintenance of fluid balance, blood pressure control, head elevation, and use of diuretics such as mannitol. Intensive care support may be needed (p. 199).

Brain tumours

Primary brain tumours are a heterogeneous collection of neoplasms arising from the brain tissue or meninges, and vary from benign to highly malignant. Primary malignant brain tumours (Box 26.89) are rare, accounting for 1% of all adult tumours but a higher proportion in children. The most common benign brain tumour is a meningioma. Primary brain tumours do not metastasise due to the absence of lymphatic drainage in the brain. There are rare pathological subtypes, however, such as medulloblastoma, which do have a propensity to metastasise; the reasons for this are not clear. Most cerebral tumours are sporadic but may be associated with genetic syndromes such as neurofibromatosis or tuberous sclerosis. Brain tumours are not classified by the usual TNM system but by the WHO grading I–IV; this is based on histology (e.g. nuclear pleomorphism, presence of mitoses and presence of necrosis), with grade I being the most benign and grade IV the most malignant. Gliomas account for 60% of brain tumours, with the aggressive glioblastoma multiforme (WHO grade IV) being the most common glioma, followed by meningiomas (20%) and pituitary tumours (10%). Although the lower-grade gliomas (I and II) may be very indolent, with prognosis measured in terms of many years, these tumours may transform to higher-grade disease at any time, with a resultant sharp decline in life expectancy.

Most malignant brain tumours are due to metastases, with intracranial metastases complicating about 20% of extracranial malignancies. The rate is higher with primaries in the bronchus, breast and gastrointestinal tract (Fig. 26.37). Metastases usually occur in the white matter of the cerebral or cerebellar hemispheres, but there are diffuse leptomeningeal types.

26.89 Primary brain tumours

Histological type	Common site	Age
Malignant		
Glioma (astrocytoma)	Cerebral hemisphere Cerebellum Brainstem	Adulthood Childhood/adulthood Childhood/young adulthood
Oligodendroglioma	Cerebral hemisphere	Adulthood
Medulloblastoma	Posterior fossa	Childhood
Ependymoma	Posterior fossa	Childhood/adolescence
Cerebral lymphoma	Cerebral hemisphere	Adulthood
Benign		
Meningioma	Cortical dura Parasagittal Sphenoid ridge Suprasellar Olfactory groove	Adulthood (often incidental finding)
Neurofibroma	Acoustic neuroma	Adulthood
Craniopharyngioma	Suprasellar	Childhood/adolescence
Pituitary adenoma	Pituitary fossa	Adulthood
Colloid cyst	Third ventricle	Any age
Pineal tumours	Quadrigeminal cistern	Childhood (teratomas) Young adulthood (germ cell)

Clinical features

The presentation is variable and usually influenced by the rate of growth. High-grade disease (WHO grade III and IV) tends to present with a short 4–6-week history of mass effect (headache, nausea secondary to RIP), while more indolent tumours can present with slowly progressive focal neurological deficits, depending on their location (see Box 26.88); generalised or focal seizures are common. Headache, if present, is usually accompanied by focal deficits or seizures, and isolated stable headache is almost never due to intracranial tumour.

The size of the primary tumour is of far less prognostic significance than its location within the brain. Tumours within the brainstem will result in early neurological deficits, while those in the frontal region may be quite large before symptoms occur.

Investigations

Diagnosis is by neuroimaging (Figs 26.38 and 26.39) and pathological grading following biopsy or resection where this is possible. The more malignant tumours are more likely to demonstrate contrast enhancement on imaging. If the tumour appears to be metastatic, further investigation to find the primary will be required.

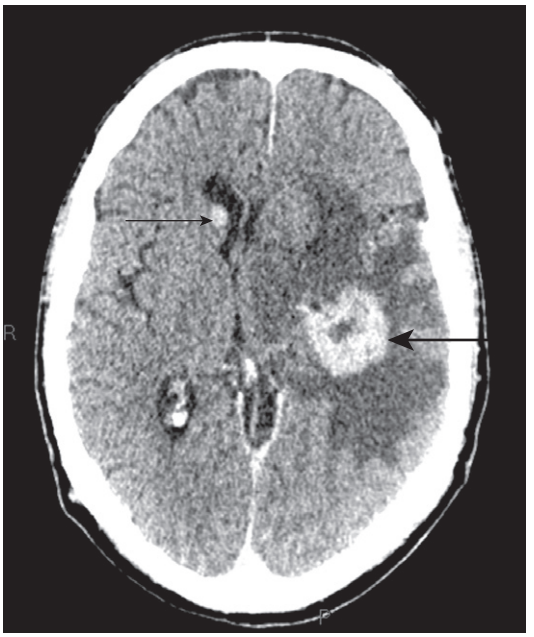

Fig. 26.37 Contrast-enhanced CT head showing a large metastasis within the left hemisphere (large arrow). There is surrounding cerebral oedema, and a smaller metastasis (small arrow) within the wall of the right lateral ventricle. The primary lesion was a lung carcinoma.

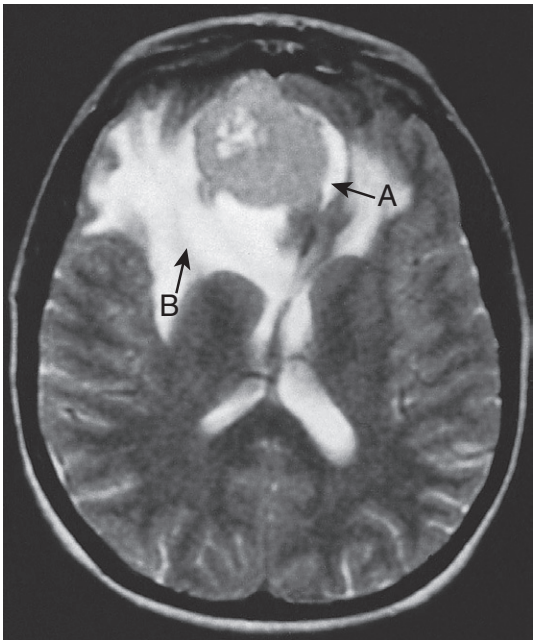

Fig. 26.38 MRI showing a meningioma in the frontal lobe (arrow A) with associated oedema (arrow B).

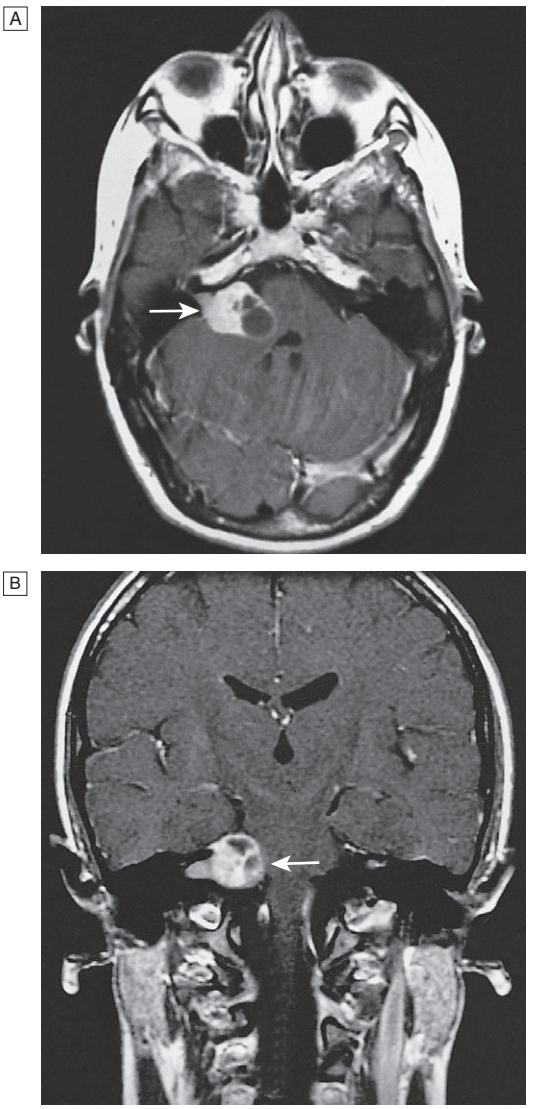

Fig. 26.39 MRI of an acoustic neuroma (arrows) in the posterior fossa compressing the brainstem. A Axial image. B Coronal image.

Management

Brain tumours are treated with a combination of surgery, radiotherapy and chemotherapy, depending on the type of tumour and the patient. Advancing age is the most powerful negative prognostic factor in CNS tumours, so best supportive care (including steroid therapy) may be most appropriate in older patients with metastases or high-grade disease. Treatment may not always be indicated in indolent (low-grade, WHO I or II) disease, and watchful waiting after surgery is often appropriate in such situations.

Dexamethasone given orally (or intravenously where RIP is acutely or severely raised) may reduce the vasogenic oedema typically associated with metastases and high-grade gliomas.

Prolactin- or growth hormone-secreting pituitary adenomas (p. 789) may respond well to treatment with dopamine agonists (such as bromocriptine, cabergoline or quinagolide); in this situation, imaging and hormone levels may be all that is required to establish a formal diagnosis, precluding the need for surgery.

Surgical

The mainstay of primary treatment is surgery, either resective (full or partial debulking) or biopsy, depending on the site and likely radiological diagnosis. Clearly, if a tumour occurs in an area of brain that is highly

important for normal function (e.g. motor strip), then biopsy may be the only safe surgical intervention but, in general, maximal safe resection is the optimal surgical management. Meningiomas and acoustic neuromas offer the best prospects for complete removal and thus cure. Some meningiomas can recur, however, particularly those of the sphenoid ridge when partial excision is often all that is possible. Thereafter, postoperative surveillance may be required, as radiotherapy is effective at preventing further growth of residual tumour. Pituitary adenomas may be removed by a transsphenoidal route, avoiding the need for a craniotomy. Unfortunately, gliomas, which account for the majority of brain tumours, cannot be completely excised, since infiltration spreads well beyond the apparent radiological boundaries of the intracranial mass. Recurrence is therefore the rule, even if the mass of the tumour is apparently removed completely; partial excision ('debulking') may be useful in alleviating symptoms caused by RIP, but although there is increasing evidence that the degree of surgical excision may have a positive influence on survival, this has not yet been demonstrated in a randomised study.

Radiotherapy and chemotherapy

In the majority of primary CNS tumours, radiation and chemotherapy are used to control disease and extend survival rather than for cure. Meningioma and pituitary adenoma offer the best chance of life-long remission. The gliomas are incurable; high-grade, WHO IV disease still carries a median survival of just over a year. In this situation, patient and family should always be involved in decisions regarding treatment. The diagnosis, and often the symptoms, are devastating, and support from palliative care and social work is crucial at an early stage. In WHO grade III disease, prognosis is a little better (2–4 years) and in rarer, more indolent tumours, very prolonged survival is possible.

Advances have been made recently in terms of therapeutic outcome. Standard care for WHO grade IV glioblastoma multiforme is now combination radiotherapy with oral temozolomide chemotherapy; although this improves median survival of the population from only 12 to 14.5 months, up to 25% of patients survive for more than 2 years (compared to approximately 10% with radiotherapy alone). Ten percent will survive more than 5 years with temozolomide (virtually unheard of with radiotherapy alone). Benefits are more likely in well-debulked patients who are younger and fitter. Implantation of chemotherapy gives a small survival benefit.

Understanding of the molecular biology of brain tumours has allowed the use of biomarkers to guide therapy and prognostic discussions. In patients with methylation of the promoter region of the *MGMT* (methyl guanine methyl transferase) gene (about 30% of the population), 2-year survival is almost 50%. MGMT reduces the cytotoxicity of temozolomide, and this mutation also reduces the enzyme's activity, rendering the tumour more sensitive to chemotherapy. In grade II and III gliomas, the presence of the loss of heterozygocity (LOH) 1p19q chromosomal abnormality confers chemosensitivity and thus improves prognosis. The presence of a rare mutation in the *IDH-1* (isocitrate dehydrogenase) gene confers a very favourable prognosis in patients with glioblastoma.

There is a small group of highly malignant grade IV tumours that can be cured with aggressive therapy. Patients with medulloblastomas have a good chance of long-term survival with maximal surgery followed by irradiation of the whole brain and spine; younger patients may also benefit from concomitant and adjuvant chemotherapy. Older patients do not tolerate this, however.

Once tumours relapse, chemotherapy response rates are low and survival is short in high-grade disease. In the more uncommon low-grade tumours, repeated courses of chemotherapy can result in much more prolonged survival.

In metastatic disease, radiotherapy offers a modest improvement in survival but with costs in terms of quality of life; treatment therefore needs careful discussion with the patient. Benefits may be superior in breast cancer but there is little to separate other pathologies. Occasional chemosensitive cancers, such as small-cell lung cancer, may benefit from systemic chemotherapy, but intracerebral metastases represent a late stage of disease and have a short prognosis.

Prognosis

The WHO histological grading system is a powerful predictor of prognosis in primary CNS tumours, though it does not yet take account of individual biomarkers. For each tumour type and grade, advancing age and deteriorating functional status are the next most important negative prognostic features. The overall 5-year survival rate of about 14% in adults masks a wide variation that depends on tumour type.

Acoustic neuroma

This is a benign tumour of Schwann cells of the 8th cranial nerve, which may arise in isolation or as part of neurofibromatosis type 2 (see below). When sporadic, acoustic neuroma occurs after the third decade and is more frequent in females. The tumour commonly arises near the nerve's entry point into the medulla or in the internal auditory meatus, usually on the vestibular division. Acoustic neuromas account for 80–90% of tumours at the cerebellopontine angle.

Clinical features

Acoustic neuroma typically presents with unilateral progressive hearing loss, sometimes with tinnitus. Vertigo is an unusual symptom, as slow growth allows compensatory brainstem mechanisms to develop. In some cases, progressive enlargement leads to distortion of the brainstem and/or cerebellar peduncle, causing ataxia and/or cerebellar signs in the limbs. Distortion of the fourth ventricle and cerebral aqueduct may cause hydrocephalus (see below), which may be the presenting feature. Facial weakness is unusual at presentation but facial palsy may follow surgical removal of the tumour. The tumour may be identified incidentally on cranial imaging.

Investigations

MRI is the investigation of choice (see Fig. 26.39).

Management

Surgery is the treatment of choice. If the tumour can be completely removed, the prognosis is excellent, although

deafness is a common complication of surgery. Stereotactic radiosurgery (radiotherapy) may be appropriate for some lesions.

Neurofibromatosis

Neurofibromatosis encompasses two clinically and genetically separate conditions, with an autosomal dominant pattern of inheritance. The more common neurofibromatosis type 1 (NF1) is caused by mutations in the *NF1* gene on chromosome 17, half of which are new mutations. NF1 is characterised by neurofibromas (benign peripheral nerve sheath tumours) and skin involvement (Fig. 26.40), and may affect numerous systems (Box 26.90). Neurofibromatosis type 2 (NF2) is caused by mutations of the *NF2* gene on chromosome 22, and is characterised by schwannomas (benign peripheral nerve sheath tumours comprising Schwann cells only), with little skin involvement; the clinical manifestations are more restricted to the eye and nervous system (see Box 26.90). Malignant change may occur in NF1 neurofibromas but is rare in NF2 schwannomas. The prevalence of NF1 and NF 2 is about 20–50 per 100 000 and 1.5 per 100 000 respectively.

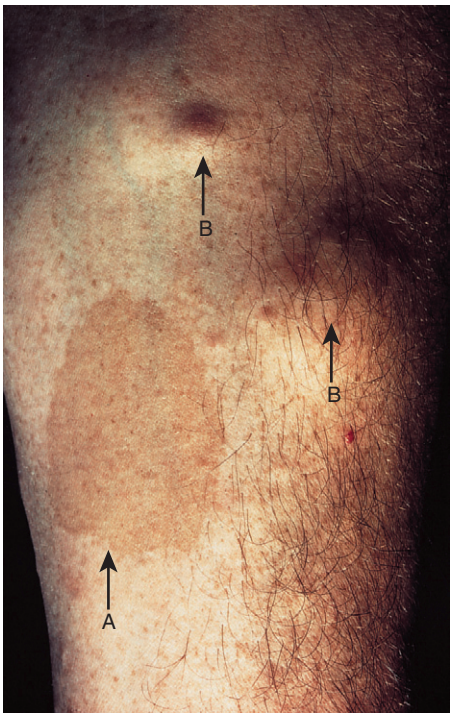

Fig. 26.40 A café au lait spot (arrow A) and subcutaneous nodules (arrows B) on the forearm of a patient with neurofibromatosis type 1.

Von Hippel–Lindau disease

This rare autosomal dominant disease is caused by mutations of the *VHL* tumour suppressor gene on chromosome 3. It promotes development of tumours affecting the kidney, adrenal gland, CNS, eye, inner ear, epididymis and pancreas, which may undergo malignant change. Benign haemangiomas and haemangioblastomas affect about 80% of patients, mostly in the cerebellum and retina.

26.90 Neurofibromatosis types 1 and 2: clinical features

Neurofibromatosis 1	Neurofibromatosis 2
Skin	
Cutaneous/subcutaneous neurofibromas	Much less commonly affected than NF1
Angiomas	Café au lait patches (usually < 6)
Café au lait patches (> 6)	Cutaneous schwannomas: plaque lesions
Axillary/groin freckling	Subcutaneous schwannomas
Hypopigmented patches	
Eyes	
Lisch nodules (iris fibromas)	Cataracts
Glaucoma	Retinal hamartoma
Congenital ptosis	Optic nerve meningioma
Nervous system	
Plexiform neurofibromas	Vestibular schwannomas
Malignant peripheral nerve sheath tumours	Cranial nerve schwannomas (not 1 and 2)
Aqueduct stenosis	Spinal schwannomas
Slight tonsillar descent	Peripheral nerve schwannomas
Cognitive impairment	Cranial meningiomas
Epilepsy	Spinal meningiomas
	Spinal/brainstem ependymomas
	Spinal/cranial astrocytoma
Bone	
Scoliosis	
Osteoporosis	
Pseudoarthrosis	
Cardiorespiratory systems	
Pulmonary stenosis	
Hypertension	
Renal artery stenosis	
Compression from neurofibroma causing restrictive lung defect	
Gastrointestinal system	
Gastrointestinal stromal tumour	
Dysplasia	
Duodenal carcinoid tumour	

Paraneoplastic neurological disease

Paraneoplastic neurological syndromes often present before the underlying tumour declares itself and cause considerable disability. They are discussed in full on page 1193.

Hydrocephalus

Hydrocephalus is the excessive accumulation of CSF within the brain, and may be caused either by increased CSF production, by reduced CSF absorption, or by obstruction of the circulation (Fig. 26.41). Symptoms range from none to sudden death, depending upon the speed at which and degree to which hydrocephalus develops. The causes are listed in Box 26.91. The terms

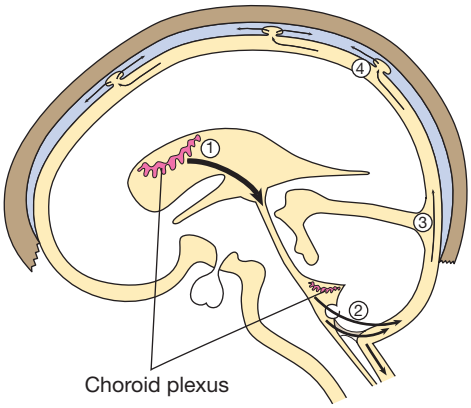

Fig. 26.41 The circulation of cerebrospinal fluid. (1) CSF is synthesised in the choroid plexus of the ventricles, and flows from the lateral and third ventricles through the aqueduct to the fourth ventricle. (2) At the foramina of Luschka and Magendie it exits the brain, flowing over the hemispheres (3) and down around the spinal cord and roots in the subarachnoid space. (4) It is then absorbed into the dural venous sinuses via the arachnoid villi.

26.91 Causes of hydrocephalus

Congenital malformations

- Aqueduct stenosis
- Chiari malformations
- Dandy–Walker syndrome
- Benign intracranial cysts
- Vein of Galen aneurysms
- Congenital CNS infections
- Craniofacial anomalies

Acquired causes

- Mass lesions (especially those in the posterior fossa)
  - Tumour
  - Colloid cyst of third ventricle
  - Abscess
  - Haematoma
- Absorption blockages due to:
  - Inflammation (e.g. meningitis, sarcoidosis)
  - Intracranial haemorrhage

'communicating' and 'non-communicating' (also known as obstructive) hydrocephalus refer to blockage either outside or within the ventricular system respectively (Fig. 26.42).

Normal pressure hydrocephalus

Normal pressure hydrocephalus (NPH) is a controversial entity, said to involve intermittent rises in CSF pressure, particularly at night. It is described in old age as being associated with a triad of gait apraxia, dementia and urinary incontinence.

Management

Diversion of the CSF by means of a shunt placed between the ventricular system and the peritoneal cavity or right atrium may result in rapid relief of symptoms in obstructive hydrocephalus. The outcome of shunting in NPH is much less predictable and, until a good response can be predicted, the management of individual cases will remain uncertain.

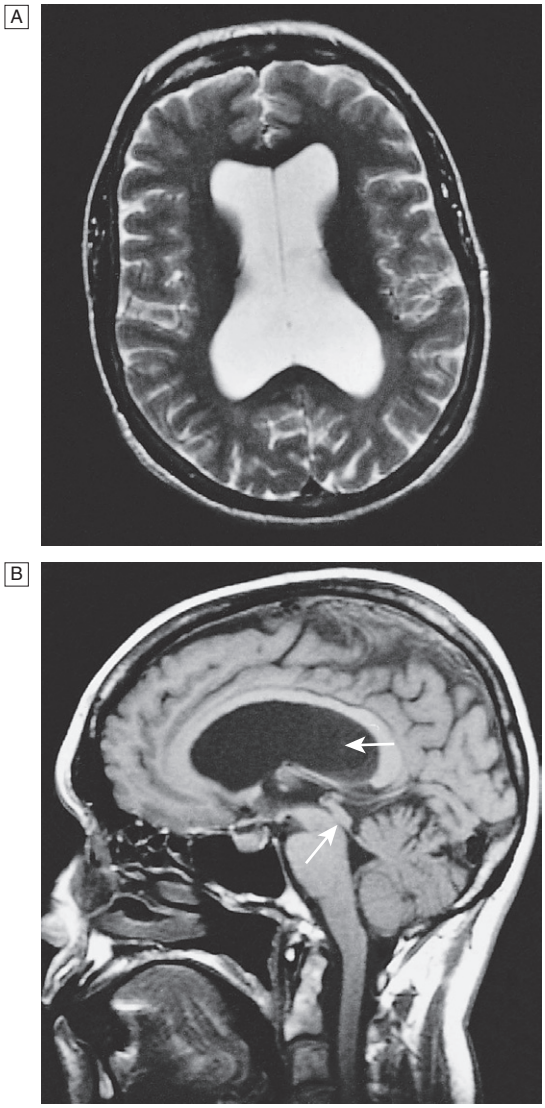

Fig. 26.42 MRI of hydrocephalus due to aqueduct stenosis. A Axial T2-weighted image (CSF appears white): note the dilated lateral ventricles. B Sagittal T2-weighted image (CSF appears black): note the dilated ventricles (top arrow) and narrowed aqueduct (bottom arrow).

Idiopathic intracranial hypertension

This usually occurs in obese young women. The annual incidence is about 3 per 100000. RIP occurs in the absence of a structural lesion, hydrocephalus or other identifiable cause. The aetiology is uncertain but there may be a defect of CSF reabsorption by the arachnoid villi. It may be associated with a number of drugs, including tetracycline, and with vitamin A and its derivatives.

Clinical features

The usual presentation is with headache, sometimes accompanied by diplopia and visual disturbance (most commonly transient obscurations of vision associated with changes in posture). Clinical examination reveals papilloedema but little else. False localising cranial nerve palsies (usually of the 6th nerve) may be present.

It is important to record visual fields accurately for future monitoring.

Investigations

Brain imaging is required to exclude a structural or other (e.g. cerebral venous sinus thrombosis, p. 1247) cause. The ventricles are typically normal in size or small ('slit' ventricles). The diagnosis may be confirmed by lumbar puncture, which shows raised CSF pressure (usually > 30 cm CSF) but normal CSF constituents.

Management

Management can be difficult and there is no evidence to support any specific treatment. Weight loss in overweight patients may be helpful but is difficult to achieve. Acetazolamide or topiramate may help to lower intracranial pressure, the latter perhaps aiding weight loss in some patients. Repeated lumbar puncture is an effective treatment for headache, but may be technically difficult in obese patients and is often poorly tolerated. Patients failing to respond, in whom chronic papilloedema threatens vision, may require optic nerve sheath fenestration or a lumbo-peritoneal shunt.

Head injury

Diagnosis of head trauma is usually clear – either from the history or from signs of external trauma to the head. Brain injury is more likely with skull fracture but can occur without. Individual cranial nerves may be damaged in fractures of the facial bones or skull base. Intracranial effects can be substantial and take several forms: extradural haematoma (collection of blood between the skull and dura); subdural haematoma (collection of blood between the dura and the surface of the brain); and intracerebral haematoma or diffuse axonal injury.

Whatever pathology occurs, the resultant RIP may lead to coning (see Figs 26.35 and 26.36). Haematomas are identified by CT and management is by surgical drainage, usually via a burr-hole. Penetrating skull fractures lead to increased infection risk. Long-term sequelae include headache, cognitive decline and depression, all contributing to significant social, work, personality and family difficulties.

Subdural haematoma may occur spontaneously, particularly in patients on anticoagulants, in old age, and with alcohol misuse. There may or may not be a history of trauma. Patients present with subacute impairment of brain function, both globally (obtundation and coma) and focally (hemiparesis, seizures). Headache may not be present. The diagnosis should always be considered in those who present with reduced conscious level.

DISORDERS OF CEREBELLAR FUNCTION

Cerebellar dysfunction can manifest as incoordination of limb function, gait ataxia (p. 1168), speech or eye movements. Acute dysfunction may be caused by alcohol or prescription drugs (especially the sodium channel-blocking anti-epileptic drugs, phenytoin and carbamazepine).

Inflammatory changes in the cerebellum may cause symptoms in the aftermath of some infections (especially herpes zoster) or as a paraneoplastic phenomenon. The hereditary spinocerebellar ataxias are described on page 1198; they manifest as progressive ataxias in middle and old age, often with other neurological features that aid specific diagnosis.

DISORDERS OF THE SPINE AND SPINAL CORD

The spinal cord and spinal roots may be affected by intrinsic disease or by disorders of the surrounding meninges and bones. The clinical presentation of these conditions depends on the anatomical level at which the cord or roots are affected, as well as the nature of the pathological process involved. It is important to recognise when the spinal cord is at risk of compression (p. 1220) so that urgent action can be taken.

Cervical spondylosis

Cervical spondylosis is the result of osteoarthritis in the cervical spine. It is characterised by degeneration of the intervertebral discs and osteophyte formation. Such 'wear and tear' is extremely common and radiological changes are frequently found in asymptomatic individuals over the age of 50. Spondylosis may be associated with neurological dysfunction. In order of frequency, the C5/6, C6/7 and C4/5 vertebral levels affect C6, C7 and C5 roots, respectively (Fig. 26.43).

Cervical radiculopathy

Acute onset of compression of a nerve root occurs when a disc prolapses laterally. More gradual onset may be due to osteophytic encroachment of the intervertebral foramina.

Fig. 26.43 MRI showing cervical cord compression (arrow) in cervical spondylosis.

26.92 Physical signs in cervical root compression

Root	Muscle weakness	Sensory loss	Reflex loss
C5	Biceps, deltoid, spinati	Upper lateral arm	Biceps
C6	Brachioradialis	Lower lateral arm, thumb, index finger	Supinator
C7	Triceps, finger and wrist extensors	Middle finger	Triceps

Clinical features

The patient complains of pain in the neck that may radiate in the distribution of the affected nerve root. The neck is held rigidly and neck movements may exacerbate pain. Paraesthesia and sensory loss may be found in the affected segment and there may be lower motor neuron signs, including weakness, wasting and reflex impairment (Box 26.92).

Investigations

Where there is no trauma, imaging should not be carried out for isolated cervical pain. X-rays offer limited benefit, except in excluding destructive lesions. MRI is the investigation of choice in those with radicular symptoms. Electrophysiological studies rarely add to clinical examination and have become less important with the emergence of MRI.

Management

Conservative treatment with analgesics and physiotherapy results in resolution of symptoms in the great majority of patients, but a few require surgery in the form of discectomy or radicular decompression.

Cervical myelopathy

Dorsomedial herniation of a disc and the development of transverse bony bars or posterior osteophytes may result in pressure on the spinal cord or the anterior spinal artery, which supplies the anterior two-thirds of the cord (see Fig. 26.43).

Clinical features

The onset is usually insidious and painless, but acute deterioration may occur after trauma, especially hyperextension injury. Upper motor neuron signs develop in the limbs, with spasticity of the legs usually appearing before the arms are involved. Sensory loss in the upper limbs is common, producing tingling, numbness and proprioception loss in the hands, with progressive clumsiness. Sensory manifestations in the legs are much less common. Neurological deficit usually progresses gradually and disturbance of micturition is a very late feature.

Investigations

MRI (see Fig. 26.43) (or rarely myelography) will direct surgical intervention. MRI also provides information on the state of the spinal cord at the level of compression.

Management

Surgical procedures, including laminectomy and anterior discectomy, may arrest progression of disability but neurological improvement is not the rule. The decision as to whether surgery should be undertaken may be difficult. Manual manipulation of the cervical spine is of no proven benefit and may precipitate acute neurological deterioration.

Prognosis

The prognosis of cervical myelopathy is variable. In many patients, the condition stabilises or even improves without intervention. If progression results in sphincter dysfunction or pyramidal signs, surgical decompression should be considered.

Lumbar spondylosis

This term covers degenerative disc disease and osteoarthritic change in the lumbar spine. Pain in the distribution of the lumbar or sacral roots ('sciatica') is almost always due to disc protrusion but can be a feature of other rare but important disorders, including spinal tumour, malignant disease in the pelvis and tuberculosis of the vertebral bodies.

Lumbar disc herniation

While acute lumbar disc herniation is often precipitated by trauma (usually lifting heavy weights while the spine is flexed), genetic factors may also be important. The nucleus pulposus may bulge or rupture through the annulus fibrosus, giving rise to pressure on nerve endings in the spinal ligaments, changes in the vertebral joints or pressure on nerve roots.

Pathophysiology

The altered mechanics of the lumbar spine result in loss of lumbar lordosis and there may be spasm of the paraspinal musculature. Root pressure is suggested by limitation of flexion of the hip on the affected side if the straight leg is raised (Lasègue's sign). If the third or fourth lumbar root is involved, Lasègue's sign may be negative, but pain in the back may be induced by hyperextension of the hip (femoral nerve stretch test). The roots most frequently affected are S1, L5 and L4; the signs of root pressure at these levels are summarised in Box 26.93.

26.93 Physical signs in lumbar root compression

Disc level	Root	Sensory loss	Weakness	Reflex loss
L3/L4	L4	Inner calf	Inversion of foot	Knee
L4/L5	L5	Outer calf and dorsum of foot	Dorsiflexion of hallux/ toes	
L5/S1	S1	Sole and lateral foot	Plantar flexion	Ankle

Clinical features

The onset may be sudden or gradual. Alternatively, repeated episodes of low back pain may precede sciatica by months or years. Constant aching pain is felt in the lumbar region and may radiate to the buttock, thigh, calf and foot. Pain is exacerbated by coughing or straining but may be relieved by lying flat.

Investigations

Plain X-rays of the lumbar spine are of little value in the diagnosis of lumbar disc disease, although they may show other conditions such as malignant infiltration of a vertebral body. While CT can provide helpful images of the disc protrusion and/or narrowing of the exit foramina, MRI is the investigation of choice if available, since soft tissues are well imaged.

Management

Some 90% of patients with sciatica recover following conservative treatment with analgesia and early mobilisation; bed rest does not help recovery. The patient should be instructed in back-strengthening exercises and advised to avoid physical manœuvres likely to strain the lumbar spine. Injections of local anaesthetic or corticosteroids may be useful adjunctive treatment if symptoms are due to ligamentous injury or joint dysfunction. Surgery may have to be considered if there is no response to conservative treatment or if progressive neurological deficits develop. Central disc prolapse with bilateral symptoms and signs and disturbance of sphincter function requires urgent surgical decompression.

Lumbar canal stenosis

This occurs with a congenitally narrowed lumbar spinal canal, exacerbated by the degenerative changes that commonly occur with age.

Pathophysiology

The symptoms of spinal stenosis are thought to be due to local vascular compromise secondary to the canal stenosis, rendering the nerve roots ischaemic and intolerant of the increased demand that occurs on exercise.

Clinical features

Patients, who are usually elderly, develop exercise-induced weakness and paraesthesia in the legs ('spinal claudication'). These symptoms progress with continued exertion, often to the point that the patient can no longer walk, but are quickly relieved by a short period of rest. Physical examination at rest shows preservation of peripheral pulses with absent ankle reflexes. Weakness or sensory loss may only be apparent if the patient is examined immediately after exercise.

Investigations

The investigation of first choice is MRI, but contraindications (body habitus, metallic implants) may make CT or myelography necessary.

Management

Lumbar laminectomy may provide relief of symptoms and recovery of normal exercise tolerance.

Spinal cord compression

Spinal cord compression is one of the more common neurological emergencies encountered in clinical practice and the usual causes are listed in Box 26.94. A space-occupying lesion within the spinal canal may damage nerve tissue either directly by pressure or indirectly by interfering with blood supply. Oedema from venous obstruction impairs neuronal function, and ischaemia from arterial obstruction may lead to necrosis of the spinal cord. The early stages of damage are reversible but severely damaged neurons do not recover; hence the importance of early diagnosis and treatment.

Clinical features

The onset of symptoms of spinal cord compression is usually slow (over weeks) but can be acute as a result of trauma or metastases, especially if there is associated arterial occlusion. The symptoms are shown in Box 26.95.

Pain and sensory symptoms occur early, while weakness and sphincter dysfunction are usually late manifestations. The signs vary according to the level of the cord compression and the structures involved. There may be

26.94 Causes of spinal cord compression

Site	Frequency	Causes
Vertebral	80%	Trauma (extradural) Intervertebral disc prolapse Metastatic carcinoma (e.g. breast, prostate, bronchus) Myeloma Tuberculosis
Meninges (intradural, extramedullary)	15%	Tumours (e.g. meningioma, neurofibroma, ependymoma, metastasis, lymphoma, leukaemia) Epidural abscess
Spinal cord (intradural, intramedullary)	5%	Tumours (e.g. glioma, ependymoma, metastasis)

26.95 Symptoms of spinal cord compression

Pain
• Localised over the spine or in a root distribution, which may be aggravated by coughing, sneezing or straining
Sensory
• Paraesthesia, numbness or cold sensations, especially in the lower limbs, which spread proximally, often to a level on the trunk
Motor
• Weakness, heaviness or stiffness of the limbs, most commonly the legs
Sphincters
• Urgency or hesitancy of micturition, leading eventually to urinary retention

26.96 Signs of spinal cord compression

Cervical, above C5

- Upper motor neuron signs and sensory loss in all four limbs
- Diaphragm weakness (phrenic nerve)

Cervical, C5–T1

- Lower motor neuron signs and segmental sensory loss in the arms; upper motor neuron signs in the legs
- Respiratory (intercostal) muscle weakness

Thoracic cord

- Spastic paraplegia with a sensory level on the trunk
- Weakness of legs, sacral loss of sensation and extensor plantar responses

Cauda equina

- Spinal cord ends approximately at the T12/L1 spinal level and spinal lesions below this level can only cause lower motor neuron signs by affecting the cauda equina

26.97 Investigation of acute spinal cord syndrome

- MRI of spine or myelography
- Plain X-rays of spine
- Chest X-ray
- CSF
- Serum B_{12}

tenderness to percussion over the spine if there is vertebral disease and this may be associated with a local kyphosis. Involvement of the roots at the level of the compression may cause dermatomal sensory impairment and corresponding lower motor signs. Interruption of fibres in the spinal cord causes sensory loss (p. 1164) and upper motor neuron signs below the level of the lesion, and there is often disturbance of sphincter function. The distribution of these signs varies with the level of the lesion (Box 26.96).

The Brown–Séquard syndrome (see Fig. 26.19E, p. 1164) results if damage is confined to one side of the cord; the findings are explained by the anatomy of the sensory tracts (see Fig. 26.10, p. 1147). With compressive lesions, there is usually a band of pain at the level of the lesion in the distribution of the nerve roots subject to compression.

Investigations

Patients with a history of acute or subacute spinal cord syndrome should be investigated urgently, as listed in Box 26.97. The investigation of choice is MRI (Fig. 26.44), as it can define the extent of compression and associated soft-tissue abnormality (Fig. 26.45). Plain X-rays may show bony destruction and soft-tissue abnormalities. Routine investigations, including chest X-ray, may provide evidence of systemic disease. If myelography is performed, CSF should be taken for analysis; in cases of complete spinal block, this shows a normal cell count with a very elevated protein causing yellow discoloration of the fluid (Froin's syndrome). The risk of acute deterioration after myelography in spinal cord compression means that the neurosurgeons should be alerted

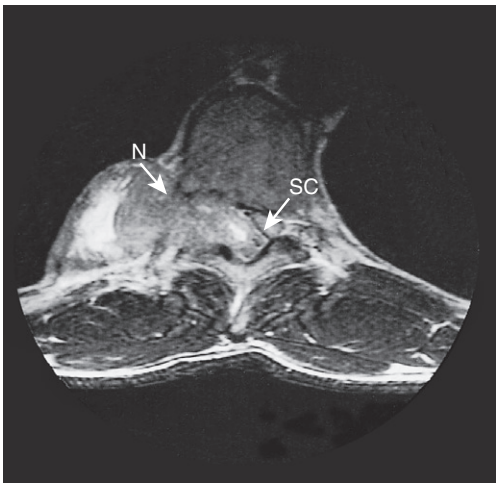

Fig. 26.44 Axial MRI of thoracic spine. A neurofibroma (N) is compressing the spinal cord (SC) and emerging in a 'dumbbell' fashion through the vertebral foramen into the paraspinal space.

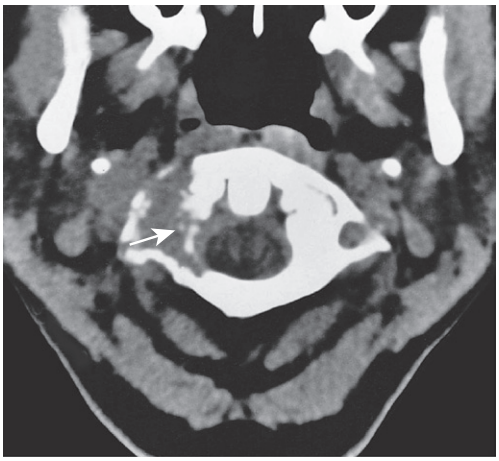

Fig. 26.45 CT myelogram of cervical spine at the level of C2 showing bony erosion of vertebra by a metastasis (arrow).

before it is undertaken. Where a secondary tumour is causing the compression, needle biopsy may be required to establish a tissue diagnosis.

Management

Treatment and prognosis depend on the nature of the underlying lesion. Benign tumours should be surgically excised, and a good functional recovery can be expected unless a marked neurological deficit has developed before diagnosis. Extradural compression due to malignancy is the most common cause of spinal cord compression in developed countries and has a poor prognosis. Useful function can be regained if treatment, such as radiotherapy, is initiated within 24 hours of the onset of severe weakness or sphincter dysfunction; management should involve close cooperation with both oncologists and neurosurgeons.

Spinal cord compression due to tuberculosis is common in some areas of the world, and may require surgical treatment. This should be followed by appropriate antituberculous chemotherapy (p. 693) for an

extended period. Traumatic lesions of the vertebral column require specialised neurosurgical treatment.

Intrinsic diseases of the spinal cord

There are many disorders that interfere with spinal cord function due to non-compressive involvement of the spinal cord itself. A list of these disorders is given in Box 26.98. The symptoms and signs are generally similar to those that would occur with extrinsic compression (see Boxes 26.95 and 26.96), although a suspended sensory loss (see Fig. 26.19F, p. 1164) can only occur with intrinsic disease such as syringomyelia. Urinary symptoms usually occur earlier in the course of an intrinsic cord disorder than with compressive disorders.

Investigation of intrinsic disease starts with imaging to exclude a compressive lesion. MRI provides most information about structural lesions such as diastematomyelia, syringomyelia (Fig. 26.46) or intrinsic tumours. Non-specific signal change may be seen in the spinal cord in inflammatory (see Fig. 26.28, p. 1191) or infective conditions and other disorders such as vitamin B_{12} deficiency. Lumbar puncture or blood tests may be required to make a specific diagnosis.

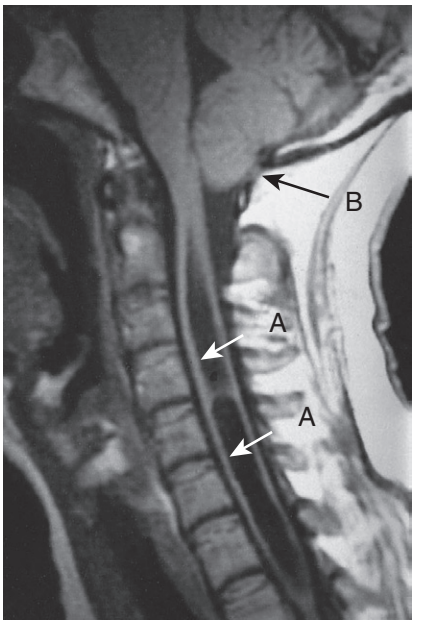

Fig. 26.46 MRI scan showing syrinx (arrows A), with herniation of cerebellar tonsils (arrow B).

26.98 Intrinsic diseases of the spinal cord

Type of disorder	Condition	Clinical features
Congenital	Diastematomyelia (spina bifida)	Features variably present at birth and deteriorate thereafter LMN features, deformity and sensory loss of legs Impaired sphincter function Hairy patch or pit over low back Incidence reduced by increased maternal intake of folic acid during pregnancy
	Hereditary spastic paraplegia	Onset usually in adult life Autosomal dominant inheritance usual Slowly progressive UMN features affecting legs > arms Little or no sensory loss
Infective/ inflammatory	Transverse myelitis due to viruses (HZV), schistosomiasis, HIV, MS, sarcoidosis	Weakness and sensory loss, often with pain, developing over hours to days UMN features below lesion Impaired sphincter function
Vascular	Anterior spinal artery infarct Intervertebral disc embolus	Abrupt onset Anterior horn cell loss (LMN) at level of lesion UMN features below it Spinothalamic sensory loss below lesion but dorsal column sensation spared
	Spinal AVM/dural fistula	Onset variable (acute to slowly progressive) Variable LMN, UMN, sensory and sphincter disturbance Symptoms and signs often not well localised to site of AVM
Neoplastic	Glioma, ependymoma	Weakness and sensory loss often with pain, developing over months to years UMN features below lesion in cord; additional LMN features in conus Impaired sphincter function
Metabolic	Vitamin B_{12} deficiency (subacute combined degeneration)	Progressive spastic paraparesis with proprioception loss Absent reflexes due to peripheral neuropathy ± Optic nerve and cerebral involvement (p. 129)
Degenerative	Motor neuron disease	Relentlessly progressive LMN and UMN features, associated bulbar weakness No sensory involvement (p. 1200)
	Syringomyelia	Gradual onset over months or years, pain in cervical segments Anterior horn cell loss (LMN) at level of lesion, UMN features below it Suspended spinothalamic sensory loss at level of lesion, dorsal columns preserved. See Figures 26.19F (p. 1164) and 26.46

(AVM = arteriovenous malformation; HIV = human immunodeficiency virus; HZV = herpes zoster virus; LMN = lower motor neuron; MS = multiple sclerosis; UMN = upper motor neuron)

DISEASES OF PERIPHERAL NERVES

Disorders of the peripheral nervous system are common and may affect the motor, sensory or autonomic components, either in isolation or combination. The site of pathology may be nerve root (radiculopathy), nerve plexus (plexopathy) or nerve (neuropathy). Neuropathies may present as mononeuropathy (single nerve affected), multiple mononeuropathies ('mononeuritis multiplex') or a symmetrical polyneuropathy (Box 26.99). Cranial nerves 3–12 share the same tissue characteristics as peripheral nerves elsewhere and are subject to the same range of diseases.

Pathophysiology

Damage may occur to the nerve cell body (axon) or the myelin sheath (Schwann cell), leading to axonal or demyelinating neuropathies. The distinction is important, as only demyelinating neuropathies are usually susceptible to treatment; making the distinction requires neurophysiology (nerve conduction studies and electromyography, pp. 1151 and 1152). Neuropathies can occur in association with many systemic diseases, toxins and drugs (Box 26.100).

Clinical features

Motor nerve involvement produces features of a lower motor neuron lesion (p. 1162). Symptoms and signs of sensory nerve involvement depend on the type of sensory nerve involved (p. 1164); small-fibre neuropathies are often painful. Autonomic involvement may cause postural hypotension, disturbance of sweating, cardiac rhythm, and gastrointestinal, bladder and sexual functions; isolated autonomic neuropathies are rare, and more commonly complicate other neuropathies.

Investigations

The investigations required reflect the wide spectrum of causes (Box 26.101). Neurophysiological tests are key in discriminating between demyelinating and axonal neuropathies, and in identifying entrapment neuropathies. Most neuropathies are of the chronic axonal type.

26.99 Causes of polyneuropathy

Genetic

- Charcot–Marie–Tooth disease (CMT)
- Hereditary neuropathy with liability to pressure palsies (HNPP)
- Hereditary sensory ± autonomic neuropathies (HSN, HSAN)
- Familial amyloid polyneuropathy
- Hereditary neuralgic amyotrophy

Drugs

- Amiodarone
- Antibiotics (dapsone, isoniazid, metronidazole, ethambutol)
- Antiretrovirals
- Chemotherapy (cisplatin, vincristine, thalidomide)
- Phenytoin

Toxins

- Alcohol
- Nitrous oxide (recreational use)
- Rarely: lead, arsenic, mercury, organophosphates, solvents

Vitamin deficiencies

- Thiamin
- Pyridoxine
- Vitamin B_{12}
- Vitamin E

Infections

- HIV
- Leprosy
- Brucellosis

Inflammatory

- Guillain–Barré syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Vasculitis (polyarteritis nodosa, granulomatosis with polyangiitis (also known as Wegener's granulomatosis), rheumatoid arthritis, SLE)
- Paraneoplastic (antibody-mediated)

Systemic medical conditions

- Diabetes
- Renal failure
- Sarcoidosis

Malignant disease

- Infiltration

Others

- Paraproteinaemias
- Amyloidosis
- Critical illness polyneuropathy/myopathy

26.100 Common causes of axonal and demyelinating chronic polyneuropathies

Axonal

- Diabetes mellitus
- Alcohol
- Uraemia
- Cirrhosis
- Amyloid
- Myxoedema
- Acromegaly
- Paraneoplastic
- Drugs and toxins (see Box 26.99)
- Deficiency states (see Box 26.99)
- Hereditary
- Infection (see Box 26.99)
- Idiopathic

Demyelinating

- Chronic inflammatory demyelinating polyradiculoneuropathy
- Multifocal motor neuropathy
- Paraprotein-associated demyelinating neuropathy
- Charcot–Marie–Tooth disease type I and type X

26.101 Investigation of peripheral neuropathy

Initial tests

- Glucose (fasting)
- Erythrocyte sedimentation rate, C-reactive protein
- Full blood count
- Urea and electrolytes
- Liver function tests
- Serum protein electrophoresis
- Vitamin B_{12}, folate
- ANA, ANCA
- Chest X-ray
- HIV testing

If initial tests are negative

- Nerve conduction studies
- Vitamins E and A
- Genetic testing (see Box 26.99)
- Lyme serology (p. 335)
- Serum ACE
- Serum amyloid

(ACE = angiotensin-converting enzyme; ANCA = antineutrophil cytoplasmic antibody; ANA = antineutrophil antibody)

26.102 Symptoms and signs in common entrapment neuropathies

Nerve	Symptoms	Muscle weakness/ muscle-wasting	Area of sensory loss
Median (at wrist) (carpal tunnel syndrome)	Pain and paraesthesia on palmar aspect of hands and fingers, waking the patient from sleep. Pain may extend to arm and shoulder	Abductor pollicis brevis	Lateral palm and thumb, index, middle and lateral half 4th finger
Ulnar (at elbow)	Paraesthesia on medial border of hand, wasting and weakness of hand muscles	All small hand muscles, excluding abductor pollicis brevis	Medial palm and little finger, and medial half 4th finger
Radial	Weakness of extension of wrist and fingers, often precipitated by sleeping in abnormal posture, e.g. arm over back of chair	Wrist and finger extensors, supinator	Dorsum of thumb
Common peroneal	Foot drop, trauma to head of fibula	Dorsiflexion and eversion of foot	Nil or dorsum of foot
Lateral cutaneous nerve of the thigh (meralgia paraesthetica)	Tingling and dysaesthesia on lateral border of thigh	Nil	Lateral border of thigh

Entrapment neuropathy

Focal compression or entrapment is the usual cause of a mononeuropathy. Symptoms and signs of entrapment neuropathy are listed in Box 26.102. Entrapment neuropathies may affect anyone, but diabetes, excess alcohol or toxins, or genetic syndromes may be predisposing causes. Unless axonal loss has occurred, entrapment neuropathies will recover, provided the primary cause is removed, either by avoiding the precipitation of activity or by surgical decompression.

Multifocal neuropathy

Multifocal neuropathy (mononeuritis multiplex) is characterised by lesions of multiple nerve roots, peripheral nerves or cranial nerves (Box 26.103). Vasculitis is a common cause, either as part of a systemic disease or isolated to the nerves, or it may arise on a background of a polyneuropathy (e.g. diabetes). Multifocal motor neuropathy (MMN) with conduction block is a rare pure motor neuropathy, typically affecting the arms; it is associated with anti-GM1 antibodies in about 50%, and responds to intravenous immunoglobulin.

26.103 Causes of multifocal mononeuropathy

Axonal (defined on nerve conduction studies)

- Vasculitis (systemic or non-systemic)
- Diabetes mellitus
- Sarcoidosis
- Infection (HIV, hepatitis C, Lyme disease, leprosy, diphtheria)

Focal demyelination with/without conduction block

- Multifocal motor neuropathy
- Multiple compression neuropathies (usually in association with underlying disease, such as diabetes or alcoholism)
- Multifocal acquired demyelinating sensory and motor neuropathy (MADSAM)
- Hereditary neuropathy with a predisposition to pressure palsy (autosomal dominant, peripheral myelin protein 22 gene)
- Lymphoma

Polyneuropathy

A polyneuropathy is typically associated with a 'length-dependent' pattern, occurring in the longest peripheral nerves first and affecting the distal lower limbs before the upper limbs. Sensory symptoms and signs develop in an ascending 'glove and stocking' distribution (p. 1164). In inflammatory demyelinating neuropathies, the pathology may be more patchy, affecting the upper rather than lower limbs.

Guillain–Barré syndrome

Guillain–Barré syndrome (GBS) is a heterogeneous group of immune-mediated conditions with an incidence of 1–2/100 000/year. In Europe and North America, the most common variant is an acute inflammatory demyelinating polyneuropathy (AIDP). Axonal variants, either motor (acute motor axonal neuropathy, AMAN) or sensorimotor (acute motor and sensory axonal neuropathy, AMSAN), are more common in China and Japan, and account for 10% of GBS in Western countries (often associated with *Campylobacter jejuni*). The hallmark is an acute paralysis evolving over days or weeks with loss of tendon reflexes. About two-thirds of those with AIDP have a prior history of infection, and an autoimmune response triggered by the preceding infection causes demyelination. A number of GBS variants have been described, associated with specific anti-ganglioside antibodies; the best-recognised is Miller Fisher syndrome, which involves anti-GQ1b antibodies.

Clinical features

Distal paraesthesia and pain precede muscle weakness that ascends rapidly from lower to upper limbs, and is more marked proximally than distally. Facial and bulbar weakness commonly develops, and respiratory weakness requiring ventilatory support occurs in 20% of cases. Weakness progresses over a maximum of 4 weeks

(usually less). Rapid deterioration to respiratory failure can develop within hours. Examination shows diffuse weakness with loss of reflexes. Miller Fisher syndrome presents with internal and external ophthalmoplegia, ataxia and areflexia.

Investigations

The CSF protein is raised, but may be normal in the first 10 days. There is usually no increase in CSF white cell count ($> 10 \times 10^6$ cells/L suggests an alternative diagnosis). Electrophysiological changes may emerge after a week or so, with conduction block and multifocal motor slowing, sometimes most evident proximally as delayed F waves (p. 1152). Antibodies to the ganglioside GM1 are found in about 25%, usually the motor axonal form. Other causes of an acute neuromuscular paralysis should be excluded (e.g. poliomyelitis, botulism, diphtheria, spinal cord syndromes or myasthenia), via the history and examination rather than investigations.

Management

Supportive measures to prevent pressure sores and deep venous thrombosis are essential. Regular monitoring of respiratory function (vital capacity) is needed in the acute phase, as respiratory failure may develop with little warning. Active treatment with plasma exchange or intravenous immunoglobulin therapy shortens the duration of ventilation and improves prognosis (Box 26.104). Overall, 80% of patients recover completely within 3–6 months, 4% die and the remainder suffer residual neurological disability, which can be severe. Adverse prognostic features include older age, rapid deterioration to ventilation and evidence of axonal loss on EMG.

EBM 26.104 Intravenous immunoglobulin and plasma exchange in Guillain–Barré syndrome

'In severe Guillain–Barré syndrome (GBS), intravenous immunoglobulin (IVIg) started within 2 weeks of onset hastens recovery as much as plasma exchange (PE). Adverse events are not significantly more frequent with either treatment, but IVIg is significantly much more likely to be completed than PE.'

'In mild GBS, 2 sessions of PE are significantly superior to none; in moderate disease, 4 sessions are significantly superior to 2; and in severe disease, 6 sessions are not significantly better than 4. PE is more beneficial when started within 7 days of disease onset rather than later, but is still beneficial in patients treated up to 30 days after disease onset.'

Chronic polyneuropathy

The most common axonal and demyelinating causes of polyneuropathy are shown in Box 26.100. A chronic symmetrical axonal polyneuropathy, evolving over months or years, is the most common form of chronic neuropathy. Diabetes mellitus is the most common cause but in about 25–50% no cause can be found.

Hereditary neuropathy

Charcot–Marie–Tooth disease (CMT) is an umbrella term for the inherited neuropathies. This group of syndromes has different clinical and genetic features. The most common CMT is the autosomal dominantly inherited CMT type 1, usually caused by duplication of the *PMP-22* gene on chromosome 17. Common signs are distal wasting ('inverted champagne bottle' legs), often with pes cavus, and predominantly motor involvement. X-linked and recessively inherited forms of CMT, causing demyelinating or axonal neuropathies, also occur.

Chronic demyelinating polyneuropathy

The acquired chronic demyelinating neuropathies include chronic inflammatory demyelinating peripheral neuropathy (CIDP), multifocal motor neuropathy (see above) and paraprotein-associated demyelinating neuropathy. CIDP typically presents with relapsing or progressive motor and sensory changes, evolving over more than 8 weeks (in distinction to the more acute GBS). It is important to recognise, as it usually responds to corticosteroids, plasma exchange or intravenous immunoglobulin.

Some 10% of patients with acquired demyelinating polyneuropathy have an abnormal serum paraprotein, sometimes associated with a lymphoproliferative malignancy. They may also demonstrate positive antibodies to myelin-associated glycoprotein (anti-MAG antibodies).

Brachial plexopathy

Trauma usually damages either the upper or the lower parts of the brachial plexus, according to the mechanics of the injury. The clinical features depend on the anatomical site of the damage (Box 26.105). Lower parts of the brachial plexus are vulnerable to infiltration from breast or apical lung tumours (Pancoast tumour, p. 701)

26.105 Physical signs in brachial plexus lesions

Site	Affected muscles	Sensory loss
Upper plexus (Erb–Duchenne)	Biceps, deltoid, spinati, rhomboids, brachioradialis (triceps, serratus anterior)	Patch over deltoid
Lower plexus (Déjerine–Klumpke)	All small hand muscles, claw hand (ulnar wrist flexors)	Ulnar border of hand/forearm
Thoracic outlet syndrome	Small hand muscles, ulnar forearm	Ulnar border of hand/forearm/upper arm

or damage by therapeutic irradiation; they may also be compressed by a cervical rib or fibrous band between C7 and the first rib at the thoracic outlet.

An acute brachial plexopathy of probable inflammatory origin may present with 'neuralgic amyotrophy'. Severe shoulder pain precedes the appearance of a patchy upper brachial plexus lesion, with motor and/or sensory involvement. There is no specific treatment and recovery is often incomplete; it may recur in about 25%, and there is a rare autosomal dominant hereditary form. The appearance of vesicles should indicate the alternative diagnosis of motor zoster.

Lumbosacral plexopathy

Lumbosacral plexus lesions may be caused by neoplastic infiltration or compression by retroperitoneal haematomas. A small-vessel vasculopathy can produce a unilateral or bilateral lumbar plexopathy in association with type 2 diabetes mellitus ('diabetic amyotrophy') or an idiopathic form in non-diabetic patients. This presents with painful wasting of the quadriceps with weakness of knee extension and an absent knee reflex.

Spinal root lesions

Spinal root lesions (radiculopathy) are described above. Clinical features include muscle weakness and wasting and dermatomal sensory and reflex loss, which reflect the pattern of the roots involved. Pain in the muscles innervated by the affected roots may be prominent.

DISEASES OF THE NEUROMUSCULAR JUNCTION

Myasthenia gravis

This is the most common cause of acutely evolving, fatigable weakness and preferentially affects ocular, facial and bulbar muscles.

Pathophysiology

Myasthenia gravis is an autoimmune disease, most commonly caused by antibodies to acetylcholine receptors in the post-junctional membrane of the neuromuscular junction, which are found in around 80% of affected patients. The resultant blockage of neuromuscular transmission and complement-mediated inflammatory response reduces the number of acetylcholine receptors and damages the end plate (Fig. 26.47). Other antibodies can produce a similar clinical picture, most notably autoantibodies to muscle-specific kinase (MuSK), which is involved in the regulation and maintenance of acetylcholine receptors.

About 15% of patients (mainly those with late onset) have a thymoma, most of the remainder displaying thymic follicular hyperplasia. Myasthenic patients are at greater risk of associated organ-specific autoimmune diseases. As with other autoimmune processes, triggers are not always evident, but some drugs (e.g. penicillamine) can trigger an antibody-mediated myasthenic syndrome that may persist after drug withdrawal. Other drugs, especially aminoglycosides and quinolones, may exacerbate the neuromuscular blockade and should be avoided in patients with myasthenia.

Clinical features

Myasthenia gravis usually presents between the ages of 15 and 50 years and there is a female preponderance in younger patients. In older patients, males are more commonly affected. It tends to run a relapsing and remitting course.

The most evident symptom is fatigable muscle weakness; movement is initially strong but rapidly weakens as muscle use continues. Worsening of symptoms towards the end of the day or following exercise is characteristic. There are no sensory signs or signs of involvement of the CNS, although weakness of the oculomotor muscles may mimic a central eye movement disorder. The first symptoms are usually intermittent ptosis or diplopia, but weakness of chewing, swallowing, speaking or limb movement also occurs. Any limb muscle may be affected, most commonly those of the shoulder girdle; the patient is unable to undertake tasks above shoulder level, such as combing the hair, without frequent rests. Respiratory muscles may be involved and respiratory failure is an avoidable cause of death. Aspiration may occur if the cough is ineffectual. Ventilatory support is required where weakness is severe or of abrupt onset.

Investigations

Intravenous injection of the short-acting anticholinesterase, edrophonium bromide (the Tensilon® test), is less widely used than before. Improvement in muscle function occurs within 30 seconds and usually persists for 2–3 minutes, but the test is not universally specific or sensitive. Cover with intravenous atropine is necessary to avoid bradycardia. Planning the assessment beforehand (e.g. speech or limb movements) allows some objectivity in gauging the effect.

Repetitive stimulation during nerve conduction studies may show a characteristic decremental response (p. 1151) if the muscle has been clinically affected. Anti-MuSK antibodies are more common in acetylcholine receptor antibody-negative patients with prominent bulbar involvement. All patients should have a thoracic CT to exclude thymoma, especially those without anti-acetylcholine receptor antibodies. Screening for associated autoimmune disorders, particularly thyroid disease, is important.

Management

The goals of treatment are to maximise the activity of acetylcholine at remaining receptors in the neuromuscular junctions and to limit or abolish the immunological attack on motor end plates.

The duration of action of acetylcholine is prolonged by inhibiting acetylcholinesterase. The most commonly used anticholinesterase drug is pyridostigmine. Muscarinic side-effects, including diarrhoea and colic, may be controlled by propantheline. Overdosage of anticholinesterase drugs may cause a 'cholinergic crisis' due to depolarisation block of motor end plates, with muscle fasciculation, paralysis, pallor, sweating, excessive salivation and small pupils. This may be

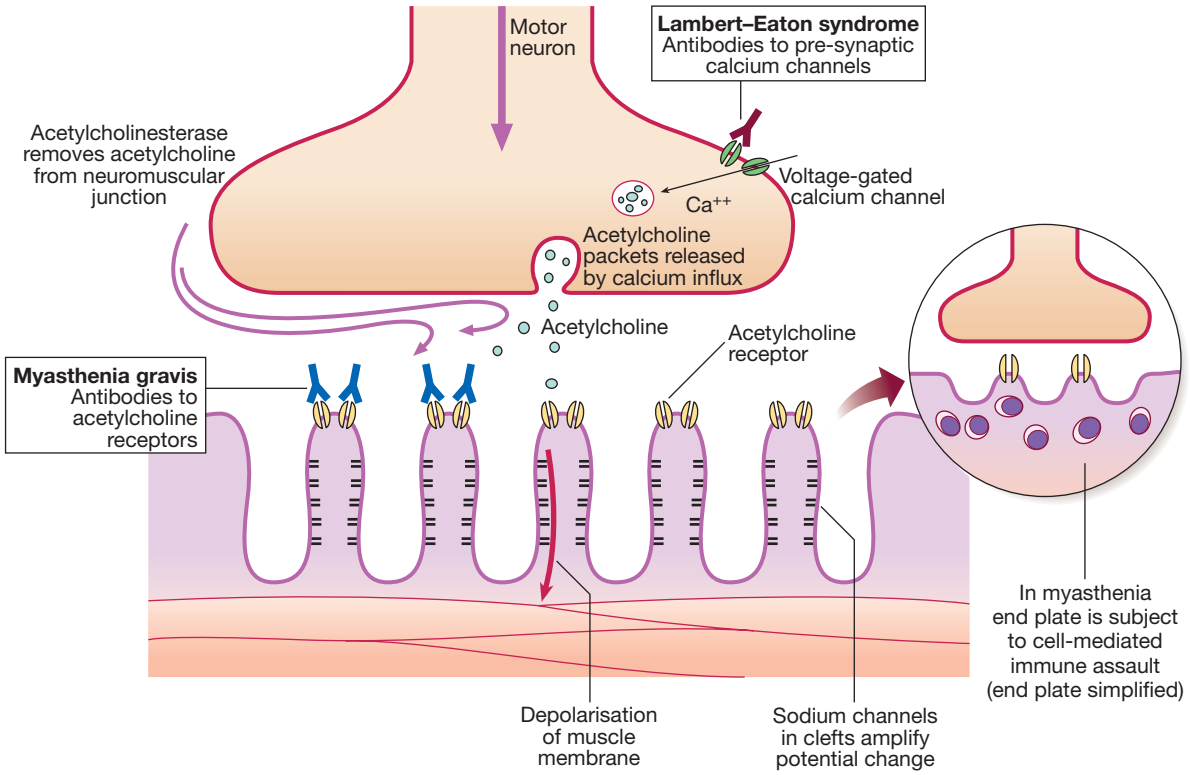

Fig. 26.47 Myasthenia gravis and Lambert–Eaton myasthenic syndrome (LEMS). In myasthenia there are antibodies to the acetylcholine receptors on the post-synaptic membrane, which block conduction across the neuromuscular junction (NMJ). Myasthenic symptoms can be transiently improved by inhibition of acetylcholinesterase (e.g. with Tensilon® – edrophonium bromide), which normally removes the acetylcholine. A cell-mediated immune response produces simplification of the post-synaptic membrane, further impairing the 'safety factor' of neuromuscular conduction. In LEMS, antibodies to the pre-synaptic voltage calcium channels impair release of acetylcholine from the motor nerve ending; calcium is required for the acetylcholine-containing vesicle to fuse with the pre-synaptic membrane for release into the NMJ.

26.106 Immunological treatment of myasthenia

Acute treatments

Intravenous immunoglobulin
- Reduces production of antibodies and rapidly reduces weakness

Plasma exchange
- Removing antibody from the blood may produce marked improvement; this is usually brief, so is normally reserved for myasthenic crisis or for pre-operative preparation

Long-term treatments

Corticosteroid treatment
- Improvement is commonly preceded by marked exacerbation of myasthenic symptoms, so treatment should be initiated in hospital
- Usually necessary to continue treatment for months or years, risking adverse effects

Pharmacological immunosuppression treatment
- Azathioprine 2.5 mg/kg daily reduces the necessary dosage of steroids and may allow their withdrawal. Effect on clinical features may be delayed for months
- Mycophenolate: less commonly used

Thymectomy
- Should be considered in any antibody-positive patient under 45 yrs with symptoms not confined to extraocular muscles, unless the disease has been established for more than 7 yrs
- May be required for thymoma

distinguished from severe weakness due to exacerbation of myasthenia ('myasthenic crisis') by the clinical features and, if necessary, by the injection of a small dose of edrophonium.

The immunological treatment of myasthenia is outlined in Box 26.106. Thymectomy may improve overall prognosis but awaits clinical trial confirmation. Prognosis is variable and remissions may occur spontaneously. When myasthenia is entirely ocular, prognosis is excellent and disability slight. Young female patients with generalised disease may benefit from thymectomy, whilst older patients are less likely to have a remission despite treatment. Rapid progression of the disease more than 5 years after onset is uncommon.

Other myasthenic syndromes

Other rarer conditions can present with muscle weakness due to impaired transmission across the neuromuscular junction. The most common of these is the Lambert–Eaton myasthenic syndrome (LEMS), which can occur as an inflammatory or paraneoplastic phenomenon. Antibodies to pre-synaptic voltage-gated calcium channels (see Fig. 26.47) impair transmitter release. Patients may have autonomic dysfunction (e.g. dry mouth) in addition to muscle weakness, but the cardinal clinical sign is absence of tendon reflexes, which return after sustained contraction of the relevant

muscle. The condition is associated with underlying malignancy in a high percentage of cases and investigation must be directed towards identifying any neoplasm. The condition is diagnosed electrophysiologically by the presence of post-tetanic potentiation of motor response to nerve stimulation at a frequency of 20–50/s. Treatment is with 3,4-diaminopyridine, or pyridostigmine and immunosuppression.

DISEASES OF MUSCLE

Muscle disease, either hereditary or acquired, is rare. Most typically, it presents with a proximal symmetrical weakness. Diagnosis is dependent on recognition of clinical clues, such as cardiorespiratory involvement, evolution, family history, exposure to drugs, the presence of contractures, myotonia and other systemic features, and on investigation findings, most importantly EMG and muscle biopsy. Hereditary syndromes include the muscular dystrophies, muscle channelopathies, metabolic myopathies (including mitochondrial diseases) and congenital myopathies.

Muscular dystrophies

These are inherited disorders with progressive muscle destruction, and may be associated with cardiac and/or respiratory involvement and sometimes non-myopathic features (Box 26.107). Myotonic dystrophy is the most common, with a prevalence of about 12/100 000.

Clinical features

The pattern of the clinical features is defined by the specific syndromes. Onset is often in childhood, although some patients, especially those with myotonic dystrophy, may present as adults. Wasting and weakness are usually symmetrical, without fasciculation or sensory loss, and tendon reflexes are usually preserved until a late stage. Weakness is usually proximal, except in myotonic dystrophy type 1, when it is distal.

Investigations

The diagnosis can be confirmed by specific molecular genetic testing, supplemented with EMG and muscle biopsy if necessary. Creatine kinase is markedly elevated in the dystrophinopathies (Duchenne and Becker) but is normal or moderately elevated in the other dystrophies. Screening for an associated cardiac abnormality (cardiomyopathy or dysrhythmia) is important.

Management

There is no specific therapy for most of these conditions but physiotherapy and occupational therapy help patients cope with their disability. Steroids are used in Duchenne muscular dystrophy. Treatment of associated cardiac failure or arrhythmia (with pacemaker insertion if necessary) may be required; similarly, management of respiratory complications (including nocturnal hypoventilation) can improve quality of life. Improvements in non-invasive ventilation have led to significant improvements in survival for patients with

26.107 The muscular dystrophies

Type	Genetics	Age of onset	Muscles affected	Other features
Myotonic dystrophy (DM1)	Autosomal dominant; expanded triplet repeat chromosome 19q	Any	Face (including ptosis), sternomastoids, distal limb, generalised later	Myotonia, cognitive impairment, cardiac conduction abnormalities, lens opacities, frontal balding, hypogonadism
Proximal myotonic myopathy (PROMM; DM2)	Autosomal dominant; quadruplet repeat expansion in *Zn finger protein 9* gene chromosome 3q	8–50	Proximal, especially thigh, sometimes muscle hypertrophy	As for DM1 but cognition not affected Muscle pain
Duchenne	X-linked; deletions in *dystrophin* gene Xp21	< 5 yrs	Proximal and limb girdle	Cardiomyopathy and respiratory failure
Becker	X-linked; deletions in *dystrophin* gene Xp21	Childhood/ early adult	Proximal and limb girdle	Cardiomyopathy, respiratory failure uncommon
Limb girdle	Many mutations on different chromosomes	Childhood/ early adult	Limb girdle	Very variable depending on genetic subtype, some involve cardiac and respiratory systems
Facioscapulohumeral (FSH)	Autosomal dominant; tandem repeat deletion chromosome 4q35	7–30 yrs	Face and upper limb girdle, distal lower limb weakness	Pain in shoulder girdle common, deafness Cardiorespiratory involvement rare
Oculopharyngeal	Autosomal dominant and recessive; triplet repeat expansion in *PABP2* gene chromosome 14q	30–60 yrs	Ptosis, external ophthalmoplegia, dysphagia, tongue weakness	Mild lower limb weakness
Emery–Dreifuss	X-linked recessive; mutations in *emerin* gene	4–5 yrs	Humero-peroneal, proximal limb girdle later	Contractures develop early Cardiac involvement leads to sudden death

Duchenne muscular dystrophy. Genetic counselling is important.

Inherited metabolic myopathies

There are a large number of rare inherited disorders that interfere with the biochemical pathways that maintain the energy supply (adenosine triphosphate, ATP) to muscles. These are mostly recessively inherited deficiencies in the enzymes necessary for glycogen or fatty acid (β-oxidation) metabolism (Box 26.108). They typically present with muscle weakness and pain.

Mitochondrial disorders

Mitochondrial diseases are discussed on page 65. Mitochondria are present in all tissues and dysfunction causes widespread effects, on vision (optic atrophy, retinitis pigmentosa, cataracts), hearing (sensorineural deafness), and the endocrine, cardiovascular, gastrointestinal and renal systems. Any combination of these should raise the suspicion of a mitochondrial disorder, especially if there is evidence of maternal transmission.

Mitochondrial dysfunction can be caused by alterations in either mitochondrial DNA or genes encoding for oxidative processes. Genetic abnormalities or mutations in mitochondrial DNA may affect single individuals and single tissues (most commonly muscle). Thus, patients with exercise intolerance, myalgia and sometimes recurrent myoglobinuria may have isolated pathogenic mutations in genes encoding for oxidation pathways.

Inherited disorders of the oxidative pathways of the respiratory chain in mitochondria cause a group of disorders, either restricted to the muscle or associated with non-myopathic features (Box 26.109). Many of these mitochondrial disorders are inherited via the mitochondrial genome, down the maternal line (p. 53). Diagnosis is based on clinical appearances, supported by muscle biopsy appearance (usually with 'ragged red' and/or cytochrome oxidase negative fibres), and specific mutations either on blood or, more reliably, muscle testing. Mutations may be due either to point mutations or to deletions of mitochondrial DNA.

A disorder called Leber hereditary optic neuropathy (LHON) is characterised by acute or subacute loss of vision, most frequently in males, due to bilateral optic atrophy. Three point mutations account for more than 90% of LHON cases.

Channelopathies

Inherited abnormalities of the sodium, calcium and chloride ion channels in striated muscle produce various syndromes of familial periodic paralysis, myotonia and malignant hyperthermia, which may be recognised by

26.108 Inherited disorders of muscle metabolism

	Disease	Clinical features	Diagnosis
Carbohydrate (glycogen) metabolism	Myophosphorylase deficiency (McArdle's disease): autosomal recessive	Exercise-induced myalgia, stiffness, weakness (with 'second wind' phenomenon), myoglobinuria	Creatine kinase (CK) elevated Muscle biopsy Enzyme assay
	Acid maltase deficiency (Pompe's disease): autosomal recessive	Infantile form: death within 2 yrs Childhood: death in 20–30s Adult: progressive proximal myopathy with respiratory failure	CK elevated Blood lymphocyte analysis for glycogen granules Muscle biopsy Enzyme assay
Lipid metabolism (β-oxidation)	Carnitine-palmitoyl transferase (CPT) deficiency	Myalgia *after* exercise, myoglobinuria, weakness	CK normal between attacks Urinary organic acids Enzyme assays Muscle biopsy

26.109 Mitochondrial syndromes

Syndrome	Clinical features
Myoclonic epilepsy with ragged red fibres (MERRF)	Myoclonic epilepsy, cerebellar ataxia, dementia, sensorineural deafness ± peripheral neuropathy, optic atrophy and multiple lipomas
Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)	Episodic encephalopathy, stroke-like episodes often preceded by migraine-like headache, nausea and vomiting
Chronic progressive external ophthalmoplegia (CPEO)	Progressive ptosis and external oculomotor palsy, proximal myopathy ± deafness, ataxia and cardiac conduction defects
Kearns–Sayre syndrome	Like CPEO but early age of onset (< 20 yrs), heart block, pigmentary retinopathy
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)	Progressive ptosis, external oculomotor palsy, gastrointestinal dysmotility (often pseudo-obstruction), diffuse leucoencephalopathy, thin body habitus, peripheral neuropathy and myopathy
Neuropathy, ataxia and retinitis pigmentosa (NARP)	Weakness, ataxia and progressive loss of vision, along with dementia, seizures and proximal weakness

26.110 Muscle channelopathies

Channel	Muscle disease	Gene and inheritance	Clinical features
Sodium	Paramyotonia congenita	*SCN4A* (17q35) Autosomal dominant	Cold-evoked myotonia with episodic weakness provoked by exercise and cold
	Potassium-aggravated myotonia	*SCN4A*	Pure myotonia without weakness provoked by potassium
	Hyperkalaemic periodic paralysis	*SCN4A* Autosomal dominant	Brief (mins to hrs), frequent episodes of weakness provoked by rest, cold, potassium, fasting, pregnancy, stress Less common than hypokalaemic periodic paralysis
	Hypokalaemic periodic paralysis	*SCN4A* Autosomal dominant (one-third new mutations)	Longer (hrs to days) episodic weakness triggered by rest, carbohydrate loading, cold
Chloride	Myotonia congenita		
	Thomsen's disease	*CLCN1* Autosomal dominant	Myotonia usually mild, little weakness
	Becker's disease	*CLCN1* Autosomal recessive	Myotonia often severe, transient weakness
Calcium	Hypokalaemic periodic paralysis	*CACNA1S* Autosomal dominant	Episodic weakness triggered by carbohydrate meal
	Malignant hyperthermia	*CACNA1S*, *CACNL2A* Autosomal dominant	Hyperpyrexia due to excess muscle activity, precipitated by drugs, usually anaesthetic agents; most common cause of death during general anaesthetic
Potassium	Andersen–Tawil syndrome	*KCNJ2* Autosomal dominant	Similar to hypokalaemic periodic paralysis, associated with cardiac and non-myopathic features (skeletal and facial)
Ryanodine receptor	Malignant hyperthermia	*RYR1* (19q13)	As malignant hyperthermia above
	Central core and multicore disease	*RYR1* Mostly autosomal dominant	Present in infancy with mild progressive weakness

26.111 Causes of acquired proximal myopathy

Inflammatory (p. 1114)

- Polymyositis
- Dermatomyositis
- Inclusion body myositis (additional distal effects)

Endocrine and metabolic

- Hypothyroidism
- Hyperthyroidism
- Acromegaly
- Cushing's syndrome (including iatrogenic)
- Addison's disease
- Conn's syndrome
- Osteomalacia
- Hypokalaemia (liquorice, diuretic and purgative abuse)
- Hypercalcaemia (disseminated bony metastases)

Toxic

- Alcohol (chronic and acute syndromes)
- Amphetamines/cocaine/heroin
- Vitamin E
- Organophosphates
- Snake venoms

Drugs

- Corticosteroids
- Statins
- Amiodarone
- Beta-blockers
- Opiates
- Chloroquine
- Ciclosporin
- Vincristine
- Clofibrate
- Zidovudine

Paraneoplastic

- Carcinomatous neuromyopathy
- Dermatomyositis

their clinical characteristics and potassium abnormalities (Box 26.110). Genetic testing is available.

Acquired myopathies

These include the inflammatory myopathies, or myopathy associated with a range of metabolic and endocrine disorders, or drug and toxin exposure (Box 26.111).

CLINICAL EXAMINATION IN STROKE DISEASE

General examination

Skin

- Xanthelasma
- Rash (arteritis, splinter haemorrhages)
- Colour change (limb ischaemia, deep vein thrombosis)
- Pressure injury

Eyes

- Arcus senilis
- Diabetic retinopathy
- Hypertensive retinopathy
- Retinal emboli

Cardiovascular system

- Heart rhythm (?atrial fibrillation)
- Blood pressure (high or low)
- Carotid bruit
- Jugular venous pulse (raised if heart failure, low in hypovolaemia)
- Murmurs (source of embolism)
- Peripheral pulses and bruits (?generalised arteriopathy)

Respiratory system

- Signs of pulmonary oedema or infection
- Oxygen saturation

Abdomen

- Palpable bladder (urinary retention)

Locomotor

- Injuries sustained during collapse
- Comorbidities that influence recovery e.g. osteoarthritis

Rapid assessment of suspected stroke

Rosier scale

Can be used by emergency staff to indicate probability of a stroke in acute presentations:

Unilateral facial weakness	+1	Loss of consciousness	–1
Unilateral grip weakness	+1	Seizure	–1
Unilateral arm weakness	+1		
Unilateral leg weakness	+1		
Speech loss	+1		
Visual field defect	+1		

Total (–2 to +6); score of > 0 indicates stroke is possible cause

Exclude hypoglycaemia

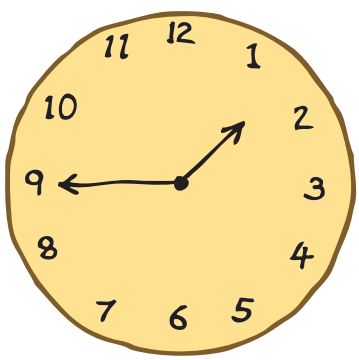
- Bedside blood glucose testing with BMstix

Language deficit

- The history and examination may indicate a language deficit
- Check comprehension ('lift your arms, close your eyes') to identify a receptive dysphasia
- Ask patient to name people/objects (e.g. nurse, watch, pen) to identify a nominal dysphasia
- Check articulation (ask patient to repeat phrases after you) for dysarthria

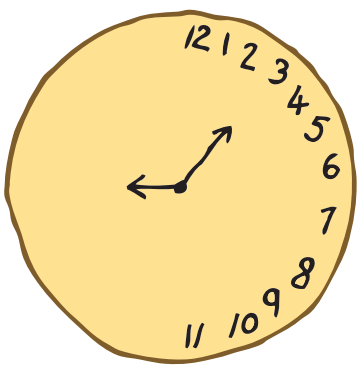
Motor deficit

Subtle pyramidal signs



- Check for pronator drift: ask patient to hold out arms and maintain their position with eyes closed (see opposite)
- Check for clumsiness of fine finger movements

Sensory and visual inattention



- Establish that sensation/visual field is intact on testing one side at a time
- Retest sensation/visual fields on simultaneous testing of both sides; the affected side will no longer be felt/seen
- Perform clock drawing test (see below)

Truncal ataxia

- Check if patient can sit up or stand without support

A

B

Clock drawing test A Image drawn by doctor. B Image drawn by patient with left-sided neglect.

Cerebrovascular disease is the third most common cause of death in high-income countries after cancers and ischaemic heart disease, and the most common cause of severe physical disability. It includes a range of disorders of the central nervous system (Fig. 27.1). Stroke is the most common clinical manifestation of cerebrovascular disease, and results in episodes of brain dysfunction due to focal ischaemia or haemorrhage. Subarachnoid haemorrhage (SAH) and cerebral venous thrombosis (CVT) will be discussed separately, since their pathophysiology, clinical manifestations and management are distinct from those of stroke. Vascular dementia is described in Chapters 10 and 26.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The main arterial supply of the brain comes from the internal carotid arteries, which supply the anterior brain, and the vertebral and basilar arteries (vertebrobasilar

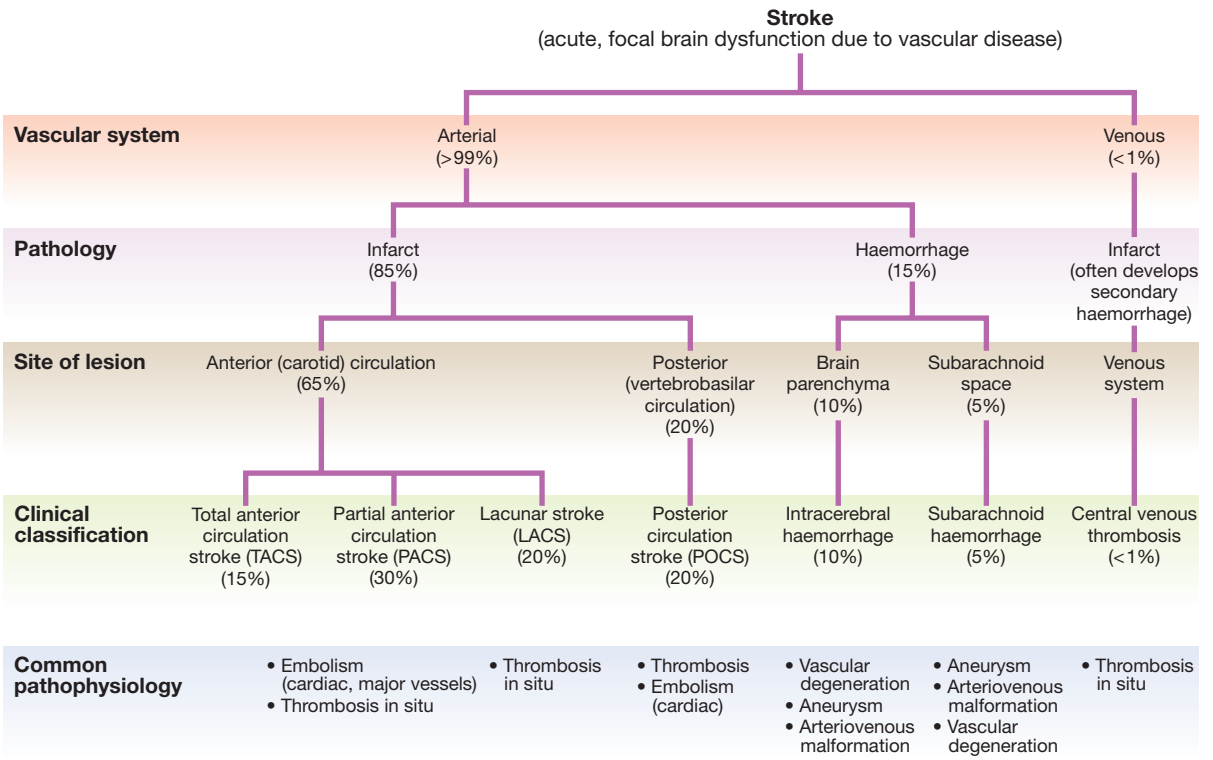


Fig. 27.1 A classification of stroke disease.

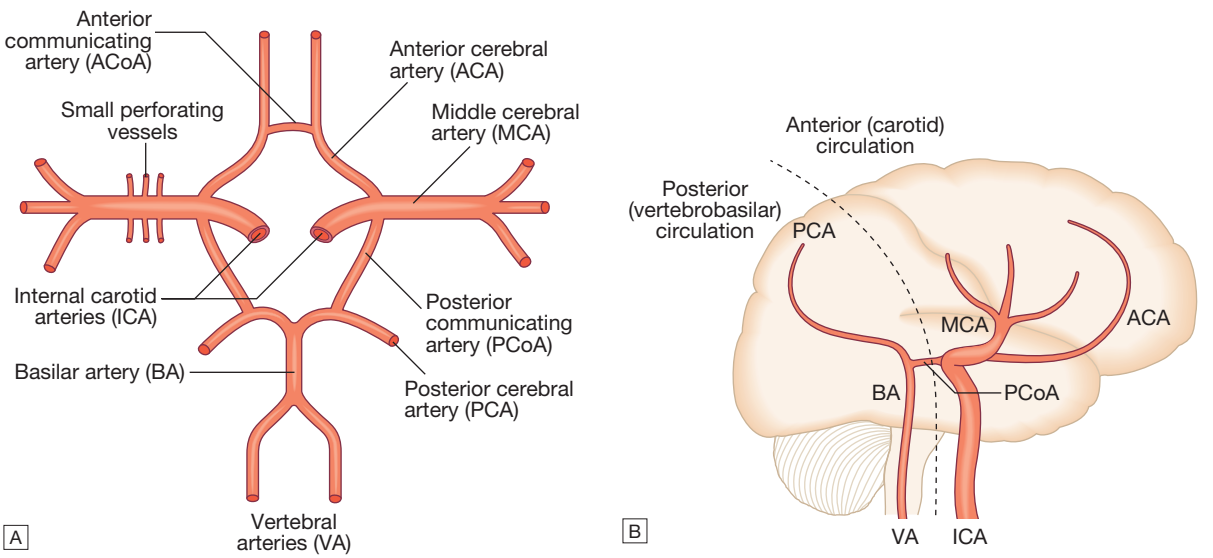

Fig. 27.2 Arterial circulation of the brain. A Horizontal view. B Lateral view.

system), which provide the posterior circulation. The anterior and middle cerebral arteries supply the frontal and parietal lobes, while the posterior cerebral artery supplies the occipital lobe. The vertebral and basilar arteries perfuse the brain stem, mid-brain and cerebellum (Fig. 27.2). The functions of each of these areas of the brain are described on page 1141. Communicating arteries provide connections between the anterior and posterior circulations and between left and right hemispheres, creating protective anastomotic connections that form the circle of Willis. In health, regulatory mechanisms maintain a constant cerebral blood flow across a wide range of arterial blood pressures to meet the high resting metabolic activity of brain tissue; cerebral blood vessels dilate when systemic blood pressure is lowered and constrict when it is raised. This autoregulatory mechanism can be disrupted after stroke. The venous collecting system is formed by a collection of sinuses over the surface of the brain, which drain into the jugular veins (Fig. 27.3).

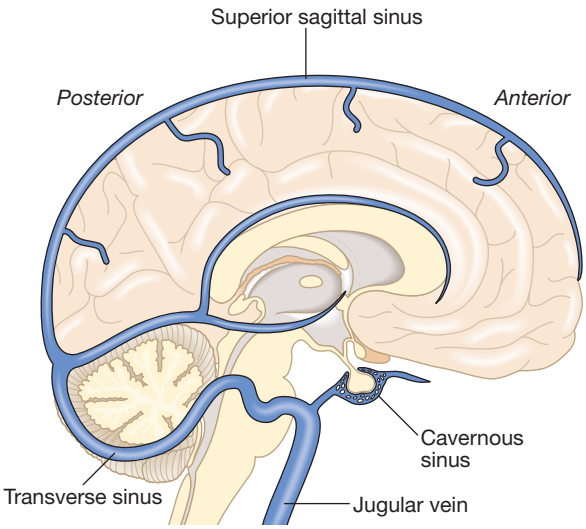

Fig. 27.3 Venous circulation of the brain.

INVESTIGATIONS

A range of investigations may be required to answer specific questions about brain structure and function and about the function of the vascular system.

Neuroimaging

Computed tomography (CT) scanning is the mainstay of stroke imaging. It allows the rapid identification of intracerebral bleeding and stroke 'mimics' (i.e. pathologies other than stroke that have similar presentations), such as tumours. Magnetic resonance imaging (MRI) is used when there is diagnostic uncertainty or delayed presentation, and when more information on brain structure and function is required (Fig. 27.4). Contraindications to MRI include cardiac pacemakers and claustrophobia on entering the scanner. These techniques are described on page 1149.

Vascular imaging

Various techniques are used to obtain images of extracranial and intracranial blood vessels (Fig. 27.5). The least invasive is ultrasound (Doppler or duplex scanning), which is used to image the carotid and the vertebral arteries in the neck. In skilled hands, reliable information can be provided about the degree of arterial stenosis and the presence of ulcerated plaques. Blood flow in the intracerebral vessels can be examined using transcranial Doppler. While the anatomical resolution is limited, it is improving and many centres no longer require formal angiography before proceeding to carotid endarterectomy (see below). Blood flow can also be detected by specialised sequences in MR angiography (MRA) but the anatomical resolution is still not comparable to that of intra-arterial angiography, which outlines blood vessels by the injection of radio-opaque contrast intravenously or intra-arterially. The X-ray images obtained can be enhanced by the use of computer-assisted digital subtraction or spiral CT. Because of the significant risk of complications, intra-arterial contrast angiography is reserved for patients in whom

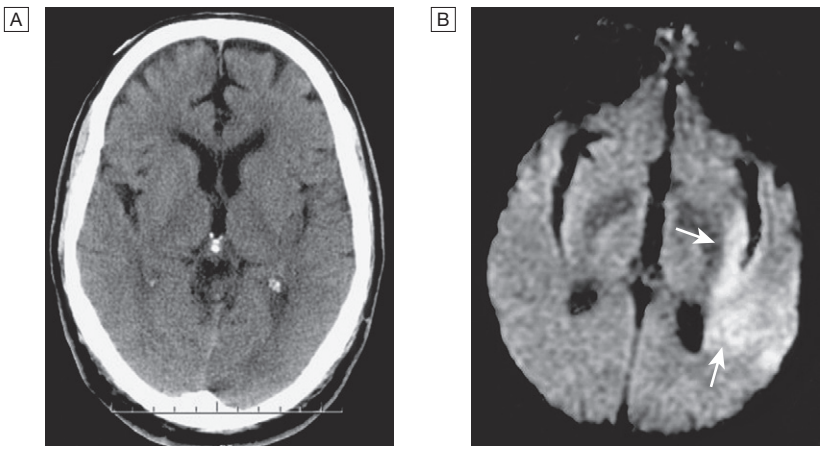

Fig. 27.4 Acute stroke seen on CT scan with corresponding MRI appearance. A CT may show no evidence of early infarction. B Corresponding image seen on MRI diffusion weighted imaging (DWI) with changes of infarction in middle cerebral artery (MCA) territory (arrows).

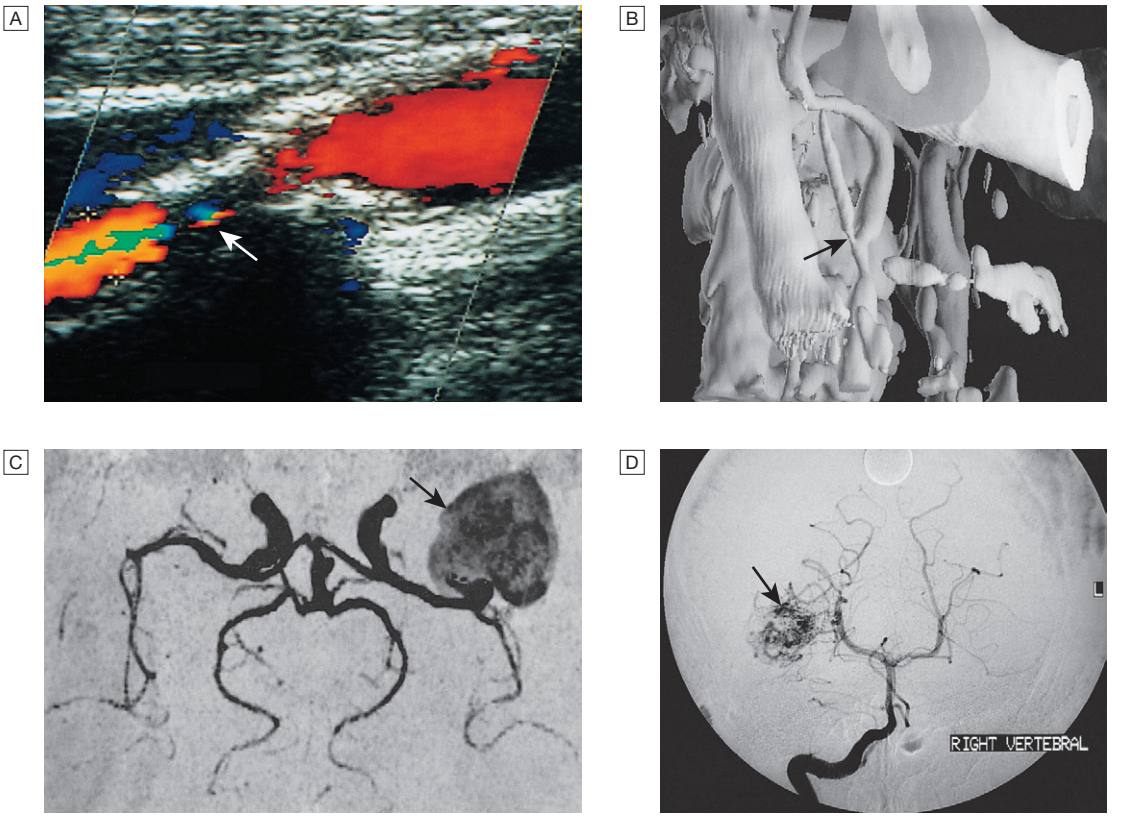

Fig. 27.5 Different techniques of imaging blood vessels. A Doppler scan showing 80% stenosis of the internal carotid artery (arrow). B Three-dimensional reconstruction of CT angiogram showing stenosis at the carotid bifurcation (arrow). C MR angiogram showing giant aneurysm at the middle cerebral artery bifurcation (arrow). D Intra-arterial angiography showing arteriovenous malformation (arrow).

non-invasive methods have provided a contradictory picture or incomplete information, or in whom it is necessary to image the intracranial circulation in detail: for example, to delineate a saccular aneurysm, an arteriovenous malformation or vasculitis.

Blood tests

These help identify underlying causes of cerebrovascular disease: for example, blood glucose (diabetes mellitus), triglycerides and cholesterol (hyperlipidaemia) or full blood count (polycythaemia) in stroke. Erythrocyte sedimentation rate (ESR) and immunological tests, such as measurement of antineutrophil cytoplasmic antibodies (ANCA) (p. 1068), may be required when vasculitis is suspected. Genetic testing for rarer inherited conditions, such as CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy), may be indicated.

Lumbar puncture

Lumbar puncture (p. 1153) is largely reserved for the investigation of SAH.

Cardiovascular investigations

Electrocardiography (ECG; p. 532) and echocardiography (p. 537) may reveal abnormalities that may cause cardiac embolism in stroke.

PRESENTING PROBLEMS

Most vascular lesions develop suddenly within a matter of minutes or hours, and so should be considered in the differential diagnosis of patients with any acute neurological presentation.

Weakness

Unilateral weakness is the classical presentation of stroke and, much more rarely, of cerebral venous thrombosis. The weakness is sudden, progresses rapidly and follows a hemiplegic pattern (see Fig. 26.18, p. 1163). There is rarely any associated abnormal movement. Reflexes are initially reduced but then become increased with a spastic pattern of increased tone (see Box 26.20, p. 1162). Upper motor neuron weakness of the face (7th cranial nerve) is often present.

Speech disturbance

Dysphasia and dysarthria are the most common presentations of disturbed speech in stroke (p. 1168). Dysphasia indicates damage to the dominant frontal or parietal lobe (see Box 26.2, p. 1142), while dysarthria is a non-localising feature reflecting weakness or incoordination of the face, pharynx, lips, tongue or palate.

Visual deficit

Visual loss in stroke can be due to unilateral optic ischaemia (called amaurosis fugax if transient), caused by disturbance of blood flow in the internal carotid artery and ophthalmic artery, which leads to monocular blindness. Ischaemic damage to the occipital cortex or post-chiasmic nerve tracts results in a contralateral hemianopia (p. 1169).

Visuo-spatial dysfunction

Damage to the non-dominant cortex often results in contralateral visuo-spatial dysfunction, such as sensory or visual neglect and apraxia (inability to perform complex tasks despite normal motor, sensory and cerebellar function; p. 1167). This is sometimes misdiagnosed as acute confusion.

Ataxia

Stroke causing damage to the cerebellum and its connections can present as an acute ataxia (p. 1168) and there may be associated brainstem features such as diplopia (p. 1170) and vertigo (p. 1167). The differential diagnosis includes vestibular disorders (p. 1186).

Headache

Sudden severe headache is the cardinal symptom of SAH but also occurs in intracerebral haemorrhage. Although some degree of headache is common in acute ischaemic stroke, it is rarely a dominant feature (p. 1156). Headache also occurs in cerebral venous disease.

Seizure

Seizure is unusual in acute stroke but may be generalised or focal in cerebral venous disease.

Coma

Coma is an uncommon feature of stroke, though it may occur with a brainstem event. If it is present in the first 24 hours, it usually indicates a subarachnoid or intracerebral haemorrhage (see Box 26.16, p. 1160).

STROKE

Stroke is a common medical emergency. The incidence rises steeply with age, and in many lower- and middle-income countries it is rising in association with less healthy lifestyles. About one-fifth of patients with an acute stroke die within a month of the event and at least half of those who survive are left with physical disability.

Pathophysiology

Of the 180–300 patients per 100 000 population presenting annually with a stroke, 85% sustain a cerebral infarction due to inadequate blood flow to part of the brain, and most of the remainder have an intracerebral haemorrhage (see Fig. 27.1).

Cerebral infarction

Cerebral infarction is mostly caused by thromboembolic disease secondary to atherosclerosis in the major extracranial arteries (carotid artery and aortic arch). About 20% of infarctions are due to embolism from the heart, and a further 20% are due to thrombosis in situ caused by intrinsic disease of small perforating vessels (lenticulostriate arteries), producing so-called lacunar infarctions. The risk factors for ischaemic stroke reflect the risk factors for the underlying vascular disease (Box 27.1). About 5% are due to rare causes, including vasculitis (p. 1115), endocarditis (p. 625) and cerebral venous disease (see below). Cerebral infarction takes some hours to complete, even though the patient's deficit may be maximal shortly after the vascular occlusion. After the occlusion of a cerebral artery, infarction may be forestalled by the opening of anastomotic channels from other arterial territories that restore perfusion to its territory. Similarly, reduction in perfusion pressure leads to compensatory homeostatic changes to maintain tissue oxygenation (Fig. 27.6). These compensatory changes can sometimes prevent occlusion of even a carotid artery from having any clinically apparent effect.

However, if and when these homeostatic mechanisms fail, the process of ischaemia starts, and ultimately leads to infarction unless the vascular supply is restored. As the cerebral blood flow declines, different neuronal functions fail at various thresholds (Fig. 27.7). Once blood flow falls below the threshold for the maintenance of electrical activity, neurological deficit develops. At this level of blood flow, the neurons are still viable; if

27.1 Risk factors for stroke

Fixed risk factors

- Age
- Gender (male > female except at extremes of age)
- Race (Afro-Caribbean > Asian > European)
- Previous vascular event
  - Myocardial infarction
  - Stroke
  - Peripheral vascular disease
- Heredity
- High fibrinogen

Modifiable risk factors

- Blood pressure
- Cigarette smoking
- Hyperlipidaemia
- Heart disease
  - Atrial fibrillation
  - Congestive cardiac failure
  - Infective endocarditis
- Diabetes mellitus
- Excessive alcohol intake
- Oestrogen-containing drugs
  - Oral contraceptive pill
  - Hormone replacement therapy
- Polycythaemia

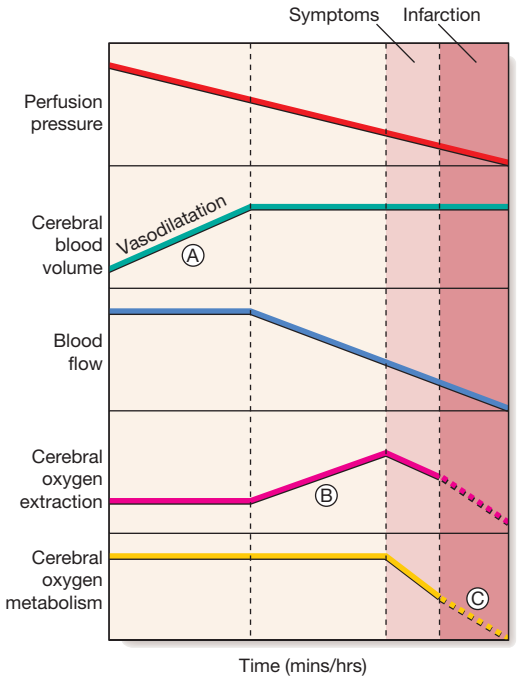

Fig. 27.6 Homeostatic responses to falling perfusion pressure in the brain following arterial occlusion. Vasodilatation initially maintains cerebral blood flow (A), but after maximal vasodilatation further falls in perfusion pressure lead to a decline in blood flow. An increase in tissue oxygen extraction, however, maintains the cerebral metabolic rate for oxygen (B). Still further falls in perfusion, and therefore blood flow, cannot be compensated; cerebral oxygen availability falls and symptoms appear, then infarction (C).

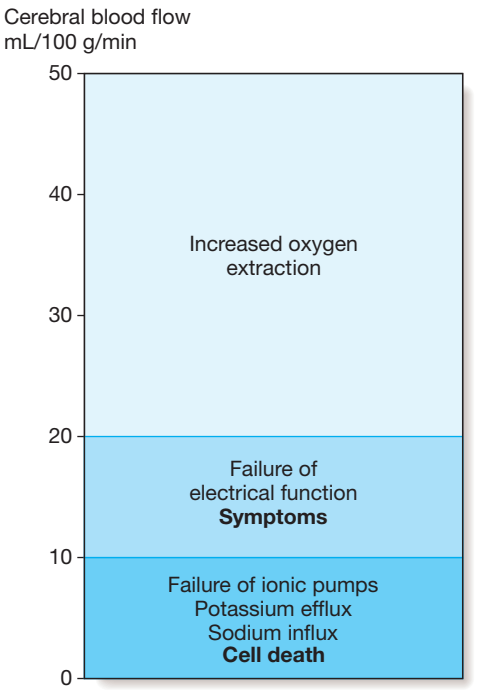

Fig. 27.7 Thresholds of cerebral ischaemia. Symptoms of cerebral ischaemia appear when the blood flow has fallen to less than half of normal and energy supply is insufficient to sustain neuronal electrical function. Full recovery can occur if this level of flow is returned to normal but not if it is sustained. Further blood flow reduction below the next threshold causes failure of cell ionic pumps and starts the ischaemic cascade, leading to cell death.

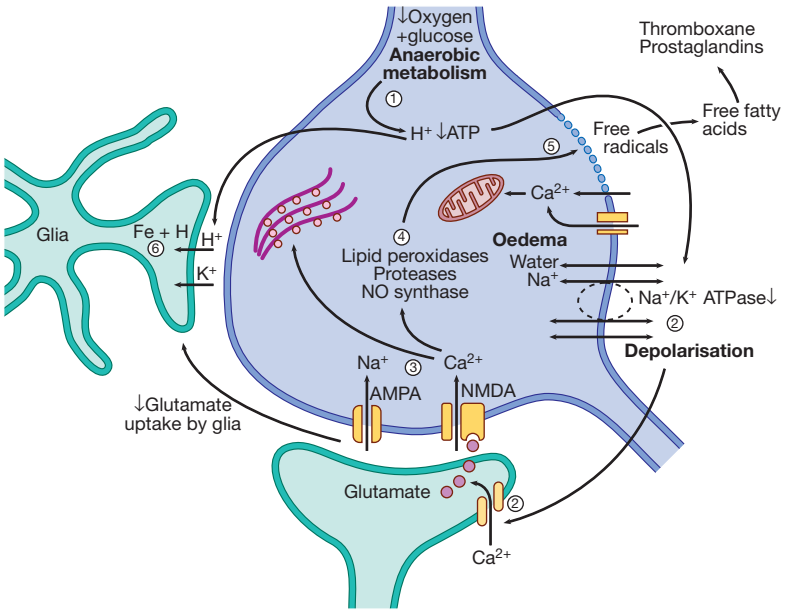

Fig. 27.8 The process of neuronal ischaemia and infarction. (1) Reduction of blood flow reduces supply of oxygen and hence ATP. H^+ is produced by anaerobic metabolism of available glucose. (2) Energy-dependent membrane ionic pumps fail, leading to cytotoxic oedema and membrane depolarisation, allowing calcium entry and releasing glutamate. (3) Calcium enters cells via glutamate-gated channels and (4) activates destructive intracellular enzymes (5), destroying intracellular organelles and cell membrane, with release of free radicals. Free fatty acid release activates pro-coagulant pathways that exacerbate local ischaemia. (6) Glial cells take up H^+, can no longer take up extracellular glutamate and also suffer cell death, leading to liquefactive necrosis of whole arterial territory.

the blood flow increases again, function returns and the patient will have had a transient ischaemic attack (TIA). However, if the blood flow falls further, a level is reached at which irreversible cell death starts. Hypoxia leads to an inadequate supply of adenosine triphosphate (ATP), which leads to failure of membrane pumps, thereby allowing influx of sodium and water into the cell (cytotoxic oedema) and the release of the excitatory neurotransmitter glutamate into the extracellular fluid. Glutamate opens membrane channels, allowing the influx of calcium and more sodium into the neurons. Calcium entering the neurons activates intracellular enzymes that complete the destructive process. The release of inflammatory mediators by microglia and

astrocytes causes death of all cell types in the area of maximum ischaemia. The infarction process is worsened by the anaerobic production of lactic acid (Fig. 27.8) and consequent fall in tissue pH. There have been attempts to develop neuroprotective drugs to slow down the processes leading to irreversible cell death but so far these have proved disappointing.

The final outcome of the occlusion of a cerebral blood vessel therefore depends upon the competence of the circulatory homeostatic mechanisms, the metabolic demand, and the severity and duration of the reduction in blood flow. Higher brain temperature, as occurs in fever, and higher blood sugar have both been associated with a greater volume of infarction for a given reduction in cerebral blood flow. Subsequent restoration of blood flow may cause haemorrhage into the infarcted area ('haemorrhagic transformation'). This is particularly likely in patients given antithrombotic or thrombolytic drugs, and in patients with larger infarcts.

Radiologically, a cerebral infarct can be seen as a lesion that comprises a mixture of dead brain tissue that is already undergoing autolysis, and tissue that is ischaemic and swollen but recoverable (the 'ischaemic penumbra'). The infarct swells with time and is at its maximal size a couple of days after stroke onset. At this stage, it may be big enough to exert mass effect both clinically and radiologically; sometimes, decompressive craniectomy is required (see below). After a few weeks, the oedema subsides and the infarcted area is replaced by a sharply defined fluid-filled cavity.

Intracerebral haemorrhage

Intracerebral haemorrhage causes about 10% of acute stroke events but is more common in low-income countries. It usually results from rupture of a blood vessel within the brain parenchyma but may also occur in a patient with an SAH (see below) if the artery ruptures into the brain substance as well as into the subarachnoid space. Haemorrhage frequently occurs into an area of brain infarction and, if the volume of haemorrhage is large, it may be difficult to distinguish from primary intracerebral haemorrhage both clinically and radiologically (Fig. 27.9). The risk factors and underlying causes of intracerebral haemorrhage are listed in Box 27.2. The explosive entry of blood into the brain parenchyma causes immediate cessation of function in that area as neurons are structurally disrupted and white-matter fibre tracts are split apart. The haemorrhage itself may expand over the first minutes or hours, or it may be associated with a rim of cerebral oedema, which, along with the haematoma, acts like a mass lesion to cause progression of the neurological deficit. If big enough, this can cause shift of the intracranial contents, producing transtentorial coning and sometimes rapid death (p. 1212). If the patient survives, the haematoma is gradually absorbed, leaving a haemosiderin-lined slit in the brain parenchyma.

27.2 Causes of intracerebral haemorrhage and associated risk factors

Disease	Risk factors
Complex small-vessel disease with disruption of vessel wall	Age Hypertension High cholesterol
Amyloid angiopathy	Familial (rare) Age
Impaired blood clotting	Anticoagulant therapy Blood dyscrasia Thrombolytic therapy
Vascular anomaly	Arteriovenous malformation Cavernous haemangioma
Substance misuse	Alcohol Amphetamines Cocaine

Clinical features

Acute stroke and TIA are characterised by a rapid-onset, focal deficit of brain function. The typical presentation occurs over minutes, affects an identifiable area of the brain and is 'negative' in character (i.e. abrupt loss of function without positive features such as abnormal movement). Provided that there is a clear history of this, the chance of a brain lesion being anything other than vascular is 5% or less (Box 27.3). If symptoms progress over hours or days, other diagnoses must be excluded. Confusion and memory or balance disturbance are more often due to stroke mimics. Transient symptoms, such as syncope, amnesia, confusion and dizziness, do not reflect focal cerebral dysfunction, but are often

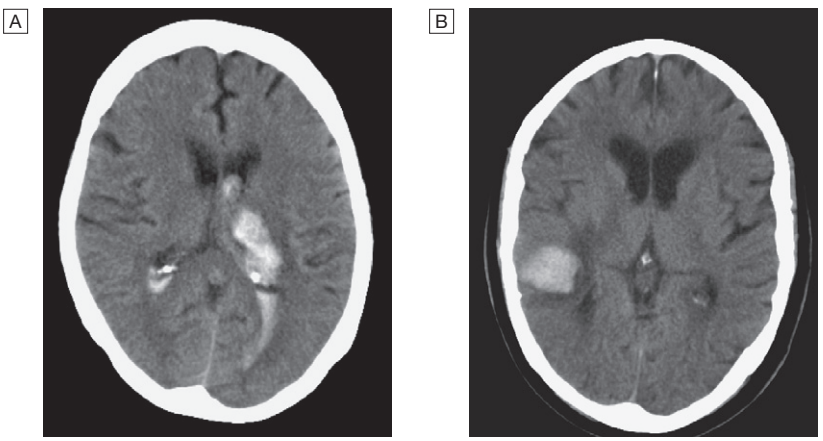

Fig. 27.9 CT scans showing intracerebral haemorrhage. A Basal ganglia haemorrhage with intraventricular extension. B Small cortical haemorrhage.

27.3 Differential diagnosis of stroke and TIA

'Structural' stroke mimics	
• Primary cerebral tumours • Metastatic cerebral tumours • Subdural haematoma	• Cerebral abscess • Peripheral nerve lesions (vascular or compressive) • Demyelination
'Functional' stroke mimics	
• Todd's paresis (after epileptic seizure) • Hypoglycaemia • Migrainous aura (with or without headache)	• Focal seizures • Ménière's disease or other vestibular disorder • Conversion disorder (p. 246) • Encephalitis

27.4 Characteristic features of stroke and non-stroke syndromes ('stroke mimics')

Feature	Stroke	Stroke mimics
Symptom onset	Sudden (minutes)	Often slower onset
Symptom progression	Rapidly reaches maximum severity	Often gradual onset
Severity of deficit	Unequivocal	May be variable/ uncertain
Pattern of deficit	Hemispheric pattern	May be non-specific with confusion, memory loss, balance disturbance
Loss of consciousness	Uncommon	More common

mistakenly attributed to TIA (see Fig. 26.17, p. 1158, and Box 27.4). Public health campaigns to raise awareness of the emergency nature of stroke exploit the fact that weakness of the face or arm, or disturbance of speech is the commonest presentation.

The clinical presentation of stroke depends upon which arterial territory is involved and the size of the lesion (see Fig. 27.1). These will both have a bearing on management, such as suitability for carotid endarterectomy. The neurological deficit can be identified from the patient's history and (if it is persistent) the neurological examination. The presence of a unilateral motor deficit, a higher cerebral function deficit such as aphasia or neglect, or a visual field defect usually places the lesion in the cerebral hemisphere. Ataxia, diplopia, vertigo and/or bilateral weakness usually indicate a lesion in the brainstem or cerebellum. Different combinations of these deficits define several stroke syndromes (Fig. 27.10), which reflect the site and size of the lesion and may provide clues to underlying pathology.

Reduced conscious level usually indicates a large-volume lesion in the cerebral hemisphere but may result from a lesion in the brainstem or complications such as obstructive hydrocephalus, hypoxia or severe systemic infection. The combination of severe headache and vomiting at the onset of the focal deficit is suggestive of intracerebral haemorrhage.

General examination may provide clues to the cause, and identify important comorbidities and complications.

Several terms have been used to classify strokes, often based on the duration and evolution of symptoms.

- *Transient ischaemic attack (TIA)* describes a stroke in which symptoms resolve within 24 hours – an arbitrary cutoff that has little value in practice, apart from perhaps indicating that underlying cerebral haemorrhage or extensive cerebral infarction is extremely unlikely. The term TIA traditionally also includes patients with amaurosis fugax, usually due to a vascular occlusion in the retina.
- *Stroke* describes those events in which symptoms last more than 24 hours. The differential diagnosis of patients with symptoms lasting a few minutes or hours is similar to those with persisting symptoms (see Box 27.3).
- *Progressing stroke (or stroke in evolution)* describes a stroke in which the focal neurological deficit worsens after the patient first presents. Such worsening may be due to increasing volume of infarction, haemorrhagic transformation or increasing cerebral oedema.
- *Completed stroke* describes a stroke in which the focal deficit persists and is not progressing.

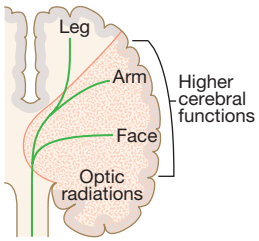
When assessing a patient within hours of symptom onset, it is not possible to distinguish stroke from TIA unless symptoms have already resolved. In clinical practice, it is important to distinguish those patients with strokes who have persisting focal neurological symptoms when seen from those whose symptoms have resolved.

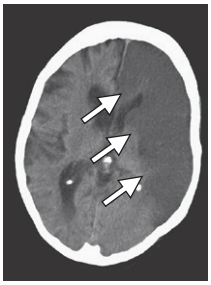
Investigations

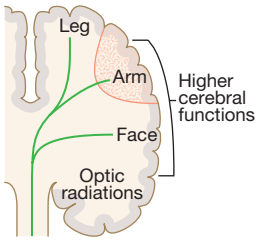
Investigation of acute stroke aims to confirm the vascular nature of the lesion, distinguish cerebral infarction from haemorrhage and identify the underlying vascular disease and risk factors (Box 27.5).

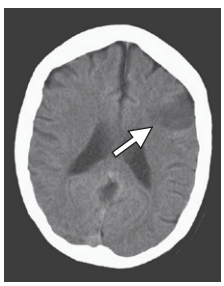
27.5 Investigation of a patient with an acute stroke

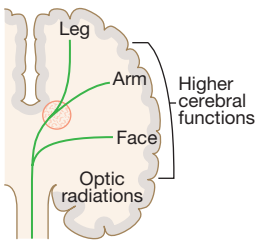
Diagnostic question	Investigation
Is it a vascular lesion?	CT/MRI
Is it ischaemic or haemorrhagic?	CT/MRI
Is it a subarachnoid haemorrhage?	CT/lumbar puncture
Is there any cardiac source of embolism?	Electrocardiogram (ECG) 24-hour ECG Echocardiogram
What is the underlying vascular disease?	Duplex ultrasound of carotids Magnetic resonance angiography (MRA) CT angiography (CTA) Contrast angiography
What are the risk factors?	Full blood count Cholesterol Blood glucose
Is there an unusual cause?	Erythrocyte sedimentation rate (ESR) Serum protein electrophoresis Clotting/thrombophilia screen

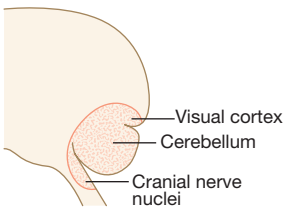












Clinical syndrome	Common symptoms	Common cause	CT scan features
Total anterior circulation syndrome (TACS) 	Combination of: Hemiparesis Higher cerebral dysfunction (e.g. aphasia) Hemisensory loss Homonymous hemianopia (damage to optic radiations)	Middle cerebral artery occlusion (Embolism from heart or major vessels)	
Partial anterior circulation syndrome (PACS) 	Isolated motor loss (e.g. leg only, arm only, face) Isolated higher cerebral dysfunction (e.g. aphasia, neglect) Mixture of higher cerebral dysfunction and motor loss (e.g. aphasia with right hemiparesis)	Occlusion of a branch of the middle cerebral artery or anterior cerebral artery (Embolism from heart or major vessels)	
Lacunar syndrome (LACS) 	Pure motor stroke – affects two limbs Pure sensory stroke Sensory-motor stroke No higher cerebral dysfunction or hemianopia	Thrombotic occlusion of small perforating arteries (Thrombosis in situ)	
Posterior circulation stroke (POCS) (lateral view) 	Homonymous hemianopia (damage to visual cortex) Cerebellar syndrome Cranial nerve syndromes	Occlusion in vertebral, basilar or posterior cerbral artery territory (Cardiac embolism or thrombosis in situ)	

Fig. 27.10 Clinical and radiological features of the stroke syndromes. The top three diagrams show coronal sections of the brain, and the bottom one shows a sagittal section. The anatomical locations of cerebral functions are shown with the nerve tracts in green. A motor (or sensory) deficit (shown by the red shaded areas) can occur with damage to the relevant cortex (PACS), nerve tracts (LACS) or both (TACS). The corresponding CT scans show horizontal slices at the level of the lesion, highlighted by the arrows.

Risk factor analysis

Initial investigation includes a range of simple blood tests to detect common vascular risk factors and markers of rarer causes, an ECG and brain imaging. Where there is uncertainty about the nature of the stroke, further investigations are indicated. This especially applies to younger patients, who are less likely to have atherosclerotic disease (Box 27.6).

Neuroimaging

Brain imaging with either CT or MRI should be performed in all patients with acute stroke. Exceptions are where results would not influence management, such as in the advanced stage of a terminal illness. CT remains the most practical and widely available method of imaging the brain. It will usually exclude non-stroke lesions, including subdural haematomas and brain tumours, and will demonstrate intracerebral haemorrhage within minutes of stroke onset (see Fig. 27.9). However, especially within the first few hours after symptom onset, CT changes in cerebral infarction may be completely absent or only very subtle. Changes often develop over time (see Fig. 27.11, p. 1245), but small cerebral infarcts may never show up on CT scans. For most purposes, a CT scan performed within 24 hours is

27.6 Causes and investigation of acute stroke in young patients

Cause	Investigation
Cerebral infarct	
Cardiac embolism	Echocardiography (including transoesophageal)
Premature atherosclerosis	Serum lipids
Arterial dissection	MRI Angiography
Thrombophilia	Protein C, protein S Antithrombin III Factor V Leiden, prothrombin
Homocystinuria (p. 449)	Urinary amino acids Methionine loading test
Antiphospholipid antibody syndrome (p. 1055)	Anticardiolipin antibodies/ lupus anticoagulant
Systemic lupus erythematosus	Antinuclear antibodies
Vasculitis	ESR C-reactive protein Antineutrophil cytoplasmic antibody (ANCA)
CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy)	MRI brain Genetic analysis Skin biopsy
Mitochondrial cytopathy	Serum lactate White cell mitochondrial DNA Muscle biopsy Mitochondrial molecular genetics
Fabry's disease	Alpha-galactosidase levels
Neurovascular syphilis	Syphilis serology
Primary intracerebral haemorrhage	
Arteriovenous malformation (AVM)	MRI/angiography
Drug misuse	Drug screen (amphetamine, cocaine)
Coagulopathy	Prothrombin time (PT) and activated partial thromboplastin time (APTT) Platelet count
Subarachnoid haemorrhage	
Saccular ('berry') aneurysm	MRI/angiography
AVM	MRI/angiography
Vertebral dissection	MRI/angiography

adequate but there are certain circumstances in which an immediate CT scan is essential (Box 27.7). Even in the absence of changes suggesting infarction, abnormal perfusion of brain tissue can be imaged with CT after injection of contrast media (i.e. perfusion scanning). This can be useful in guiding immediate treatment of ischaemic stroke.

MRI is not as widely available as CT and scanning times are longer. However, MRI diffusion weighted imaging (DWI) can detect ischaemia earlier than CT, and other MRI sequences can also be used to demonstrate abnormal perfusion (see Fig. 27.4). MRI is more sensitive than CT in detecting strokes affecting the brainstem and cerebellum, and unlike CT, can reliably distinguish haemorrhagic from ischaemic stroke even several weeks after the onset. CT and MRI may reveal clues as to the nature of the arterial lesion. For example, there may be a small, deep lacunar infarct indicating small-vessel disease, or a more peripheral infarct suggesting an extracranial source of embolism (see Fig. 27.10). In a haemorrhagic lesion, the location might indicate the presence of an underlying vascular malformation, saccular aneurysm or amyloid angiopathy.

27.7 Indications for emergency CT/MRI in acute stroke

- Patient on anticoagulants or with abnormal coagulation
- Consideration of thrombolysis or immediate anticoagulation
- Deteriorating conscious level or rapidly progressing deficits
- Suspected cerebellar haematoma, to exclude hydrocephalus

Vascular imaging

Many ischaemic strokes are caused by atherosclerotic thromboembolic disease of the major extracranial vessels. Detection of extracranial vascular disease can help establish why the patient has had an ischaemic stroke and, in highly selected patients, may lead on to specific treatments, including carotid endarterectomy to reduce the risk of further stroke (see below). The presence or absence of a carotid bruit is not a reliable indicator of the degree of carotid stenosis. Extracranial arterial disease can be non-invasively identified with duplex ultrasound, MRA or CT angiography (see Fig. 27.5), or occasionally intra-arterial contrast radiography as above.

Cardiac investigations

Approximately 20% of ischaemic strokes are due to embolism from the heart. The most common causes are atrial fibrillation, prosthetic heart valves, other valvular abnormalities and recent myocardial infarction. These may be identified by clinical examination and ECG, but a transthoracic or transoesophageal echocardiogram is also required to confirm the presence of a clinically apparent cardiac source or to identify an unsuspected source such as endocarditis, atrial myxoma, intracardiac thrombus or patent foramen ovale. Such findings may lead on to specific cardiac treatment.

Management

Management is aimed at minimising the volume of brain that is irreversibly damaged, preventing complications (Box 27.8), reducing the patient's disability and handicap through rehabilitation, and reducing the risk of recurrent stroke or other vascular events. With TIA there is no brain damage and disability, so the priority is to reduce the risk of further vascular events.

Supportive care

Early admission of patients to a specialised stroke unit facilitates coordinated care from a specialised multidisciplinary team (Box 27.9), and has been shown to reduce both mortality and residual disability amongst survivors. Consideration of a patient's rehabilitation needs

27.8 Complications of acute stroke

Complication	Prevention	Treatment
Chest infection	Nurse semi-erect Avoid aspiration (nil by mouth, nasogastric tube, possible gastrostomy)	Antibiotics Physiotherapy
Epileptic seizures	Maintain cerebral oxygenation Avoid metabolic disturbance	Anticonvulsants
Deep venous thrombosis/ pulmonary embolism	Maintain hydration Early mobilisation Anti-embolism stockings Heparin (for high-risk patients only)	Anticoagulation (exclude haemorrhagic stroke first)
Painful shoulder	Avoid traction injury Shoulder/arm supports Physiotherapy	Physiotherapy Local corticosteroid injections
Pressure sores	Frequent turning Monitor pressure areas Avoid urinary damage to skin	Nursing care Pressure-relieving mattress
Urinary infection	Avoid catheterisation if possible Use penile sheath	Antibiotics
Constipation	Appropriate aperients and diet	Appropriate aperients
Depression and anxiety	Maintain positive attitude and provide information	Antidepressants

EBM 27.9 Specialist stroke units

'Admitting 1000 patients to a stroke unit prevents about 50 patients from being dead or dependent at 6 months.'

27.10 Management of acute stroke

Airway

- Perform bedside swallow screen and keep patient nil by mouth if swallowing unsafe or aspiration occurs

Breathing

- Check respiratory rate and oxygen saturation and give oxygen if saturation < 95%

Circulation

- Check peripheral perfusion, pulse and blood pressure and treat abnormalities with fluid replacement, anti-arrhythmics and inotropic drugs as appropriate

Hydration

- If signs of dehydration, give fluids parenterally or by nasogastric tube

Nutrition

- Assess nutritional status and provide nutritional supplements if necessary
- If dysphagia persists for > 48 hrs, start feeding via a nasogastric tube

Medication

- If patient is dysphagic, consider alternative routes for essential medications

Blood pressure

- Unless there is heart or renal failure, evidence of hypertensive encephalopathy or aortic dissection, do not lower blood pressure in first week as it may reduce cerebral perfusion. Blood pressure often returns towards patient's normal level within first few days

Blood glucose

- Check blood glucose and treat when levels are ≥ 11.1 mmol/L (200 mg/dL) (by insulin infusion or glucose/ potassium/insulin (GKI)
- Monitor closely to avoid hypoglycaemia

Temperature

- If pyrexic, investigate and treat underlying cause
- Control with antipyretics, as raised brain temperature may increase infarct volume

Pressure areas

- Reduce risk of skin breakdown:
  - Treat infection
  - Maintain nutrition
  - Provide pressure-relieving mattress
  - Turn immobile patients regularly

Incontinence

- Check for constipation and urinary retention; treat appropriately
- Avoid urinary catheterisation unless patient is in acute urinary retention or incontinence is threatening pressure areas

Mobilisation

- Avoid bed rest

should commence at the same time as acute medical management. Dysphagia is common and can be detected by an early bedside test of swallowing. This allows hydration, feeding and medication to be given safely, if necessary by nasogastric tube or intravenously. In the acute phase, a checklist may be useful (Box 27.10) to ensure that all the factors that might influence outcome have been addressed.

The patient's neurological deficits may worsen during the first few hours or days after their onset. This is most common in those with lacunar infarcts but may occur in other patients, due to extension of the area of infarction, haemorrhage transformation, or the development of oedema with consequent mass effect. It is important to distinguish these patients from those who are deteriorating as a result of complications such as hypoxia, sepsis, epileptic seizures or metabolic abnormalities that may be reversed more easily. Patients with cerebellar haematomas or infarcts with mass effect may develop obstructive hydrocephalus and some will benefit from insertion of a ventricular drain and/or decompressive

EBM 27.11 Role of treatments in acute stroke

Treatment	Target group	Approximate proportion of patients eligible for treatment	NNT to prevent 1 death or disability in those treated
Aspirin[1]	Acute ischaemic stroke	90%	80
Thrombolysis with rt-PA[2]	Acute ischaemic stroke		
	Treated within 3 hrs of onset	10%	9
	Treated within 3–4.5 hrs of onset	10%	20
Decompressive hemicraniectomy[3]	Large cerebral infarction	< 1%	2
Stroke unit care[4]	Acute stroke	80%	20

(NNT = number needed to treat; rtPA = tissue plasminogen activator)

surgery (Box 27.11). Some patients with large haematomas or infarction with massive oedema in the cerebral hemispheres may benefit from anti-oedema agents, such as mannitol or artificial ventilation. Surgical decompression to reduce intracranial pressure should be considered in appropriate patients.

Thrombolysis

Intravenous thrombolysis with recombinant tissue plasminogen activator (rt-PA) increases the risk of haemorrhagic transformation of the cerebral infarct with potentially fatal results. However, if it is given within 4.5 hours of symptom onset to carefully selected patients, the haemorrhagic risk is offset by an improvement in overall outcome (see Box 27.11). The earlier treatment is given, the greater the benefit.

Aspirin

In the absence of contraindications, aspirin (300 mg daily) should be started immediately after an ischaemic stroke unless rt-PA has been given, in which case it should be withheld for at least 24 hours. Aspirin reduces the risk of early recurrence and has a small but clinically worthwhile effect on long-term outcome (see Box 27.11); it may be given by rectal suppository or by nasogastric tube in dysphagic patients.

Heparin

Anticoagulation with heparin has been widely used to treat acute ischaemic stroke in the past. Whilst it reduces the risk of early ischaemic recurrence and venous thromboembolism, it increases the risk of both intracranial and extracranial haemorrhage. Furthermore, routine use of heparin does not result in better long-term outcomes, and therefore it should not be used in the routine management of acute stroke. It is unclear whether heparin might provide benefit in selected patients, such as those with recent myocardial infarction, arterial dissection or progressing strokes. Intracranial haemorrhage must be excluded on brain imaging before considering anticoagulation.

Coagulation abnormalities

In those with intracerebral haemorrhage, coagulation abnormalities should be reversed as quickly as possible to reduce the likelihood of the haematoma enlarging. This most commonly arises in those on warfarin therapy. There is no evidence that clotting factors are useful in the absence of a clotting defect.

Management of risk factors

The approaches used are summarised in Figure 27.11. The average risk of a further stroke is 5–10% within the first week of a stroke or TIA, perhaps 15% in the first year and 5% per year thereafter. The risks are not substantially different for intracerebral haemorrhage. Patients with ischaemic events should be put on long-term antiplatelet drugs and statins to lower cholesterol. For patients in atrial fibrillation, the risk can be reduced by about 60% by using oral anticoagulation to achieve an INR of 2–3. The role of newer oral anticoagulants (such as dabigatran) is currently being investigated. The risk of recurrence after both ischaemic and haemorrhagic strokes can be reduced by blood pressure reduction, even for those with relatively normal blood pressures (Box 27.12).

Carotid endarterectomy and angioplasty

A small proportion of patients with a carotid territory ischaemic stroke or TIA will have a greater than 50% stenosis of the carotid artery on the side of the brain lesion. Such patients have a greater than average risk of stroke recurrence. For those without major residual disability, removal of the stenosis has been shown to reduce the overall risk of recurrence, although the operation itself carries about a 5% risk of stroke (see Box 27.12). Surgery is most effective in patients with more severe stenoses (70–99%) and in those in whom it is performed within the first couple of weeks after the TIA or ischaemic stroke. Carotid angioplasty and stenting are technically feasible but have not been shown to be as effective as endarterectomy for the

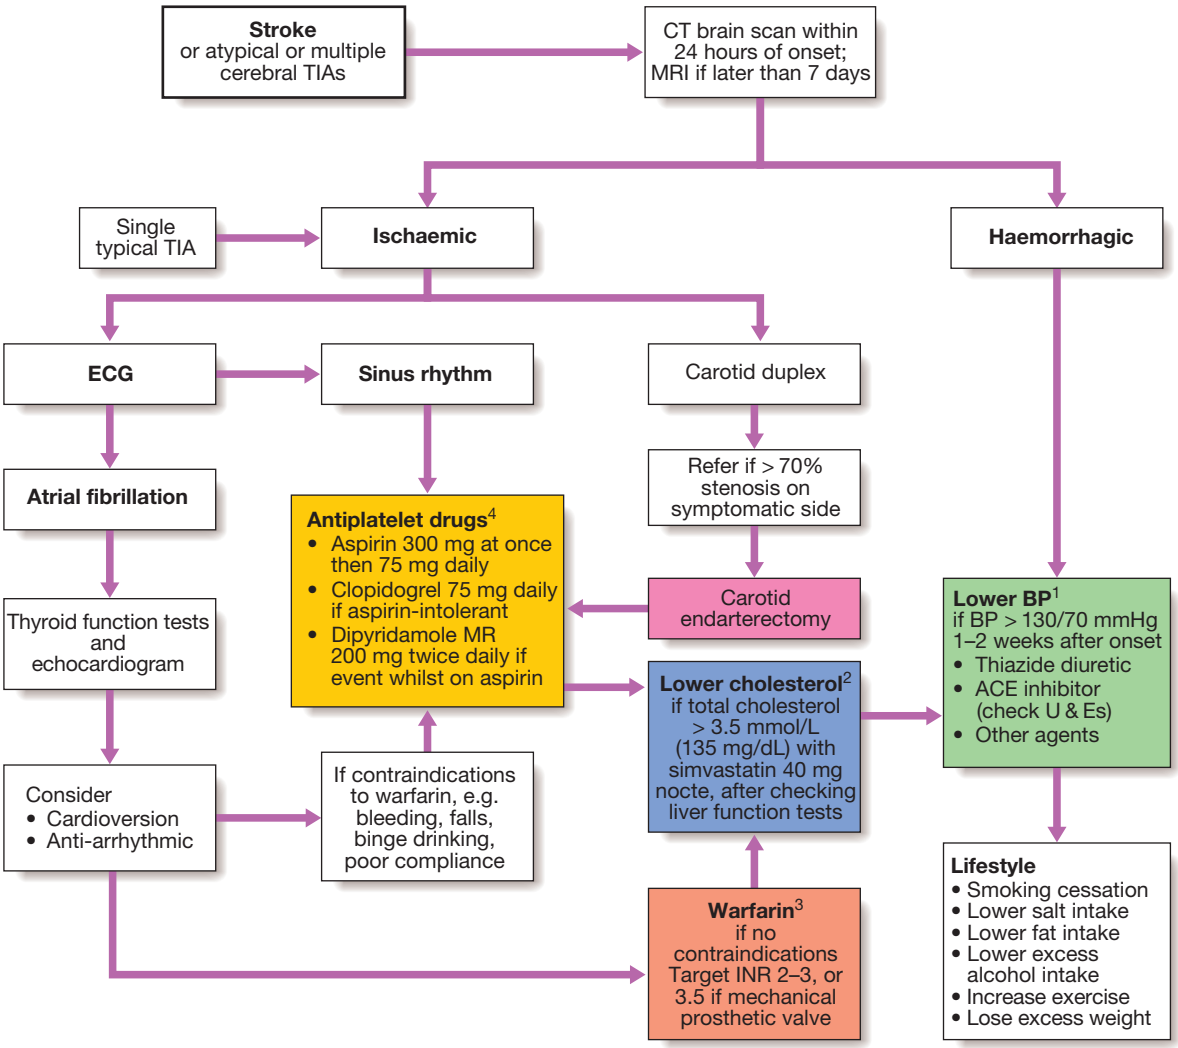

Fig. 27.11 Strategies for secondary prevention of stroke. (1) Lower BP with caution in patients with postural hypotension, renal impairment or bilateral carotid stenosis. (2) Pravastatin 40 mg can be used as an alternative to simvastatin in patients on warfarin or digoxin. (3) Warfarin and aspirin can be used in combination in patients with prosthetic heart valves. (4) The combination of aspirin and clopidogrel is only indicated in patients with unstable angina who demonstrate ECG or enzyme changes.

EBM 27.12 Strategies for secondary prevention

Treatment	Target group	Approximate proportion of patients eligible for treatment	NNT to prevent 1 recurrent stroke
Antiplatelet drugs (clopidogrel, aspirin/dipyridamole[1]	Ischaemic stroke or TIA (in sinus rhythm)	90%	100
Statins[2]	Ischaemic stroke or TIA	80%	60
Blood pressure-lowering[3]	All stroke (ischaemic or haemorrhagic) with blood pressure > 130/80 mmHg	60%	50
Anticoagulation with warfarin (or newer oral anticoagulant)[4]	Ischaemic stroke patients in atrial fibrillation	20%	15
Carotid endarterectomy[5]	Ischaemic stroke or TIA Recently symptomatic severe carotid stenosis	< 10%	15

majority of eligible patients. Endarterectomy of asymptomatic carotid stenosis has been shown to reduce the subsequent risk of stroke, but the small absolute benefit does not justify its routine use.

SUBARACHNOID HAEMORRHAGE

Subarachnoid haemorrhage (SAH) is less common than ischaemic stroke or intracerebral haemorrhage (see Fig. 27.1) and affects about 6/100 000 of the population. Women are affected more commonly than men and the condition usually presents before the age of 65. The immediate mortality of aneurysmal SAH is about 30%; survivors have a recurrence (or rebleed) rate of about 40% in the first 4 weeks and 3% annually thereafter.

Eighty-five percent of SAH are caused by saccular or 'berry' aneurysms arising from the bifurcation of cerebral arteries (see Fig. 27.2), particularly in the region of the circle of Willis. The most common sites are in the anterior communicating artery (30%), posterior communicating artery (25%) or middle cerebral artery (20%). There is an increased risk in first-degree relatives of those with saccular aneurysms, and in patients with polycystic kidney disease (p. 505) and congenital connective tissue defects such as Ehlers–Danlos syndrome (p. 1045). In about 10% of cases, SAH are non-aneurysmal haemorrhages (so-called perimesencephalic haemorrhages), which have a very characteristic appearance on CT and a benign outcome in terms of mortality and recurrence. Five percent of SAH are due to arteriovenous malformations and vertebral artery dissection.

Clinical features

SAH typically presents with a sudden, severe, 'thunderclap' headache (often occipital), which lasts for hours or even days, often accompanied by vomiting, raised blood pressure and neck stiffness or pain. It commonly occurs on physical exertion, straining and sexual excitement. There may be loss of consciousness at the onset, so SAH should be considered if a patient is found comatose. About 1 patient in 8 with a sudden severe headache has SAH and, in view of this, all who present in this way require investigation to exclude it (Fig. 27.12).

On examination, the patient is usually distressed and irritable, with photophobia. There may be neck stiffness due to subarachnoid blood but this may take some hours to develop. Focal hemisphere signs, such as hemiparesis or aphasia, may be present at onset if there is an associated intracerebral haematoma. A third nerve palsy may be present due to local pressure from an aneurysm of the posterior communicating artery, but this is rare. Fundoscopy may reveal a subhyaloid haemorrhage, which represents blood tracking along the subarachnoid space around the optic nerve.

Investigations

CT brain scanning and lumbar puncture are required. The diagnosis of SAH can be made by CT, but a negative result does not exclude it, since small amounts of blood in the subarachnoid space cannot be detected by CT (see Fig. 27.12). Lumbar puncture should be performed 12 hours after symptom onset if possible, to allow detection of xanthochromia (p. 1153). If either of these tests is positive, cerebral angiography (see Fig. 27.5) is required to determine the optimal approach to prevent recurrent bleeding.

Management

Nimodipine (30–60 mg IV for 5–14 days, followed by 360 mg orally for a further 7 days) is usually given to prevent delayed ischaemia in the acute phase. Insertion of platinum coils into an aneurysm (via an endovascular procedure) or surgical clipping of the aneurysm neck reduces the risk of both early and late recurrence. Coiling is associated with fewer perioperative complications and better outcomes than surgery; where

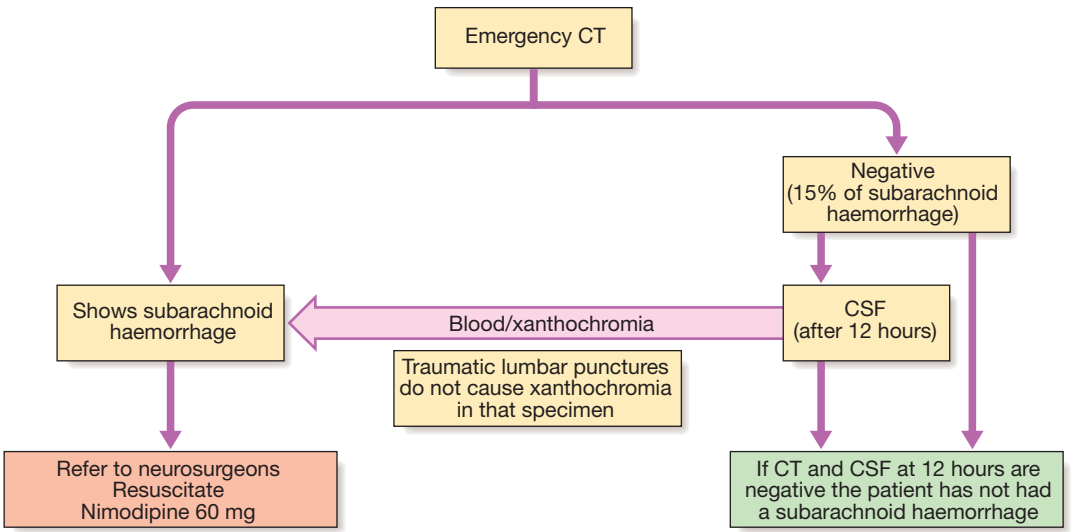

Fig. 27.12 Investigation of subarachnoid haemorrhage.

feasible, it is now the procedure of first choice. Arteriovenous malformations can be managed either by surgical removal, by ligation of the blood vessels that feed or drain the lesion, or by injection of material to occlude the fistula or draining veins. Treatment may also be required for complications of SAH, which include obstructive hydrocephalus (that may require drainage via a shunt), delayed cerebral ischaemia due to vasospasm (which may be treated with vasodilators), hyponatraemia (best managed by fluid restriction) and systemic complications associated with immobility, such as chest infection and venous thrombosis.

CEREBRAL VENOUS DISEASE

Thrombosis of the cerebral veins and venous sinuses (cerebral venous thrombosis) is much less common than arterial thrombosis. However, it has been recognised with increasing frequency in recent years, as access to non-invasive imaging of the venous sinuses using MR venography has increased. The main causes are listed in Box 27.13.

Clinical features

Cerebral venous sinus thrombosis usually presents with symptoms of raised intracranial pressure, seizures and focal neurological symptoms. The clinical features vary according to the sinus involved (Box 27.14 and see Fig. 27.3, p. 1235). Cortical vein thrombosis presents with focal cortical deficits such as aphasia and hemiparesis (depending on the area affected), and epilepsy (focal or generalised). The deficit can increase if spreading thrombophlebitis occurs.

27.13 Causes of cerebral venous thrombosis

Predisposing systemic causes

- Dehydration
- Pregnancy
- Behçet's disease (p. 1119)
- Thrombophilia (p. 1001)
- Hypotension
- Oral contraceptive use

Local causes

- Paranasal sinusitis
- Meningitis, subdural empyema
- Penetrating head and eye wounds
- Facial skin infection
- Otitis media, mastoiditis
- Skull fracture

27.14 Clinical features of cerebral venous thrombosis

Cavernous sinus thrombosis

- Proptosis, ptosis, headache, external and internal ophthalmoplegia, papilloedema, reduced sensation in trigeminal first division
- Often bilateral, patient ill and febrile

Superior sagittal sinus thrombosis

- Headache, papilloedema, seizures
- Clinical features may resemble idiopathic intracranial hypertension (p. 1217)
- May involve veins of both hemispheres, causing advancing motor and sensory focal deficits

Transverse sinus thrombosis

- Hemiparesis, seizures, papilloedema
- May spread to jugular foramen and involve cranial nerves 9, 10 and 11

Investigations and management

MR venography demonstrates a filling defect in the affected vessel.

Anticoagulation, initially with heparin followed by warfarin, is usually beneficial, even in the presence of venous haemorrhage. In selected patients, the use of endovascular thrombolysis has been advocated. Management of underlying causes and complications, such as persistently raised intracranial pressure, is also important.

About 10% of cerebral venous sinus thrombosis, particularly cavernous sinus thrombosis, is associated with infection (most commonly *Staphylococcus aureus*), which necessitates antibiotic treatment. Otherwise, the treatment of choice is anticoagulation.

CLINICAL EXAMINATION IN SKIN DISEASE

1 Distribution of rash
Symmetrical vs asymmetrical
Proximal vs distal vs facial
Localised vs widespread

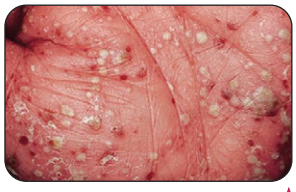
2 If symmetrical
Extensor, e.g. psoriasis
Flexor, e.g. eczema

3 Involvement of hands, including nail folds and finger webs

4 Nail involvement

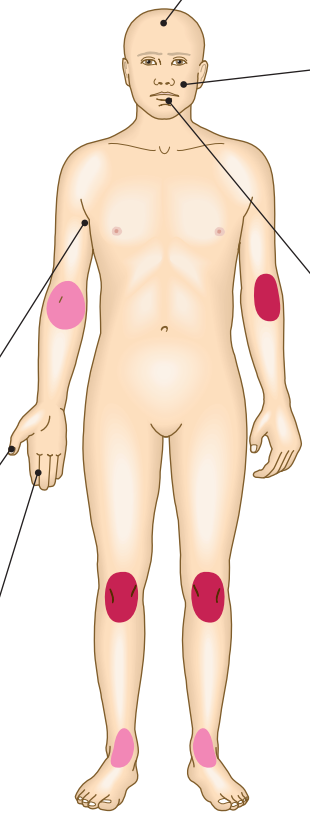
Psoriatic changes in nails and peri-ungual involvement

5 Involvement of axillae/groin
e.g. hidradenitis suppurativa



6 Morphology of rash
Monomorphic or polymorphic

7 Individual lesions
Discrete, grouped, confluent, reticulate (lace-like), linear



8 Morphology of individual lesions
Use a hand lens in good lighting to assist
Use correct terminology, e.g. macules, papules, pustules

Hand lens

Palmoplantar pustulosis

Observation

The patient must be undressed, with make-up and dressings removed, and examined in good lighting. Consider the following:
- Age
- General health
- Distress
- Scratching

9 Examination of scalp
Hair loss
Scalp changes

Heavy infestation with head lice

10 Involvement of face
Central
Hairline
Cheeks and nasal bridge: 'butterfly' distribution
Sparing of light-protected sites, e.g. behind ears, under chin

11 Eye involvement
e.g. Conjunctivitis/blepharitis in rosacea or eyelash loss in alopecia areata

12 Oral and genital involvement

Reticulate (lacy) network on buccal mucosa in lichen planus. May also be genital involvement

13 Joint involvement
e.g. Psoriatic arthritis

Arthritis, plaque psoriasis and psoriatic nail dystrophy

14 General medical examination
Including lymph nodes and other systems as indicated

Key points in the history and examination in skin disease

It may be tempting to examine the skin before anything else. This is a mistake; take a history first, and then examine the skin and the rest of the patient.

History

History-taking should follow general principles:

- What was the onset of the condition and what is its course (coming and going, fluctuating severity, persistent, progressing)?
- Are there any excerbating or relieving factors?
- Is there a past history of skin disease, atopy or autoimmune disease?
- What is the patient's medication and allergy history? This is important, as drug-induced eruptions are common
- What is the social history? Several factors, including occupation, might be relevant both in making a diagnosis and in deciding on the best treatment approach
- How does this condition affect my patient? A widespread eruption may have little effect on one individual's quality of life, whereas another person might be severely troubled by what appears to be a minor problem to an outside observer

Examination

- Assessment requires particular emphasis on examination of the skin, hair, nails, mucous membranes and peripheral lymph nodes

Terminology

- Correct use of terminology for examination findings (see below) helps in making a differential diagnosis and allows you to describe the findings so that colleagues can visualise the process

Assessment of disease severity

- Tools for objective assessment of disease severity, such as the Psoriasis Area and Severity Index (PASI) score, can be useful in determining treatment responses (p. 1288)
- Skin disease can have major psychological effects, and the impact on patients can be gauged by dermatology health-related life quality indices, e.g. the Dermatology Life Quality Index (DLQI)

Terms used to describe skin lesions

Lesion types

- **Macule**: a circumscribed flat area of skin of ≤ 1 cm diameter that appears different from the skin surrounding it, usually because of different colour
- **Patch**: the same as a macule but larger (see Fig. 28.38, p. 1295)
- **Papule**: a discrete elevation of skin of ≤ 1 cm diameter (see Fig. 28.23, p. 1279)
- **Nodule**: similar to a papule but having significant depth (into dermis or even subcutaneous layer) and usually > 1 cm in diameter (see Fig. 28.9, p. 1270)
- **Plaque**: a raised area of skin with a flat top, > 1 cm in diameter (see Fig. 28.32A, p. 1287)
- **Vesicle and bulla**: a small (≤ 1 cm) and a larger (> 1 cm in diameter) fluid-filled blister, respectively (see Fig. 28.37A, p. 1294)
- **Pustule**: a visible accumulation of pus in a blister (see opposite)

Other terms

- **Abscess**: a localised collection of pus in a cavity
- **Atrophy**: an area of thin, translucent skin caused by loss of epidermis, dermis or subcutaneous fat, e.g. secondary to excess topical corticosteroids (see Fig. 28.8, p. 1265)
- **Burrow**: a linear or curvilinear papule, caused by a burrowing scabies mite (see Fig. 28.25A, p. 1280)
- **Comedone**: a plug of keratin and sebum in a dilated pilosebaceous orifice
- **Crust**: dried exudate of blood or serous fluid (see Fig. 28.17, p. 1275)
- **Erosion**: an area of skin denuded by complete or partial loss of the epidermis
- **Excoriation**: a linear ulcer or erosion resulting from scratching
- **Fissure**: a slit-shaped deep ulcer, e.g. in irritant dermatitis of the hands
- **Petechiae, purpura and ecchymosis**: petechiae are pinhead-sized, flat macules of extravascular blood in the dermis; purpura are larger and may be palpable; ecchymosis ('bruise') is the term used to describe bleeding that involves deeper structures
- **Scale**: a flake arising from the stratum corneum. Any condition with a thickened stratum corneum, i.e. hyperkeratosis, can cause scaling. An immature thickened and cohesive stratum corneum, e.g. as in psoriasis or Bowen's disease, gives characteristic optical and physical properties that cause a different scale from that due to a thickened, but otherwise normal, stratum corneum (see Fig. 28.11, p. 1271)
- **Scar**: replacement of normal structures by fibrous tissue at the site of an injury
- **Sinus**: a cavity or channel that permits the escape of pus or fluid
- **Stria**: a linear, atrophic, pink, purple or white band caused by connective tissue changes (see Fig. 28.8, p. 1265)
- **Telangiectasia**: visible dilatation of small cutaneous blood vessels (see Fig. 28.9A, p. 1270)
- **Ulcer**: an area from which the epidermis and at least the upper part of the dermis have been lost (see Fig. 28.7, p. 1263)
- **Weal**: an evanescent discrete area of dermal oedema, often centrally white due to masking of local blood supply by fluid; weals can be papules, macules, patches and plaques, and are the hallmark of urticaria (see Fig. 28.34, p. 1291)

Disease affecting the human skin is common, and is important because the absence of normal skin function, as well as sometimes being life-threatening, can severely impair quality of life. This may be exacerbated by the fact that people with skin disease may suffer the effects of stigma, on occasion stemming from others' belief that skin changes are the result of contagious disease.

Skin diseases affect all ages and number more than two thousand. Assessment of the skin is valuable in the management of anyone presenting with any medical problem and, conversely, assessment of the other body systems is important when managing primarily skin disease. This chapter concentrates on those skin diseases seen most frequently and those that are important as components of general medical conditions affecting other organ systems along with the skin. Skin infections, including those related to the human immunodeficiency virus (HIV), are also discussed in Chapters 13, 14 and 15.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The skin covers just under 2 m^2 in the average adult. The outer layer is the epidermis, a stratified squamous epithelium consisting mainly of keratinocytes. The epidermis is attached to, but separated from, the underlying dermis by the basement membrane. The dermis is less cellular and supports blood vessels, nerves and epidermal-derived appendages (hair follicles and sweat glands). Below it is the subcutis, consisting of adipose tissue.

Epidermis

On most sites, the epidermis is only 0.1–0.2 mm thick, except on the palms or soles where it can extend to several millimetres. Keratinocytes make up approximately 90% of epidermal cells (Fig. 28.1). The main proliferative compartment is the basal layer. Keratinocytes synthesise a range of structural proteins, such as keratins, loricrin and filaggrin (filament aggregating protein), that play key roles in maintaining normal cutaneous physiology. There are more than 50 types of keratin and their expression varies by body site, site within the epidermis and disease state. Mutations of certain keratin genes can result in blistering disorders (p. 1291) and ichthyosis (characterised by scale without major inflammation). As keratinocytes migrate from the basal layer, they differentiate, producing a variety of protein and lipid products. Keratinocytes undergo apoptosis in the granular layer before losing their nuclei and becoming the flattened corneocytes of the stratum corneum (keratin layer). The epidermis is a site of lipid production, and the ability of the stratum corneum to act as a hydrophobic barrier is the result of its 'bricks and mortar' design; dead corneocytes with highly cross-linked protein membranes ('bricks') lie within a metabolically active lipid layer synthesised by keratinocytes ('mortar'). Terminal differentiation of keratinocytes relies on the keratin filaments being aggregated and this is, in part, mediated by filaggrin. Mutations of the filaggrin gene are found in icthyosis vulgaris, and occur in some patients with atopic eczema (p. 1283).

The skin is a barrier against physical stresses. Cell-to-cell attachments must be able to transmit and dissipate stress, a function performed by desmosomes. Diseases that affect desmosomes, such as pemphigus (p. 1294), result in blistering due to keratinocyte separation.

The remaining 10% of epidermal cells are:

- *Langerhans' cells*: dendritic, bone marrow-derived cells that circulate between the epidermis and local lymph nodes. Their prime function is antigen presentation to lymphocytes. Other dermal antigen-presenting dendritic cells are also present.
- *Melanocytes*: predominantly in the basal layer and of neural crest origin. They synthesise the pigment melanin from tyrosine, package it in melanosomes and transfer it to surrounding keratinocytes via their dendritic processes.
- *Merkel cells*: occur in the basal layer and are thought to play a role in signal transduction of fine touch. Their embryological derivation is unclear.

Basement membrane

The basement membrane (see Fig. 28.1) is an anchor for the epidermis and allows movement of cells and nutrients between dermis and epidermis. The cell membrane of the epidermal basal cell is attached to the basement membrane via hemi-desmosomes. The lamina lucida lies immediately below the basal cell membrane and is composed predominantly of laminin. Anchoring filaments extend through the lamina lucida to attach to the lamina densa. This electron-dense layer consists mostly of type IV collagen; from it extend loops of type VII collagen, forming anchoring fibrils that fasten the basement membrane to the dermis.

Dermis

The dermis is vascular and supports the epidermis structurally and nutritionally. It varies in thickness from just over 1 mm on the inner forearm to 4 mm on the back. Fibroblasts are the predominant cells; others include mast cells, mononuclear phagocytes, T lymphocytes, dendritic cells, neurons and endothelial cells. The acellular part of the dermis consists mainly of fibres, including collagen I and III, elastin and reticulin, synthesised by fibroblasts. Support is provided by an amorphous ground substance (mostly glycosaminoglycans, hyaluronic acid and dermatan sulphate), whose production and catabolism are altered by hormonal changes and ultraviolet radiation (UVR). Based on the pattern of collagen fibrils, the superficial dermis is termed the 'papillary dermis', and the deeper, coarser part is the 'reticular dermis'.

Epidermal appendages

Hair follicles

There are 3–5 million hair follicles, epidermal invaginations that develop during the second trimester. They occur throughout the skin, with the exception of palms, soles and parts of the genitalia (glabrous skin). The highest density of hair follicles is on the scalp (500–1000/cm^2). Newborns are covered with fine 'lanugo' hairs, which are usually non-pigmented and lack a central medulla; these are subsequently replaced by vellus hair, which is similar but more likely to be

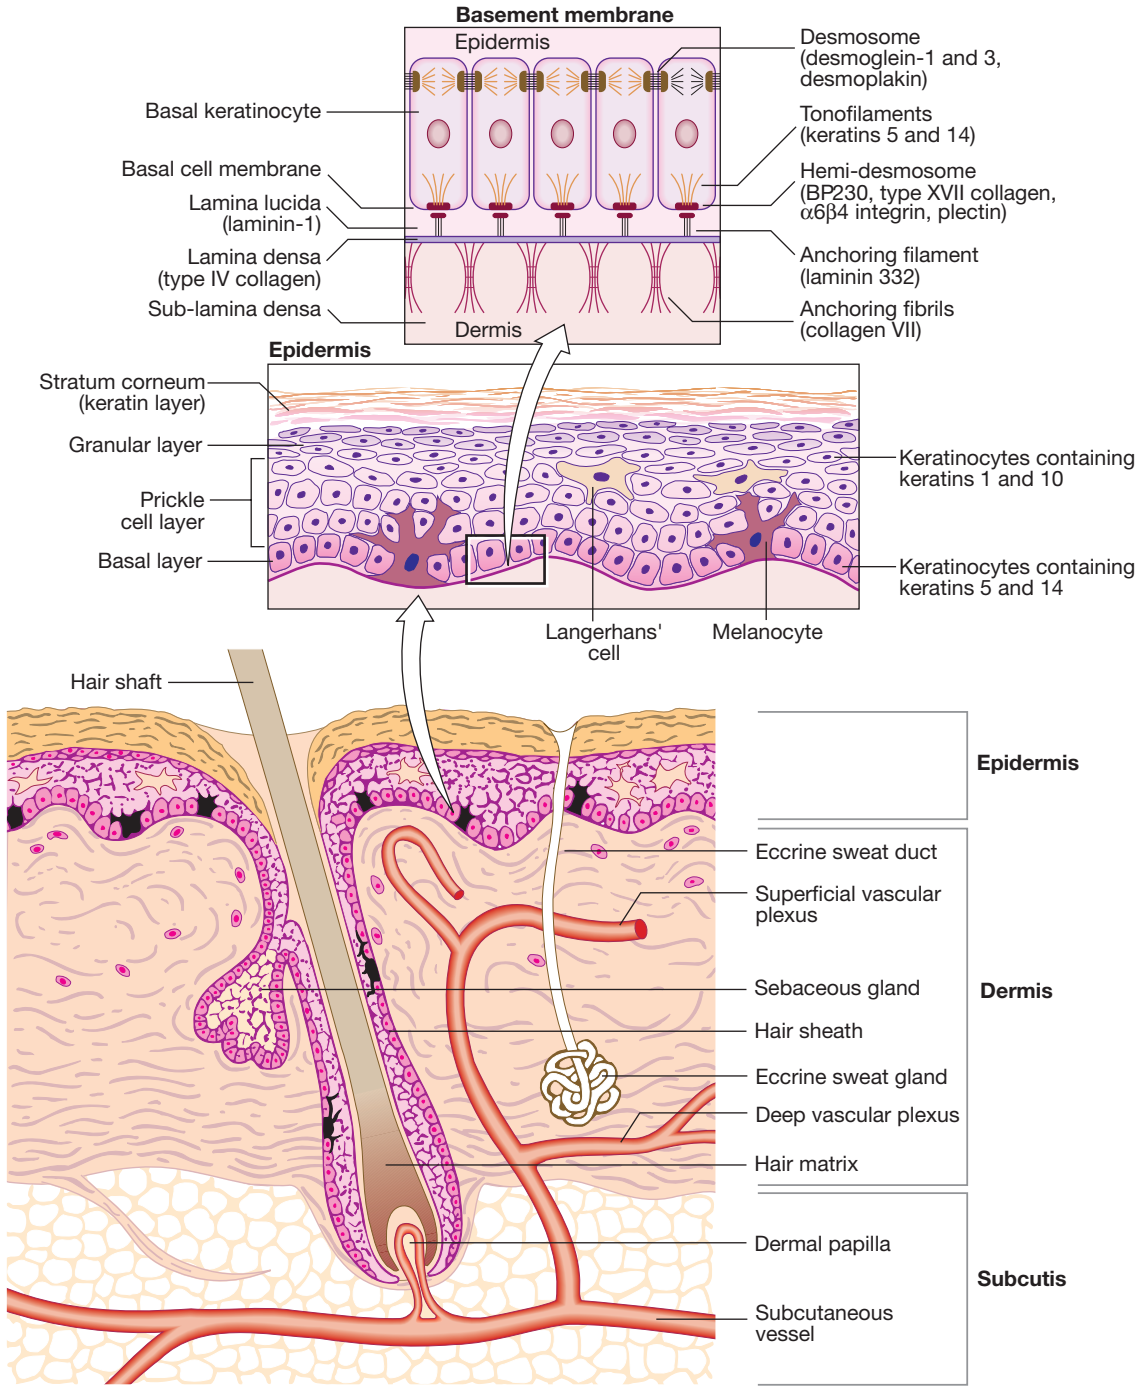


Fig. 28.1 Structure of normal skin.

pigmented. By contrast, scalp hair becomes terminal hair, which is thicker with a central medulla, is usually pigmented and grows longer. At puberty, vellus hairs in hormonally sensitive regions, such as the axillary and genital areas, become terminal.

Human hairs grow in a cycle with three phases: anagen (active hair growth), catagen (transitional phase) and telogen (resting phase). The duration of each phase varies by site. On the scalp, anagen lasts several years, catagen a few days and telogen around 3 months. The length of hair at different sites reflects the differing lengths of anagen.

Sebaceous glands

Sebaceous glands are epidermal downgrowths, usually associated with hair follicles and comprised of modified keratinocytes. The cells of the sebaceous gland (sebocytes) produce a range of lipids, discharging the contents into the duct around the hair follicle. Sebum excretion is under hormonal control, with androgens

28.1 Functions of the skin

Function	Structure/cell involved
Protection against:	
Chemicals, particles, desiccation	Stratum corneum
Ultraviolet radiation (UVR)	Melanin produced by melanocytes and transferred to keratinocytes Stratum corneum hyperproliferation
Antigens, haptens	Langerhans' cells, lymphocytes, mononuclear phagocytes, mast cells, dermal dendritic cells
Microorganisms	Stratum corneum, Langerhans' cells, mononuclear phagocytes, mast cells, dermal dendritic cells
Maintenance of fluid balance Prevents loss of water, electrolytes and macromolecules	Stratum corneum
Shock absorber Strong, elastic and compliant covering	Dermis and subcutaneous fat
Sensation	Specialised nerve endings mediating pain and withdrawal Itch leading to scratch and (e.g.) removal of a parasite
Vitamin D synthesis	Keratinocytes
Metabolism e.g. Detoxification of xenobiotics, retinoid metabolism, isomerisation of urocanic acid	Predominantly keratinocytes
Temperature regulation	Eccrine sweat glands and blood vessels
Protection, and fine manipulation of small objects	Nails
Hormonal Steroidogenesis, testosterone synthesis and conversion to other androgenic steroids	Hair follicles, sebaceous glands
Conversion of thyroxine (T4) to triiodothyronine (T3)	Keratinocytes
Pheromonal (Importance unknown in humans)	Apocrine sweat glands, possibly sebaceous glands
Psychosocial, grooming and sexual behaviour	Appearance, tactile quality of skin, hair, nails

28.2 Skin changes in old age

- **Chronological ageing**: due to the intrinsic ageing process.
- **Photoageing**: due to cumulative UVR exposure and superimposed on intrinsic ageing.
- **Typical changes include**: atrophy, laxity, yellow discoloration, wrinkling, dryness, irregular pigmentation, and thinning and greying of hair.
- **Causes**: age-related alterations in structure and function of the skin, cumulative effects of environmental insults, especially UVR and smoking, cutaneous consequences of disease in other organ systems.
- **Consequences**: reduction in immune and inflammatory responses, reduction in absorption and clearance of topical medications, reduced healing, increased susceptibility to irritants, dermatitis, adverse drug effects (including topical corticosteroid-induced atrophy and purpura) and diseases such as skin cancer.

increasing it (as do progesterones, to a lesser degree) and oestrogens reducing it. In animals, sebum is important for hair waterproofing but its role in humans is unclear.

Sweat glands

Eccrine sweat glands develop in the second trimester and are also epidermal invaginations found all over the body. Their coiled ducts open directly on to the skin surface. They play a major role in thermoregulation and, unusually, are innervated by cholinergic fibres of the sympathetic nervous system. Eccrine glands of the palms and soles are innervated differently and are activated in the 'fight or flight' response. Apocrine sweat glands are restricted to the axillae and the mammary and genital areas, are connected to hair follicles and are not involved in thermoregulation.

Nails

Fingernail growth commences at approximately 8 weeks of gestation and is complete by 32 weeks. Toenails develop slightly later. The anatomy of the nail apparatus is covered later in the chapter (p. 1297).

Blood vessels and nerves

Human skin has a plentiful blood supply, arranged in superficial and deep plexuses consisting of arterioles, arterial and venous capillaries, and venules. The upper plexus in the papillary dermis communicates with the lower plexus at the junction between the dermis and the subcutis. Capillary loops arise from terminal arterioles in the horizontal papillary plexus. Blood vessels are supplied by sympathetic and parasympathetic nerves, with the relative contributions of the pathways differing by site. Sympathetic signals are important in mediating autonomic-induced vasoconstriction. The blood supply of skin is far greater than that required for normal skin physiology and reflects the importance of skin in thermoregulation.

Functions of the skin

The skin has many functions, all of which can be affected by disease (Box 28.1). Skin changes associated with ageing are shown in Box 28.2.

INVESTIGATIONS

Magnifying glass

A hand lens used under good lighting conditions (ideally daylight) is valuable in examination of the skin.

Wood's light

Wood's light is a long-wavelength ultraviolet A/short-wavelength visible (violet) light source that can be used in various ways. In hypopigmentation, such as in vitiligo, it can help in appreciating the extent of disease. In pigmented conditions, such as melasma, it can determine whether pigmentation is mainly epidermal (sharp cut-off under Wood's lamp) or mixed epidermal and dermal (ill-defined cut-off). Wood's lamp can also be used to help with the diagnosis of some fungal infections because of their characteristic fluorescence.

Dermatoscopy and diascopy

Dermatoscopy (also known as dermoscopy and epiluminescence microscopy) is increasingly performed with hand-held dermatoscopes. What makes dermatoscopy unique is the fact that it allows visualisation through contact of a glass plate on the instrument with a liquid film applied to the skin, or through special optics to allow non-contact dermatoscopy, enabling deeper structures to be seen without interference by reflection and refraction of light in the epidermis.

Diascopy is simply pressing on the lesion with a glass slide. This provides some of the effect of dermatoscopy, but is mainly used to remove blood from vascular lesions to make the appearance of the lesion clearer.

Histopathology

Histopathological examination of skin biopsies is especially useful for tumour diagnosis. When a dermatologist or pathologist with dermatopathology expertise is involved, it can also assist in the diagnosis of inflammatory skin diseases. It is rare for histopathology of a previously undiagnosed inflammatory skin disease to provide a diagnosis on its own; clinico-pathological correlation is key. Most biopsies are stained with haematoxylin and eosin, but other stains may be useful in special situations, such as for fungal hyphae, iron or mucin. Direct immunofluorescence can also be undertaken on a fresh skin biopsy, allowing antigen visualisation using fluorescein-labelled antibodies; this is especially important in the diagnosis of autoimmune bullous disorders.

Microbiology

Bacteriology

Bacterial swabs may identify a causative infective agent. However, organisms identified from the skin surface may not be implicated in the underlying disease but reflect colonisation of skin damaged by a primary disease. Potential pathogens grown from the skin surface are not always the cause. For example, cellulitis is nearly always caused by pyogenic streptococci, whereas a surface skin swab will often show *Staphylococcus aureus*, which may not be the cause of the cellulitis.

Virology

A number of techniques, including immunofluorescence and polymerase chain reaction (PCR), are available to diagnose herpes simplex or herpes zoster viruses from vesicle fluid (p. 139).

Mycology

Scale, nail clippings (or scrapings of crumbly subungual hyperkeratosis) and plucked hairs can be examined by light microscopy. If potassium hydroxide and a simple light microscope are available, this can be performed in any outpatient clinic. Microbiology laboratories will also examine samples and can culture for fungi and yeasts.

Patch testing

Patch testing investigates delayed, cell-mediated, type IV hypersensitivity, which manifests as dermatitis. It is a provocation test with potential allergens (see Box 28.26, p. 1285) applied, at concentrations and in vehicles to minimise false positive and false negative reactions, under occlusion to the back for 48 hours before examination. When interpreting patch test readings, it is important to determine the clinical relevance of any allergic reactions before giving avoidance advice.

Photopatch testing is similar to patch testing, but investigates delayed hypersensitivity to an agent (usually a sunscreen or a non-steroidal anti-inflammatory (NSAID)) after the absorption of UVR. It involves applying substances in duplicate and irradiating one set with UVR (typically UVA, 5 J/cm^2), with readings then conducted in a similar manner to patch testing.

Prick tests and specific immunoglobulin E testing

Prick tests are used to investigate cutaneous type I (immediate) hypersensitivity to various antigens such as pollen, house dust mite or dander. Skin is pricked with commercially available stylets through a dilution of the appropriate antigen solution (p. 90). Alternatively, specific immunoglobulin E (IgE) levels to antigens can be measured in serum, and occasionally challenge tests are undertaken (p. 90).

Phototesting

Phototesting is important for assessing suspected photosensitivity. The mainstay investigation is monochromator phototesting, which involves exposing the patient's back to increasing doses of irradiation using narrow wavebands across the solar spectrum and then assessing responses, using the minimal erythema dose (MED) at each waveband. This is the dose required to cause just perceptible skin reddening and is compared with values for the normal population. If a patient has reduced MEDs (i.e. develops erythema at lower doses than healthy subjects), this indicates abnormal photosensitivity. Thus, monochromator phototesting can be used to determine whether a patient is abnormally photosensitive, which wavebands are involved and how sensitive the patient is (p. 1260). Provocation testing can be performed with a broadband (usually UVA) source to induce rash at a test site (most useful for polymorphic light eruption) and can be helpful for diagnosis.

Patients who are referred for phototherapy will also usually undergo an MED test, in which they are exposed to a series of test doses of the light source that will be used therapeutically (often narrowband UVB), and the MED is determined 24 hours later (or 72–96 hours for

the psoralen–ultraviolet A (PUVA) minimal phototoxic dose) (p. 1266). This allows treatment regimens to be individualised, based on a patient's erythemal responses, and may detect abnormal photosensitivity.

PRESENTING PROBLEMS IN SKIN DISEASE

The major presentations in dermatology are outlined below. Detail about the underlying disorders is mostly provided in the disease-specific sections later on.

Lumps – new or changing lesions

A 'new or changed lesion' is one of the key dermatology presentations. The challenge is to distinguish between benign and malignant disease (p. 1269). Detailed history-taking and examination are essential:

- *Lesion*: Is this new or has a pre-existing lesion changed? What is the nature of the change – is it in size, colour, shape or surface? Has change been rapid or slow? Are there other features – pain, itch, inflammation, bleeding or ulceration?
- *Patient*: What is the patient's age? Are they fair-skinned and freckled? Has there been much sun exposure? Have they used sunbeds or lived in sunny climates? Have they used photoprotection?
- *Site*: Is it sun-exposed or covered? The scalp, face, upper limbs and back in men, and face, hands and lower legs in women, are the most chronically sun-exposed sites.
- *Are there other similar lesions?* These might include actinic keratoses (see Fig. 28.11, p. 1271) or basal cell papillomas (see Fig. 28.15, p. 1274).
- *Morphology of the lesion*: Tenderness, size, symmetry, regularity of border, colour, surface characteristics and the presence of features such as crust, scale and ulceration must be assessed. Stretching the skin and using a magnifying lens can be helpful, e.g. in detecting the raised, pearled edge of a basal cell carcinoma (p. 1270).
- *Dermatoscopy*: This can be used to detect the presence of abnormal vessels, such as in basal cell carcinoma or the characteristic keratin cysts in basal cell papillomas. It is invaluable for assessing pigmented and vascular lesions (Fig. 28.2).

Is it a melanocytic naevus or a malignant melanoma?

This is a common differential and one that it is critical to resolve correctly.

- The precise nature of the change should be determined (as above). Listen to the patient and pay attention to subtle changes, as patients know their skin well.

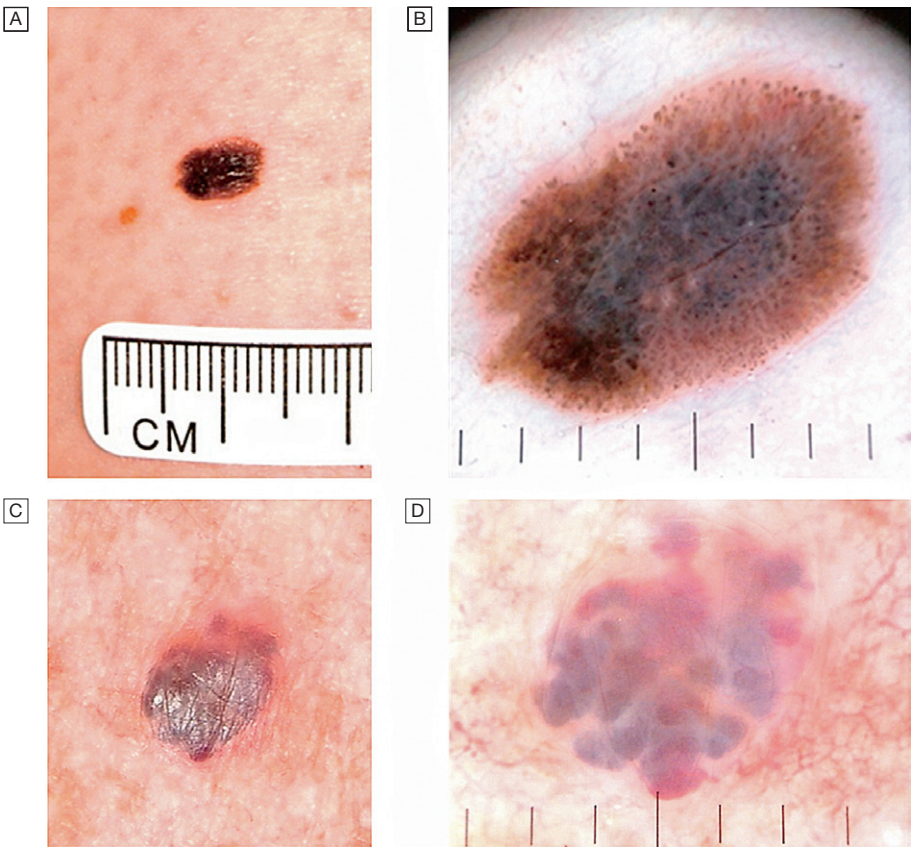

Fig. 28.2 Dermatoscopy. A A changing lesion. B Dermatoscopy highlights the abnormal pigment network and other features suggestive of melanoma. Excision biopsy confirmed the diagnosis of superficial spreading malignant melanoma (Breslow thickness 0.8 mm). C Another changing lesion. D Dermatoscopy highlights the vascular lacunae of this benign angioma and the patient was reassured.

- If the patient has other pigmented lesions, then these should be examined too, as they may be informative. For example, if the presenting lesion looks different from the others, then suspicion is needed; conversely, if the patient has multiple basal cell papillomas, this may be reassuring – although do not be falsely reassured.
- Is there a positive family history of melanoma? A suspicious naevus in a patient with a first-degree relative with melanoma probably warrants excision.

The ABCDE 'rule' is a guide to the characteristic features of melanoma (Box 28.3 and see Fig. 28.2), although, ideally, melanomas should be diagnosed before the diameter is greater than 0.5 cm. Loss of normal skin markings in a pigmented lesion may be suggestive of melanoma. Conversely, normal skin markings and fine hairs dispersed evenly over a lesion are reassuring but do not exclude melanoma. The Glasgow seven-point checklist is another useful guide:

- major features: change in size, shape and colour
- minor features: diameter over 0.5 cm, inflammation, oozing or bleeding, and itch or altered sensation.

28.3 ABCDE features of malignant melanoma

- **A**symmetry
- **B**order irregular
- **C**olour irregular
- **D**iameter > 0.5 cm
- **E**levation irregular

(+ Loss of skin markings)

Rashes – papulosquamous eruptions

A rash is the other common presentation in dermatology. The main categories of scaly rashes are listed in Box 28.4. Diagnosis can often be made on clinical grounds, although a biopsy may be required. Important aspects of the history are:

- *Age at onset and duration of rash?* For example, atopic eczema often starts in early childhood and psoriasis between 15 and 40 years, and both may be chronic. Infective or drug-induced rashes are more likely to be of short duration and the latter occur in relation to drug ingestion. Duration of individual lesions is also important, as, for example, in urticaria.
- *Body site at onset and distribution?* For example, flexural sites are involved in atopic eczema and extensor surfaces and scalp in psoriasis. Symmetry is often indicative of an endogenous disease, such as psoriasis, whereas asymmetry is more common with exogenous causes, such as contact dermatitis or infections like herpes zoster.
- *Is it itchy?* For example, eczema is usually extremely itchy and psoriasis less so.
- *Was there a preceding illness or were systemic symptoms present?* Examples include guttate psoriasis precipitated by a β-haemolytic streptococcal throat infection; almost all patients with infectious mononucleosis (p. 320) treated with amoxicillin will develop an erythematous maculopapular eruption; the rash of secondary syphilis follows a history

28.4 Causes and clinical features of common scaly rashes

Diagnosis	Distribution	Morphology	Associated signs
Atopic eczema (p. 1283)	Face and flexures	Poorly defined erythema, scaling Vesicles Lichenification if chronic	Shiny nails Infra-orbital crease 'Dirty neck' (grey-brown discoloration)
Psoriasis (p. 1286)	Extensor surfaces Lower back	Well-defined Erythematous plaques Silvery scale	Nail pitting, onycholysis Scalp involvement Axillae and genital areas often affected Joint involvement Köbner phenomenon
Pityriasis rosea (p. 1289)	'Fir tree' pattern on trunk	Well-defined Small, erythematous plaques Collarette of scale	Herald patch
Drug eruption (p. 1303)	Widespread	Macules and papules Erythema and scale Exfoliation	Possible mucosal involvement or erythroderma
Pityriasis versicolor (p. 1280)	Upper trunk and shoulders	Hypo- and hyper-pigmented scaly patches	
Lichen planus (p. 1289)	Distal limbs Flexural aspect of wrists Lower back	Shiny, flat-topped, violaceous papules Wickham's striae	White lacy network on buccal mucosa Nail changes Scarring alopecia Köbner phenomenon
Tinea corporis (p. 1279)	Asymmetrical Often isolated lesions	Erythematous, often annular plaques Peripheral scale (sometimes pustules) Expansion with central clearing	Possible associated nail, scalp, groin involvement
Secondary syphilis (p. 419)	Trunk and proximal limbs Palms and soles	Red macules and papules, which become 'gun-metal' grey	History of chancre Systemic symptoms, e.g. malaise and fever

of chancre at the site of inoculation; malaise and arthralgia are common in drug eruptions and vasculitis.

The morphology of the rash and the characteristics of individual lesions are important (see Box 28.4).

Blisters

There are a limited number of conditions that present with blisters (Box 28.5). Blistering occurs due to loss of cell adhesion within the epidermis or sub-epidermal region (see Fig. 28.1, p. 1253), and the clinical presentation depends on the site or level of blistering within the skin, which in turn reflects the underlying pathogenesis (p. 1291):

- Intact blisters are not often seen if the split is high in the epidermis (below the stratum corneum), as the blister roof is so fragile that it ruptures easily, leaving erosions (e.g. pemphigus foliaceus, staphylococcal scalded skin syndrome (see Fig. 28.18, p. 1276) and bullous impetigo).
- If the split is lower in the epidermis, then intact flaccid blisters and erosions may be seen (e.g. pemphigus vulgaris and toxic epidermal necrolysis (see Fig. 28.36, p. 1292)).
- If the split is sub-epidermal, then tense-roofed blisters occur (e.g. bullous pemphigoid (see Fig. 28.37, p. 1294), epidermolysis bullosa acquisita and porphyria cutanea tarda (see Fig. 28.47, p. 1302)).
- If there are foci of separation at different levels of the epidermis, as in a dermatitis (p. 1283), multilocular bullae (made up of coalescing vesicles) occur.

A history of onset, progression, mucosal involvement, drugs and systemic symptoms should be taken. Clinical assessment of the distribution, extent and morphology of the rash should then be made. The Nikolsky sign is useful: sliding pressure from a finger on normal-looking epidermis can dislodge the epidermis in conditions with intra-epidermal defects, such as pemphigus and toxic epidermal necrolysis.

28.5 Causes of acquired blisters

	Localised	Generalised
Vesicular	Herpes simplex Herpes zoster Impetigo Pompholyx	Eczema herpeticum* Dermatitis herpetiformis Acute eczema
Bullous	Impetigo Cellulitis Stasis oedema Acute eczema Insect bites Fixed drug eruption	Toxic epidermal necrolysis* Erythema multiforme Stevens–Johnson syndrome* Bullous pemphigoid Pemphigus* Epidermolysis bullosa acquisita Lupus erythematosus Porphyria cutanea tarda/ pseudoporphyria Drug eruptions

*Usually also mucosal involvement.

A systematic approach to diagnosis is required:

1. *Exclude infection*: e.g. herpes simplex, varicella zoster or *Staph. aureus*.
2. *Consider common skin disorders in which blistering* uncommonly *occurs*: e.g. severe peripheral oedema, cellulitis, allergic contact dermatitis and eczema.
3. *Remember that bullae may develop in drug eruptions*: e.g. fixed drug eruption (p. 1303), erythema multiforme (p. 1302) and vasculitis (p. 1115). Toxic epidermal necrolysis (TEN) is a medical emergency (p. 1292).
4. *Consider immunobullous disease* (p. 1292): the age of the patient may be informative (see Box 28.35, p. 1293).

Investigations and management are guided by the clinical presentation and differential diagnosis, and are described in this chapter under the specific diseases.

Itch (pruritus)

Itch is an unpleasant sensation that leads to scratching or rubbing. The terms 'itch' and 'pruritus' are synonymous; however, 'pruritus' is often used when itch is generalised. Itch can arise from primary cutaneous disease or from systemic disease, which may cause itch by central or peripheral mechanisms. Even when the mechanism is peripheral, there are not always signs of primary skin disease.

The nerve endings that signal itch are in the epidermis or near the dermo–epidermal junction. Transmission is by unmyelinated slow-conducting C fibres through the spinothalamic tract to the thalamus and then the cortex. There is an inhibitory relationship between pain and itch. Scratching either causes inhibition of itch receptors by stimulating ascending sensory pathways that inhibit itch at the spinal cord (Wall's 'gate' mechanism), or interferes directly with cutaneous itch fibres by direct damage.

The mechanisms of itch in most systemic diseases remain unclear. The itch of kidney disease, for example, may be mediated by circulating endogenous opioids. The clinical observation that peritoneal dialysis helps reduce itch more frequently than haemodialysis is consistent with this, smaller molecules generally being dialysed more readily if the peritoneal membrane is used rather than a dialysis machine membrane.

Clinical assessment

Diagnosis is important and full assessment, through history, examination and, sometimes, investigations, is necessary. When a patient presents with generalised

28.6 Primary skin diseases causing pruritus

Generalised pruritus

- Scabies
- Eczemas
- Pre-bullous pemphigoid
- Urticarias
- Xeroderma of old age
- Psoriasis

Localised pruritus

- Eczemas
- Lichen planus
- Dermatitis herpetiformis
- Pediculosis
- Tinea infections

28.7 Secondary causes of pruritus

Medical condition	Cause of pruritus	Treatment*
Liver disease	Central opioid effect Elevation in bile salts may contribute	Naltrexone Colestyramine Rifampicin Sedative antihistamines UVB
Renal failure	Unknown; uraemia contributes	UVB Oral activated charcoal
Haematological disease		
Anaemia	Iron deficiency	Iron replacement
Polycythaemia rubra vera	Unknown (often aquagenic pruritus)	
Lymphoma, Leukaemia, Myeloma	Unknown	
Endocrine disease		
Diabetes mellitus	Increased infection risk, e.g. candidiasis, tinea	Treatment of infection
Thyrotoxicosis	Unknown	Emollients
Hypothyroidism	Unknown	Emollients
Carcinoid syndrome (p. 782)	5HT-mediated	
HIV infection	Infection, infestation, e.g. *Candida*	Treatment of infection
	Eosinophilic folliculitis	Local corticosteroids, UVB
	Seborrhoeic dermatitis	Anti-pityrosporal treatment
	Unknown	UVB
Malignancy	Unknown	
Psychogenic	Unknown	Psychotherapy, anxiolytics, antidepressants

*In addition to specific treatment of the primary condition. (5-HT = 5-hydroxytryptamine, serotonin).

28.8 Causes of pruritus in pregnancy

Diagnosis	Pregnancy, gestation and features	Treatment
Polymorphic eruption of pregnancy (pruritic urticarial papules and plaques, PUPP)	Typically first pregnancy and uncommonly recurs 3rd trimester, after delivery Polymorphic urticated papules and plaques, start in striae	Chlorphenamine, emollients Topical steroids
Acute cholestasis of pregnancy (p. 977)	3rd trimester and commonly recurs in subsequent pregnancies Abnormal liver function tests Increased fetal and maternal risk	Emollients Chlorphenamine Colestyramine UVB Early delivery
Pemphigoid gestationis	Any stage, often 2nd trimester and commonly recurs in subsequent pregnancies Urticated erythema, blistering initially periumbilical Characteristic histology and immunofluorescence	Topical or oral corticosteroids
Prurigo gestationis	2nd trimester Excoriated papules	Emollients Topical corticosteroids Chlorphenamine UVB
Pruritic folliculitis	3rd trimester Sterile pustules on trunk	Topical corticosteroids UVB

itch, it is important to determine whether skin changes are primary (a process in the skin causing itch) or secondary (skin changes caused by rubbing and scratching because of itch). Many common primary skin disorders are associated with itch (Box 28.6). If itch is not connected with primary skin disease, many causes should be considered (Box 28.7); these include liver diseases (mainly cholestatic diseases, such as primary biliary cirrhosis), malignancies (e.g. generalised itch may be the presenting feature of lymphoma), haematological conditions (e.g. generalised itch in chronic iron deficiency or water contact-provoked (aquagenic) intense itch in polycythaemia), endocrine diseases (including hypo- and hyperthyroidism), chronic kidney disease (in which severity of itch is not always clearly associated with plasma creatinine concentration) and psychogenic causes (such as in 'delusions of infestation'). Pruritus is common in pregnancy and may be due to one of the pregnancy-specific dermatoses. Diagnosis is particularly important in pregnancy, as some disorders can be associated with increased fetal risk (Box 28.8).

Management

There are no consistently effective therapies to suppress itch, regardless of its cause but establishing the diagnosis is the first step. If a clear-cut diagnosis is not

apparent, various non-specific approaches can be used for symptom control. It is important to re-assess the patient intermittently in order to avoid missing the diagnosis.

Approaches to symptomatic relief include sedation, often with H_1 antagonist antihistamines; emollients; and counter-irritants (such as topical menthol-containing preparations). UVB phototherapy is useful in itch stemming from a variety of causes, although the only randomised controlled study evidence of its efficacy in generalised itch not caused by a skin disease is for the itch of chronic kidney disease. Other treatments include tricyclic antidepressants (probably through similar mechanisms to those involved when these drugs are used for chronic pain) and opiate antagonists. Itch can be severe and its effects on quality of life are not always appreciated.

Photosensitivity

Cutaneous photosensitivity is an abnormal response of the skin to ultraviolet (UVR) or visible radiation. The sun is the natural source but patients may also be exposed to artificial sources of UVR through the use of sunbeds and/or phototherapy (p. 1266). Chronic UVR exposure increases skin cancer risk and photoageing (p. 1254). Acute exposure can induce erythema (redness) as a normal response (Fig. 28.3). However, abnormal photosensitivity occurs when a patient reacts to lower doses than would normally cause a response, either with a heightened erythemal reaction or the development of a rash. Photoaggravated skin diseases are exacerbated by sunlight but not caused by it. The main photosensitive and photoaggravated diseases are listed in Box 28.9.

Sunlight consists mainly of visible light, and the UVR component is divided into three wavebands (Fig. 28.4):

- *UVC* (280–300 nm), which is absorbed by ozone and does not reach the earth's surface.
- *UVB* (300–320 nm), which constitutes less than 10% of UVR exposure but is around 1000-fold more biologically effective than UVA and so accounts for the erythemal 'sunburning' effects of sunlight.
- *UVA* (320–400 nm), which is the most abundant UVR component reaching the earth's surface.

Fig. 28.3 Sunburn. Acute exposure to ultraviolet radiation results in an erythemal response which peaks 12–24 hours later. Sensitivity depends on the individual's constitutive skin phototype.

28.9 The photosensitivity and photoaggravated diseases

Cause	Condition	Clinical features
Idiopathic	Polymorphic light eruption (PLE)	Itchy, papulovesicular rash on photo-exposed sites; face and back of hands often spared. Often hours of UVR exposure needed to provoke; lasts a few days; affects 20% in Northern Europe, more common in young women
	Chronic actinic dermatitis (CAD)	Chronic dermatitis on sun-exposed sites. Most common in elderly males. UVB, UVA and often visible light photosensitivity. Most also have contact allergies
	Solar urticaria	Immediate-onset urticaria on photo-exposed sites, usually UVA and visible light photosensitivity. Can occur at any age
	Actinic prurigo	Uncommon, presents in childhood. Often familial. Some similarities to PLE, although scarring occurs
	Hydroa vacciniforme	Rare childhood photodermatosis. Varioliform scarring
Drugs	Variety of mechanisms	Usually UVA (and visible) light photosensitivity
	Phototoxicity	Most common. Exaggerated sunburn and exfoliation. Many drugs such as thiazides, tetracyclines, fluoroquinolones, quinine, NSAIDs
	Pseudoporphyria	e.g. NSAIDs, retinoids, tetracyclines, furosemide
	Photoallergy	Usually to topical agents, such as sunscreens and NSAIDs
Metabolic	Porphyrias	Mainly porphyria cutanea tarda and erythropoietic protoporphyria (p. 458). Photoexposed site dermatitis due to tryptophan deficiency (see Fig. 16.17, p. 459)
	Pellagra	
Photogenodermatoses	Xeroderma pigmentosum	Rare. Defect in DNA excision repair, abnormal photosensitivity, photoageing and skin cancer. May be neurological features
Photo-aggravation of pre-existing conditions	e.g. Lupus erythematosus	Can also be drug-induced, e.g. by thiazides (see Box 28.44, p. 1304)
	Erythema multiforme	p. 1302
	Rosacea	p. 1283

(NSAID = non-steroidal anti-inflammatory drug)

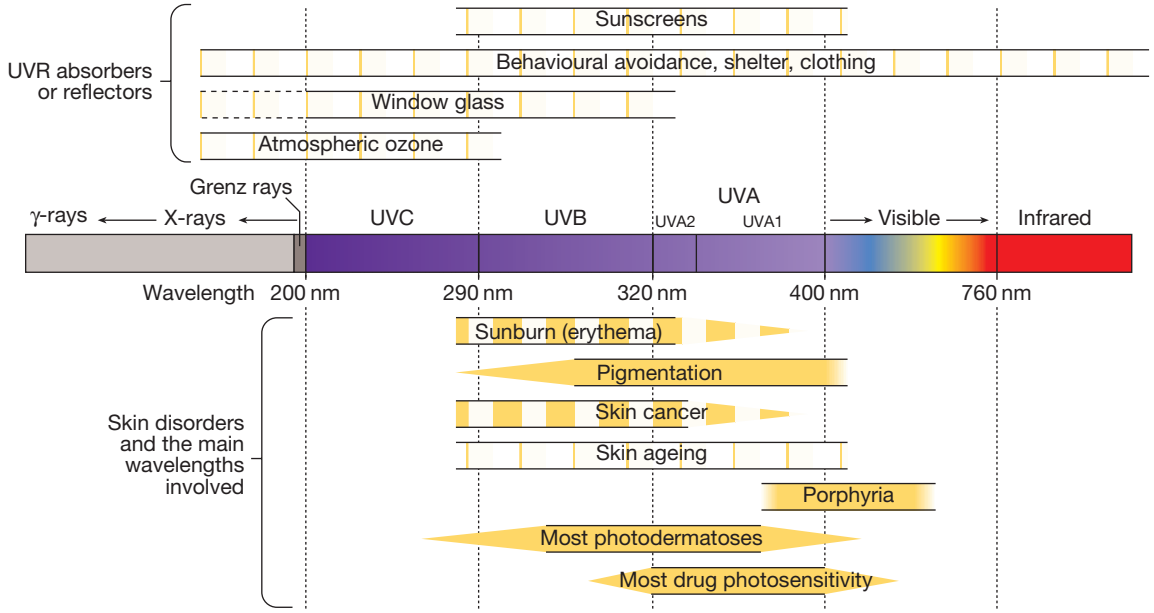

Fig. 28.4 The electromagnetic spectrum. The action spectrum is not well defined for many conditions and, for some, is approximate and may vary between patients. The action spectrum for non-melanoma skin cancer mirrors that for erythema. The action spectrum for melanoma is not known but includes UVB. Photoprotection measures vary, depending on condition, although the mainstay always includes behavioural modification and clothing cover.

Fig. 28.5 Chronic actinic dermatitis. Note the sharp cut-off and sparing behind the ear in the shadow cast by the earlobe (Wilkinson's triangle).

Patients with photosensitivity diseases can be abnormally sensitive to UVB, UVA, visible light (over 400 nm) or, commonly, a combination of wavebands. UVB is absorbed by window glass, whereas UVA and visible light are transmitted through glass.

Clinical assessment

History-taking is essential, as the patient may not have the rash when assessed. Seasonal pattern and distribution of rash are important. Key sites are the face (particularly nose, cheeks and forehead), top of ears, neck (Fig. 28.5), bald scalp, back of hands and forearms. Sparing is often seen under the chin and nose, behind the ears, on the upper eyelids and the distal digits – as we normally walk about with our eyes open and fingers flexed! It can be misleading if there is covered site involvement (patients who are sensitive to UVA and visible light may be affected through clothing, and some photosensitive conditions, such as actinic prurigo, typically also involve covered sites), or if habitually exposed sites, such as the face, are not involved (this 'hardening' phenomenon is commonly seen in polymorphic light eruption (PLE)). Furthermore, if patients have UVA and/or visible light photosensitivity, they will commonly experience perennial symptoms and may not be aware of the association with daylight exposure. Although some conditions, such as solar urticaria, develop rapidly after sunlight exposure, others, such as cutaneous lupus, can take several days to evolve.

Investigations and management

If photosensitivity is suspected, the patient should be referred to a specialist centre for monochromator phototesting (p. 1255), if feasible. Other investigations will often include provocation, patch or photopatch testing, and screening for lupus and the porphyrias (p. 1301).

Management depends on the diagnosis. If there is a phototoxic drug or chemical cause, this must be addressed: for instance, by stopping the drug or treating the porphyria. Counselling regarding sun avoidance is essential: keeping out of direct sun in the middle of the day, covering up with clothing, wearing hats with a wide brim and careful use of high-factor sunscreens. Paradoxically, in some conditions, particularly PLE and solar urticaria, phototherapy can be used to induce 'hardening'; the mechanism is uncertain. Other approaches may be necessary, depending on disease and severity, and may include antihistamines (useful in two-thirds of patients with solar urticaria) and systemic immunosuppression (sometimes required in the

idiopathic photodermatoses). Patients with photosensitivity are at risk of vitamin D deficiency, as UVB-induced cutaneous photosynthesis of vitamin D is an important source (p. 126). Patients should optimise dietary vitamin D intake and take supplements if levels are low (p. 1127).

Sunscreens

Sunscreen agents can be divided into two categories: chemical sunscreens, which absorb specific wavelengths of UVR, and physical sunscreens, which reflect UVR and the shorter visible wavelengths (see Fig. 28.4). Current sunscreen products are highly refined and most contain several sunscreen agents, offering protection against UVB and most UVA wavelengths. If a patient has photosensitivity to the longer wavelengths of UVA and the visible part of the spectrum, then conventional sunscreens that offer maximal protection in the UVB region will not be beneficial and specific reflectant sunscreens will be required. Historically, due to visible light reflection, these agents were less cosmetically acceptable, although current formulations, some of which are tinted, have reduced this problem.

Sunscreen protection levels are described by sun protection factor (SPF). This is the ratio of the dose of UVR required to produce skin erythema in the presence and absence of the sunscreen. Thus, a sunscreen of SPF20 theoretically means that it would take 20 times as long for a person to develop sunburn in the presence of the sunscreen, as compared to not using it. Therefore, SPF is really a sunburn protection factor and is not a good guide to how well a sunscreen will perform in protecting against other reactions (such as skin pain in erythropoietic protoporphyria). SPF values are determined under experimental conditions and, in practice, people use 25–33% of the amount of sunscreen required to achieve the stated SPF – thus, a sunscreen of SPF30 will, in practice, offer an SPF10 at best, and patients need to be counselled regarding application. There is also no such thing as a 'sunblock', as all sunscreens offer, at best, only partial protection and are no substitute for modifying behaviour and covering up.

Leg ulcers

Ulceration of the skin is defined as complete epidermal loss, thus exposing dermal (or deeper) layers. 'Leg ulcer' is not a diagnosis. Making a comprehensive diagnosis is the key to management. Ulcers on the lower leg are frequently caused by vascular disease, particularly, at least in part, venous hypertension. For each cause of leg ulceration there are several different underlying pathologies that have to be considered (Box 28.10).

Clinical assessment

A detailed history of the onset and course of leg ulceration and predisposing conditions should be taken. The site and surrounding skin should be assessed. Varicose veins are often present, although not inevitably. The site of ulceration may help indicate the cause (Fig. 28.6).

Appropriate investigations include:

- *Urinalysis* for glycosuria.
- *Full blood count* to detect anaemia and blood dyscrasias.

28.10 Causes of leg ulceration

Venous hypertension	
• Sometimes following deep vein thrombosis	
Arterial disease	
• Atherosclerosis • Vasculitis	• Buerger's disease
Small-vessel disease	
• Diabetes mellitus	• Vasculitis
Haematological disorders	
• Sickle-cell disease • Cryoglobulinaemia • Spherocytosis	• Hyperviscosity states, e.g. polycythaemia • Immune complex disease
Neuropathy	
• Diabetes mellitus • Leprosy (Hansen's disease)	• Syphilis
Tumour	
• Squamous cell carcinoma • Basal cell carcinoma	• Malignant melanoma • Kaposi's sarcoma
Trauma	
• Injury	• Artefact

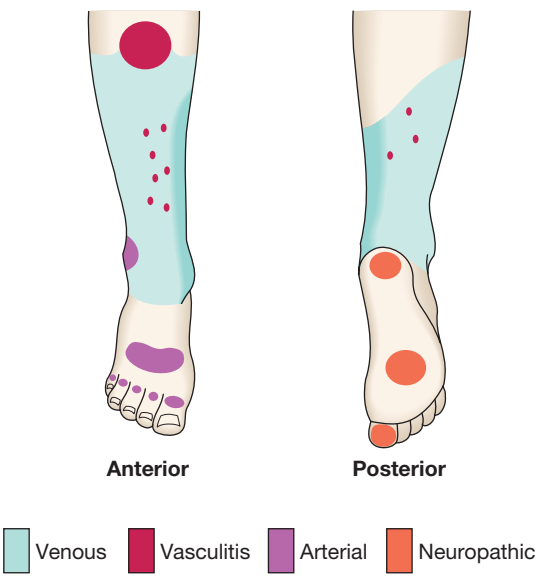

Fig. 28.6 Causes of lower limb ulceration. The main types of leg ulcer tend to affect particular sites.

- *Bacterial swab* if there is a purulent discharge, rapid extension, cellulitis, lymphangitis or septicaemia. This can guide antibiotic therapy for secondary infection but pathogenic bacteria are not always the same as those identified from the ulcer surface.
- *Doppler ultrasound* to assess arterial circulation. The normal ratio of ankle systolic pressure to brachial systolic pressure (ABPI) is 1.1 or more; if it is below 0.8, this suggests significant arterial disease. However, arterial calcification, such as in diabetes, can produce a spuriously high ABPI.

Fig. 28.7 A chronic venous ulcer on the medial lower leg, with surrounding lipodermatosclerosis.

Leg ulceration due to venous disease

Varicose veins, a history of deep venous thrombosis and obesity are predisposing factors. Incompetent valves in the deep and perforating veins of the lower leg result in retrograde flow of blood to the superficial system, and a rise in capillary pressure ('venous hypertension'). Pericapillary fibrin cuffing occurs, leading to impairment of local tissue oxygenation and homeostasis.

The first symptom in venous ulceration is often heaviness of the legs, followed by oedema. Haemosiderin pigmentation, pallor and firmness of surrounding skin, and sometimes venous/gravitational eczema (p. 1285) subsequently develop. This progresses to lipodermatosclerosis – firm induration due to fibrosis of the dermis and subcutis, which may produce the well-known 'inverted champagne bottle' appearance. Ulceration, often precipitated by trauma or infection, follows. Venous ulcers typically occur on the medial lower leg (Fig. 28.7).

Complications of venous leg ulceration include bacterial colonisation and infection, and contact allergic dermatitis to topical medicaments, dressings and bandages. Lipodermatosclerosis may cause lymphoedema and hyperkeratosis, and, rarely, a squamous cell carcinoma (SCC) may develop in a long-standing venous ulcer (Marjolin's ulcer).

Leg ulceration due to arterial disease

Deep, painful, punched-out ulcers on the lower leg, especially the shin and foot and in the context of intermittent claudication, are likely to be due to arterial disease. Risk factors include smoking, hypertension, diabetes and hyperlipidaemia. The foot is cold and dusky and the skin atrophic and hairless. Peripheral pulses are absent or reduced. If the ABPI is below 0.8, a vascular surgical assessment should be sought (p. 601).

Leg ulceration due to vasculitis

Vasculitis can cause leg ulceration directly through epidermal necrosis due to damage to the underlying vasculature or indirectly due to neuropathy (e.g. in systemic polyarteritis nodosa, p. 1117).

Leg ulceration due to neuropathy

The most common causes of neuropathic ulcers are diabetes and Hansen's disease (leprosy). Microangiopathy also contributes to ulceration in diabetes (p. 833). The ulcers occur over weight-bearing areas, such as the heel. In the presence of neuropathy, protection of skin from trauma is essential to prevent ulceration.

Management

Making a diagnosis is the first step. General advice on exercise, weight loss and smoking cessation is important. Underlying factors, such as diabetes or anaemia, must be treated. Oedema must be reduced by leg elevation and, if there is no arterial compromise, graduated compression bandaging from toes to knees to enhance venous return and improve healing. Compression bandaging is effective for individuals with an ABPI of more than 0.8 but should be avoided if the ABPI is less than 0.8.

If the ulcer is purulent, weak potassium permanganate soaks may help, and exudate and slough can be removed with normal saline or clean water. Dressings do not themselves heal leg ulcers, but can reduce discomfort and odour and, by reducing colonisation by potential pathogens, may reduce the frequency of secondary infection. A variety of dressings may be used, including non-adherent and absorbent (alginates, hydrogels, hydrocolloids) types. The frequency of dressing changes will vary: heavily exudative ulcers may need daily dressings, whereas changes once weekly may suffice.

Surrounding eczema should be suppressed with a topical corticosteroid. Commonly, this is venous eczema, but there should be a low threshold for referral for patch testing, as contact allergy to topical applications is common (p. 1255). Systemic antibiotics are only indicated if there is evidence of infection, as opposed to colonisation. Various techniques of split thickness grafting (such as pinch and mince grafts) may hasten healing of clean ulcers but do not reduce recurrence risk. Leg ulcers can be very persistent. Symptomatic relief, including oral analgesics, and sometimes chronic pain treatments (such as tricyclic antidepressants) are important. Once the ulcer has healed, ongoing use of compression hosiery may limit the risk of recurrence.

Abnormal skin colour

Loss of skin pigmentation (depigmentation), reduction in pigmentation (hypopigmentation) and increased pigment (hyperpigmentation) are features of a variety of disorders. Detailed history-taking and examination, including use of a Wood's light, are required to establish the diagnosis. Investigations will depend on the presentation. For example, microscopy of skin scrapings should be undertaken if hypopigmentation is associated with inflammation and scaling; screening for autoimmune disease may be required if vitiligo is suspected; and investigation for endocrine disease or the porphyrias may be appropriate in hyperpigmentation. Further details of the specific conditions are included later (p. 1295).

Hair and nail abnormalities

Many conditions affect the skin appendages, particularly hair and nails. Conditions causing hair loss (alopecia) are listed in Box 28.39 (p. 1296). Nail changes may be a marker for systemic disease (e.g. iron deficiency) or a feature of certain skin conditions (e.g. psoriasis).

Acute skin failure

Acute skin failure is a medical emergency. Several conditions can cause widespread and acute failure of many skin functions (see Box 28.1, p. 1254), including thermoregulation, fluid balance control and barrier to infection. A lot of these conditions involve widespread dilatation of the dermal vasculature and can provoke high-output cardiac failure; they are also associated with increased protein loss from the skin and often from the gut. Many lead to acute skin failure by causing erythroderma (erythema affecting at least 80% of the body surface area), although severe autoimmune blistering diseases and the spectrum of Stevens–Johnson syndrome–toxic epidermal necrolysis (TEN) disease can produce acute skin failure without erythroderma.

Eczema, psoriasis, drug eruptions and cutaneous T-cell lymphoma (Sézary syndrome, p. 1272) are amongst the diseases which can either present with, or progress to, erythroderma. Other causes include the psoriasis-like condition, pityriasis rubra pilaris, and rare types of ichthyosis. Erythroderma may occur at any age and is associated with severe morbidity and significant mortality (see Fig. 28.32D, p. 1287). Older people are at greatest risk, especially if they have comorbidities. It may appear suddenly or evolve slowly. In dark skin, the presence of pigmentation may mask erythema, giving a purplish hue.

Erythrodermic patients are usually systemically unwell with shivering and hypothermia, secondary to excess heat loss. They may also be pyrexial, however, and unable to lose heat due to damage to sweat gland function and sweat duct occlusion. Tachycardia and hypotension may be present because of volume depletion. Peripheral oedema is common in erythroderma, owing to low albumin and high-output cardiac failure. Lymph nodes may be enlarged, either as a reaction to skin inflammation or, rarely, due to lymphomatous infiltration.

Management of erythroderma

Regardless of the cause, important aspects of the management of erythroderma include supportive measures to ensure adequate hydration, maintenance of core temperature and adequate nutrition. Insensible fluid loss can be many litres above what is normal. Protein may be lost directly from the skin and because of the protein-losing enteropathy that often accompanies conditions such as erythrodermic psoriasis. To reduce the risks of infection, any intravenous cannulae should be sited in peripheral veins, if possible. In the initial management of acute erythroderma, urinary catheterisation is often required (for patient comfort and accurate fluid balance monitoring) but such catheters should be removed as soon as possible. Frequent application of a simple ointment emollient (such as white soft paraffin/liquid paraffin mix) is usually appropriate.

THERAPEUTICS

Topical treatment of skin disease

Many skin diseases are treated effectively by topical therapies alone. Selection of the appropriate active drug/ingredient and vehicle is essential. Ointments are preferred for dry skin conditions, such as chronic eczemas, as they are more hydrating and contain fewer excipients than creams, and so allergy risk is reduced. In contrast, creams are not as hydrating and have greater allergic potential due to a higher content of excipients, although patients find creams easier to apply and so compliance may be better. Gels and lotions can be easier to use on hair-bearing sites. The molecular weight and lipid–water coefficient of a drug determine its skin penetration, with larger, water-soluble, polar molecules penetrating poorly. In skin disease, if the stratum corneum is impaired – as in eczema – increased drug absorption occurs. Occlusion under dressings also increases absorption. Drugs can be used in different potencies or concentrations, or in combination with other active ingredients, and many are available in more than one formulation. The properties of different vehicles are listed in Box 28.11. Overall, compliance with topical treatments can be problematic, so it is essential for patients to know exactly what is required of them and for regimens to be kept as simple as possible.

Emollients

These are mainstays in the treatment of eczema, psoriasis and many other conditions, and are used to moisturise, lubricate, protect and 'soften' skin. They are essentially vehicles without active drug and are available in many formulations: creams, ointments, gels, and bath, shower and soap substitutes. White soft paraffin is the most effective and is widely used.

Topical corticosteroids

Glucocorticoids are available in a variety of formulations, although most commonly as creams and ointments. Corticosteroids are available in different potencies and strengths (Box 28.12) and selection of the correct product will depend on the patient, the condition being treated, body site and duration of expected use. Mild topical corticosteroids are used in delicate areas, such as the face or genitals, and close supervision of corticosteroid use at these sites is required. In contrast, very potent corticosteroids may be required under occlusion for chronic resistant disease such as nodular prurigo.

Although the adverse cutaneous effects of chronic corticosteroid use are well known and include atrophy, striae (Fig. 28.8), purpura and telangiectasiae, infection risk and systemic absorption (causing suppression of the hypothalamic–pituitary–adrenal axis and Cushingoid features), under-treatment is more common in practice. Patients should use the lowest potency of steroid for the shortest period to gain control of their disease, but this will vary between individuals and diseases. Initial use of a more potent corticosteroid, with reduction in potency or frequency of application as control is gained, is a sensible approach. Tolerance ('tachyphylaxis') can develop with chronic use, so intermittent courses of

28.11 Characteristics of vehicles used in topical treatments

Vehicle	Definition	Use	Site	Cosmetic acceptability	Risk of contact sensitisation
Creams	Emulsions of oil and water, e.g. aqueous cream	Acute presentations Cooling, soothing Well absorbed Mild emollients	All sites, including mucous membranes and flexures, but not hair-bearing areas	Very good Helps compliance	Significant, due to preservatives, antimicrobials and often lanolin
Ointments	Greasy preparations Insoluble in water, e.g. white soft paraffin Soluble, e.g. emulsifying ointment	Chronic dry skin conditions Occlusive and emollient Hydrating Mildly anti-inflammatory	Avoid hair-bearing areas and flexures	Moderate	Low
Lotions	Water-based Liquid formulations	Cooling effect Used to clean the skin and remove exudates Often antiseptic and astringent (e.g. potassium permanganate)	Large areas of the skin and the scalp	Good, but can sting if in an alcoholic base	Rarely
Gels	Thickened lotions Hydrophilic and hydrophobic bases	For specific sites	Hair-bearing areas and the face	Good	Low
Pastes	Semi-solid preparations consisting of finely powdered solids suspended in an ointment	Occlusive, protective Hydrating Used for circumscribed skin lesions, e.g. psoriasis, lichen simplex chronicus	Any area of skin Often used in medicated bandages	Moderate	Moderate

28.12 Potencies and strengths of commonly used topical corticosteroid preparations*

Mild

- Hydrocortisone 0.5%, 1%, 2.5%
- Hydrocortisone 1% and fusidic acid 2% (Fucidin H)

Moderate

- Clobetasone butyrate 0.05% (Eumovate)
- Betamethasone valerate 0.025% (Betnovate RD)
- Fluocinolone acetonide 0.00625% (Synalar 1 : 4)

Potent

- Betamethasone valerate 0.1% (Betnovate)
- Betamethasone valerate 0.1% and clioquinol 3% (Betnovate-C)
- Fluocinolone acetonide 0.025% (Synalar)
- Hydrocortisone butyrate 0.1% (Locoid)
- Mometasone furoate 0.1% (Elocon)

Very potent

- Clobetasol propionate 0.05% (Dermovate)

*UK trade names are given in brackets.

treatment are advised. Caution is required with corticosteroid use in psoriasis, as rebound, unstable or pustular psoriasis can occur with sudden cessation of use. Nevertheless, corticosteroids are invaluable for many sites, particularly the flexures. Topical corticosteroids are often formulated in combination with antiseptics, antibiotics or antifungals, and their controlled use may be appropriate, e.g. in infected eczema or flexural psoriasis. Intralesional injections of corticosteroids can be used in a variety of indications, including nodular prurigo, keloid scar, acne cysts and alopecia areata.

Fig. 28.8 Striae induced by excess prolonged potent topical corticosteroid use.

Dithranol and coal tar

These treatments are used mainly for psoriasis; they increase cellular differentiation and inhibit proliferation. Although often effective, they are messy and time-consuming. Modified versions of Goeckerman's regimen (the combination of coal tar and UVB) are still in use. Short-contact dithranol therapy using higher concentrations applied for 15–30 minutes can be used. Dithranol is highly irritant and causes brown staining of skin and purple discoloration of light hair. In recent years, efforts have been made to improve the tolerance of tar

and dithranol preparations, but at reduced efficacy. Overall, the use of tar and dithranol has reduced in recent years.

Calcipotriol

Calcipotriol is a vitamin D agonist and is mainly used in psoriasis. It increases differentiation and reduces proliferation, and therefore lowers plaque scale and thickness. It is applied once to twice daily and, if less than 100 g of ointment is used each week, does not cause hypercalcaemia. Patient compliance is improved, as calcipotriol is odourless and does not stain. Irritancy is the main side-effect, although often temporary. Calcipotriol is a mainstay of primary care management of psoriasis.

Calcineurin inhibitors

Topical tacrolimus and, in children, pimecrolimus can be used to treat eczema and a variety of other conditions. They are calcineurin inhibitors and cause local cutaneous immunosuppression. They have an important role as steroid-sparing agents, e.g. in eczema. Initial burning and stinging may limit use but are usually transient. Caution should be employed with sun exposure and these agents should not be used in combination with phototherapy because of their immunosuppressive effects.

Anti-infective agents

Before antibiotics are used, antiseptics should be considered, as they cover a wide range of organisms and help reduce the risk of antibiotic resistance. Antiseptics can be extremely important in the treatment of patients with eczema and are often employed in combination formulations: for example, with emollients. Antibiotics can be used either for their anti-infective properties – for example, topical fusidic acid for impetigo, or for their anti-inflammatory properties – such as topical erythromycin or clindamycin for mild inflammatory acne vulgaris, or topical metronidazole for rosacea.

Anti-comedogenic agents

Benzoyl peroxide is widely used in mild comedonal acne and has both anti-comedogenic and antiseptic effects. It is an irritant, which may contribute to the therapeutic response, but this can be minimised by adjusting treatment regimes. Azelaic acid has both antimicrobial and anti-comedogenic action in acne vulgaris. Topical retinoids, in particular *all-trans* retinoic acid and adapalene, are widely employed for mild to moderate comedonal acne vulgaris. Again, irritancy is an adverse effect but dose adjustments reduce this.

Other anti-infective agents

These can be used topically for mild viral disease, such as aciclovir for prophylaxis or treatment of herpes simplex virus (cold sore) infection. Topical imidazoles are widely employed for superficial fungal and yeast infections, such as clotrimazole for candidal infections and ketoconazole for pityriasis versicolor or seborrhoeic folliculitis. Terbinafine is commonly applied topically for superficial dermatophyte infections, such as tinea pedis. Scabies and lice infections can be treated with topical permethrin or malathion.

Topical treatment for dysplasia and non-melanoma skin cancer

Medical treatment for non-melanoma skin cancer and dysplasia is a developing area and facilitates treatment of field carcinogenesis. The anti-metabolite, 5-fluorouracil (p. 1271), is used topically, mainly for actinic keratosis. Subclinical disease can be treated, highlighting the advantages of these field-directed approaches. Diclofenac in a hyaluronic acid gel base can also be employed topically for low-grade actinic keratosis; the rationale for its use is the over-expression of cyclo-oxygenase (COX)-2 in actinic keratosis. Ingenol mebutate is also now in use for actinic keratosis.

Immune response modifiers

Imiquimod was introduced for the treatment of anogenital warts but can be used for actinic keratosis, Bowen's disease, basal cell carcinoma and lentigo maligna. Its mechanism of action is via stimulation of endogenous Th2 immune responses and release of cytokines, including interferon-gamma. It can cause significant inflammation, requiring dose adjustments, but can treat subclinical disease.

Dressings

A 'wound' covering is called a dressing. Box 28.13 shows the indications for their use. The active agent, vehicle and 'wound' type should be considered. Wet lesions should be treated with wet dressings, e.g. acute eczema with potassium permanganate soaks, emollients and topical corticosteroids under wet wraps. A topical corticosteroid in a cream formulation and a paste bandage is used to soothe and cool inflamed skin. Chronic eczema may be treated with a potent topical corticosteroid in an ointment formulation and occlusion with paste bandage to ease itching and scratching. Dressings for venous leg ulcers are described on page 1263.

28.13 Indications for dressings

- Protection
- Symptomatic relief from pain or itch
- Maintenance of direct application of topical treatment
- Possible improvement in healing time
- Reduction of exudate
- Reduction of odour

Phototherapy and photochemotherapy

Ultraviolet radiation (UVR) treatments (most commonly, narrowband ultraviolet B and psoralen–ultraviolet A (PUVA)) are used in the management of many different diseases. The best study evidence for their efficacy is in psoriasis, atopic eczema, vitiligo and chronic urticaria, although there is some controlled study evidence for other phototherapy use, such as UVB to treat the generalised itch of kidney disease.

Psoralens are natural photosensitisers found in a number of plants. Psoralen molecules intercalate between the two strands of DNA and, upon excitation with UVA, photons cross-link the DNA strands. It is thus a pro-drug that is distributed throughout the body

after oral administration, but only activated in skin that is exposed to UVA. Alternatively, psoralens can be applied in a bath before irradiation with UVA ('bath PUVA'). PUVA is a more complex treatment than UVB and has greater adverse effects; in particular, cumulative exposure to high PUVA treatment numbers increases the risk of skin cancer, particularly squamous cell carcinoma. Therefore, PUVA is generally used for poor responders to UVB, or in a few diseases for which it is the first-line phototherapy choice, such as plaque-stage cutaneous T-cell lymphoma.

Longer-wavelength UVA1 (340–400 nm) is also being investigated for use in several conditions, particularly the fibrosing skin diseases, such as morphoea, although is not widely available at present.

Systemic therapies

General information is provided here, with disease-specific details given later on.

Antibiotics

Antibiotics are generally used for their anti-infective properties, particularly for staphylococcal and streptococcal skin infections. In these indications, the correct antibiotic should be selected, based on bacterial sensitivity and patient factors. As examples, oral flucloxacillin may be indicated for infected eczema, intravenous benzyl penicillin and flucloxacillin for cellulitis, and erythromycin for a patient with a staphylococcal carbuncle who is penicillin-allergic. Optimal therapeutic doses and courses must be chosen. Several antibiotics, such as tetracyclines, erythromycin and trimethoprim, can be used for their anti-inflammatory effects in indications like acne vulgaris, bullous pemphigoid and pyoderma gangrenosum. Oxytetracycline is commonly given for acne but must be taken on an empty stomach, in a dose of up to 1.5 g a day. It has a good safety profile, even with long-term use. Lymecycline is an alternative and is taken once daily, with or without food, thereby improving compliance. Doxycycline is another option but commonly causes photosensitivity. Minocycline may be given, but with caution, as it can cause hyperpigmentation, autoimmune hepatitis and drug-induced lupus, and monitoring is required.

Hormonal treatments

In women with acne, oestrogen-containing oral contraceptives can be a useful adjunct, as they are associated with a small reduction in sebum production. Combined oestrogen and anti-androgen (such as cyproterone acetate) contraceptives can also be effective, particularly in women with acne and hirsutism, as seen in polycystic ovary syndrome (p. 764).

Antifungals

The azoles (ketoconazole, miconazole), triazoles (itraconazole, fluconazole) and triallylamines (terbinafine) are used most widely in fungal skin disease. Topical or systemic use is based on clinical presentation. For example, dermatophyte nail infection requires prolonged oral terbinafine, whereas an isolated patch of tinea corporis will respond rapidly to topical treatment.

Antivirals

Systemic antivirals are indicated for significant viral skin disease. For example, systemic aciclovir is given for eczema herpeticum (see Fig. 13.13C, p. 326).

Antihistamines

A range of H_1 and H_2 antagonists are used in dermatology. For diseases in which histamine in the skin is relevant (such as urticaria), non-sedating antihistamines should be given: for example, fexofenadine or cetirizine. For pruritic conditions such as eczema, the sedating effect of antihistamines like hydroxyzine is important. Leukotriene receptor antagonists, such as montelukast, may be added to antihistamine regimes.

Retinoids

Oral retinoids are widely used in a range of conditions, including acne, psoriasis and other keratinisation disorders. They have several functions, including promotion of differentiation, reduction in hyperkeratosis, sebum production and *Propionibacterium acnes*, and anti-inflammatory effects. Isotretinoin (13-*cis*-retinoic acid) is commonly given for moderate or severe acne, at a dose of 0.5–1 mg/kg over 4 months. Low-dose continuous isotretinoin may also be used for longer periods. Acitretin can be effective in psoriasis and other keratinisation disorders, such as ichthyosis, as can alitretinoin (9-*cis*-retinoic acid) in hand and foot eczema, and bexarotene in cutaneous T-cell lymphoma.

Retinoid side-effects include drying of the skin and mucous membranes, abnormalities in liver function or hepatitis, and increase in serum triglycerides (levels should be checked before and during therapy). Depression and suicide have been reported in association with isotretinoin, although a causal role has not been established. However, pre-drug screening for depressive symptoms should be undertaken. Alitretinoin and bexarotene can cause hypothyroidism. Systemic retinoids are teratogenic; females must have a negative pregnancy test before, during and after therapy. Pregnancy must be avoided for 2 months after isotretinoin, but for 2 years after acitretin, due to differences in drug disposition.

Immunosuppressant and immunomodulatory drugs

Systemic corticosteroids

Corticosteroids, particularly prednisolone, are widely used in inflammatory and immune-based skin diseases, such as eczema, immunobullous disease and connective tissue disorders. The usual steroid side-effects occur (pp. 776 and 1102), and often other immunosuppressants are added in as steroid-sparing agents (see below).

Methotrexate

Methotrexate can be highly effective for psoriasis, eczema and several other skin diseases. In dermatology, it is used once weekly. It is an immunosuppressant (p. 1102), which is important therapeutically but also increases susceptibility to infection. It causes myelosuppression and has adverse interactions with other commonly used drugs, such as NSAIDs. Methotrexate is hepatotoxic and long-term use can be associated with hepatic fibrosis/cirrhosis; regular monitoring of liver function tests and a full blood count is required.

Hydroxycarbamide

This is an alternative immunosuppressant to methotrexate, although it appears to be less effective for psoriasis and the risk of myelosuppression is greater.

Ciclosporin

Ciclosporin (p. 1102) is an immunosuppressant with rapid onset of action and is effective in inducing clearance of psoriasis and eczema. Caution and monitoring are required, as, in addition to immunosuppression, hypertension and nephrotoxicity are important adverse effects. Furthermore, ciclosporin should be used only with caution after phototherapy, particularly PUVA, because of the increased risk of skin cancer. Chronic use of ciclosporin is not advised.

Azathioprine

This is an anti-metabolite that is converted to 6-mercaptopurine; it inhibits DNA and RNA synthesis. Azathioprine is mutagenic and detoxified via the enzyme thiopurine methyl transferase (TPMT), now routinely measured prior to drug commencement to allow individualised and safer treatment. Side-effects include myelosuppression and gastrointestinal upset.

Mycophenolate mofetil

This immunosuppressant may be effective in diseases such as psoriasis but caution is needed, as myelosuppression can occur.

Dapsone

Dapsone is an immunomodulator and may be used in diseases where neutrophils are implicated, such as dermatitis herpetiformis (p. 1294). Haemolysis, methaemoglobinaemia and hypersensitivity can occur, and monitoring is required (pp. 158 and 350).

Antimalarials

The antimalarials, such as hydroxychloroquine, have multiple anti-inflammatory actions but are of particular use in cutaneous lupus (pp. 1102 and 1112).

Fumarates

The active component of fumaric acid ester therapy is dimethyl fumarate, and efficacy in psoriasis has been confirmed. Common adverse effects are flushing and diarrhoea. Lymphopenia is expected at effective doses.

Biological therapies

An increasing variety of monoclonal antibodies, fusion proteins and cytokines has been shown to be effective for psoriasis, and these agents are sometimes used in other recalcitrant skin diseases. The anti-tumour necrosis factor-alpha (TNF-α) therapies have the longest track record (p. 1102). These include etanercept (a human recombinant TNF-α receptor fusion protein), and infliximab and adalimumab (both anti-TNF-α monoclonal antibodies). Potential side-effects include reactivation of latent tuberculosis and development of other opportunistic infections. The long-term risks of skin and other cancers are not yet well quantified. Other biological therapies (often abbreviated to 'biologics') include B cell-targeted treatments, such as rituximab, which may be used in pemphigus vulgaris, lupus erythematosus, dermatomyositis and other immune-based diseases (p. 1102), and omalizumab (an IgE monoclonal). While introduced to treat allergic asthma, the latter may also prove useful in non-allergic diseases such as chronic urticaria (pp. 91 and 671). Intravenous immunoglobulin, pooled from donor plasma, is often used in immune complex disease, such as dermatomyositis (p. 81).

Dermatological surgery

The choice of procedure is critical; for example, basal cell papillomas should be treated by cryotherapy or curettage, and melanomas widely excised. Most dermatological surgical procedures are performed under local anaesthetic. Knowledge of local anatomy is essential, particularly the locations of vessels and nerves. In certain sites, local cutaneous nerve blocks are useful (e.g. fingers, sole of foot and nose). Some sites are associated with particular risks, such as keloidal scarring on the upper trunk of young patients, unsightly scars over the scapulae, and poor healing and risk of ulceration following procedures on the lower legs.

Excisional biopsy

The lesion is removed and sent for histology. The most common indication is suspicion of malignancy. The lesion and line of excision should be marked out. Basal cell carcinoma (BCC) is usually excised with a 4 mm margin, whereas initial excision of suspicious pigmented lesions is usually with a 2 mm margin with further excision arranged if melanoma is confirmed (p. 1273). It is important to excise down to the appropriate anatomical plane. Depending on body site, a range of procedures can minimise the resulting defect. Healing by secondary intention can also achieve good cosmetic results.

Mohs' micrographic surgery

Mohs' micrographic surgery is employed to ensure adequate tumour excision margins, while conserving unaffected tissue. It is most commonly used for BCC. The method involves processing to allow examination of all margins and is done in stages (usually on the same day) until all of the tumour is removed. The procedure is time-consuming (so can be arduous for elderly, frail patients) and requires particular surgical and pathology skills. It should be considered for recurrent and for morphoeic and ill-defined BCC, and at sites where tissue conservation is particularly important, such as eyelid skin.

Curettage

Curettage involves using a small, spoon-shaped implement (curette), not only as a definitive treatment but also to obtain histology. The latter may, however, be compromised, as tissue architecture is not well preserved and it may be difficult to distinguish between dysplasia and invasive malignancy. Curettage may be effective for basal cell papillomas, actinic keratoses, intra-epidermal carcinoma and superficial BCC.

Other physical therapies

Cryotherapy

Cryotherapy is a destructive treatment that uses liquid nitrogen. The freezing and thawing process causes cell

wall and membrane destruction and cell death. Liquid nitrogen can be applied either with a cotton bud or, more effectively, with a spray gun. A wide variety of conditions can be treated but it is essential for the correct diagnosis to be made first, if necessary by diagnostic biopsy. Cryotherapy should not be employed to treat melanocytic naevi. Benign lesions, such as viral warts and basal cell papillomas, respond well, and cryotherapy can also be effective for actinic keratoses, Bowen's disease or superficial non-melanoma skin cancer. Malignant indications require more vigorous treatment, usually with two freeze–thaw cycles, and this is normally carried out in secondary care. Considerable inflammation, blistering and pigmentary change, particularly hypopigmentation, can occur.

Laser therapy

Laser therapy involves treatment with monochromatic light. Skin components, such as haemoglobin and melanin, absorb specific wavelengths of electromagnetic radiation, and these wavelengths can therefore be used to destroy these targets selectively and to treat certain skin disorders. Lasers targeting haemoglobin are employed for vascular abnormalities, such as spider naevi, telangiectasiae and port wine stains, and lasers targeting melanin can treat benign pigmentary disorders or pigment in tattoos or from drug (e.g. minocycline) deposition; the latter can also be used for hair removal if the hair is pigmented. Light delivery in short pulses restricts damage to the treated site.

The carbon dioxide laser emits infrared light that is absorbed by water in tissues and can therefore be used for destructive purposes. The depth of effect can be controlled, such that the carbon dioxide laser is widely employed for resurfacing in photorejuvenation or acne scarring. Significant morbidity is associated with this destructive laser and general anaesthesia is required.

Photodynamic therapy

Photodynamic therapy (PDT) is widely used in dermatology, predominantly for actinic keratoses, Bowen's disease and superficial BCC. Topical 'porphyrin' PDT is the most common type; it involves the application of a porphyrin pro-drug to the lesion, which is taken up and converted by the cell's haem cycle to a photosensitiser, protoporphyrin IX. This is then photochemically activated by visible (usually red) light in the presence of oxygen, which causes the production of reactive oxygen species, inflammation and destruction of treated tissue. The photosensitiser is taken up relatively selectively in diseased skin, and so inflammation and adverse effects in normal skin are minimised. PDT is as effective for superficial non-melanoma skin cancer and dysplasia as other treatments like cryotherapy and 5-fluorouracil, but may be preferred for sites of poor healing, such as the lower leg, or where cosmetic outcome is important, due to the selectivity of treatment. Pain during irradiation occurs during PDT, although adjustments to the irradiation regime can reduce discomfort.

Radiotherapy and grenz (Bucky) ray therapy

Radiotherapy can be employed for several skin conditions, including non-melanoma skin cancer or lentigo maligna that is not suitable for surgical treatment, but its use in dermatology has declined. Scarring and poikiloderma can occur at treated sites, although these are minimised if fractionated regimens are chosen. Superficial radiotherapy is now rarely employed to treat benign dermatoses. Even more superficial ionising radiation (grenz, or Bucky, rays) can be useful for localised dermatoses that are having severe effects on quality of life, if conventional treatments have been inadequate; for example, it may avoid exposure to the risks of systemic therapy for a patient with severe and hitherto unresponsive scalp psoriasis.

SKIN TUMOURS

Pathogenesis of skin malignancy

Skin cancer is the most common malignancy in fair-skinned populations. It is categorised as non-melanoma skin cancer (NMSC) and melanoma. NMSC is further subdivided into basal cell carcinoma (BCC), the most common skin cancer, and squamous cell carcinoma (SCC). The latter has precursor non-invasive states of intra-epithelial carcinoma (Bowen's disease; BD) and dysplasia (actinic keratosis; AK). Melanoma is much less common than NMSC, but because of its metastatic risk it is the cause of most skin cancer deaths.

UVR is a complete carcinogen and is the main environmental risk factor for skin cancer, which is much more common in countries with high ambient sun exposure, such as Australia. Skin cancer risk also increases if an individual migrates to such a country at a young age, particularly less than 10 years. Epidemiological evidence supports a close link between chronic UVR exposure and risk of SCC and AK, and a modest link between sun exposure and BCC risk. Melanoma usually arises on sites that are intermittently exposed to UVR, and episodes of sunburn have been implicated as a risk factor for melanoma. Sunbed exposure is also a risk for both melanoma and NMSC (Box 28.14). Strategies to reduce sun exposure are therefore important for skin cancer prevention (Box 28.15).

There may also be identifiable genetic predispositions for skin cancer, such as in xeroderma pigmentosum, an autosomal recessive condition caused by an inherited defect in DNA excision repair (pp. 267 and 67), or basal cell naevus (Gorlin's) syndrome, an autosomal dominant disorder in which the *PTCH* tumour suppressor gene on chromosome 9 is defective (p. 267). Cutaneous immune surveillance is also critical and immunosuppressed organ transplant recipients have a greatly increased risk of skin cancer, particularly SCC. Interestingly, patients who have received high numbers of

EBM 28.14 Sunbeds and skin cancer

'Recent meta-analyses have confirmed that there is an association between sunbed use and both melanoma and non-melanoma skin cancer, particularly when exposure commences in early life.'

- Boniol M, et al. Br Med J 2012; 345:14.
- Wehner MR, et al. Br Med J 2012; 345:15.

EBM 28.15 Sunscreens and skin cancer

'Sunscreen use attenuates the development of new naevi on intermittently sun-exposed sites in white-skinned (particularly freckled) schoolchildren living in areas of high ambient sun exposure. There is good evidence that regular sunscreen use in adults reduces the development of actinic keratosis and squamous cell carcinoma. There is also evidence to support a preventative role for regular sunscreen use in melanoma and, to a lesser extent, basal cell carcinoma.'

- Green AC, et al. J Clin Oncol 2011; 29:257–263.
- Ulrich C, et al. Br J Dermatol 2009; 161 (suppl. 3):78–84.

PUVA treatments (more than 150), which are immunosuppressive, are also at increased risk of skin cancer, particularly SCC. Despite UVB being a complete carcinogen, there is no evidence that UVB phototherapy markedly increases skin cancer risk, although ongoing vigilance is required. Ionising radiation, notably radiotherapy, thermal radiation and chemical carcinogens, such as arsenic or coal tar, can increase NMSC risk, particularly SCC. A role for oncogenic human papillomaviruses in NMSC development is also implicated, particularly in immunosuppressed patients with NMSC; viral DNA is detected in more than 80% of this group. Chronic inflammation is also a risk factor for SCC, which may arise in chronic skin ulcers, in skin inflammation, as in lupus, or in patients with the scarring genetic skin disease, dystrophic epidermolysis bullosa (see Box 28.32, p. 1292), in which up to 50% of patients develop SCC.

Malignant tumours

Basal cell carcinoma

The incidence of NMSC has increased dramatically over the last 30 years and basal cell carcinoma (BCC) accounts for more than 70% of cases. In Europe, the ratio of BCC to SCC is 4–5:1 in immunocompetent patients. BCC is a malignant tumour that rarely metastasises; it is thought to derive from immature pluripotent epidermal cells and is composed of cells with similarities to basal layer epidermis and appendages. Lesions typically occur at sites of moderate sun exposure, particularly the face, and are slow-growing. Incidence increases with age and males are more commonly affected. Lesions may ulcerate and invade locally; hence the term 'rodent ulcer'. Mutations in the *PTCH* tumour suppressor gene have been identified and an aberrant hedgehog signalling pathway is implicated in pathogenesis.

Clinical features

Early BCCs usually present as pale, translucent papules or nodules, with overlying superficial telangiectatic vessels (nodular BCC). If untreated, they will increase in size and ulcerate, to form a crater with a rolled, pearled edge and ectatic vessels (Fig. 28.9). There may be some pigmentation or a cystic component. A superficial multifocal type can occur, often on the trunk, and may be large (up to 10 cm in diameter); there may be multiple lesions. Superficial BCC usually presents as a red/brown plaque or patch with a raised, thread-like edge, which is often best seen by stretching the skin; this helps to distinguish it from Bowen's disease. Less commonly, a morphoeic, infiltrative BCC presents as an ill-defined, slowly enlarging, sclerotic yellow/grey plaque.

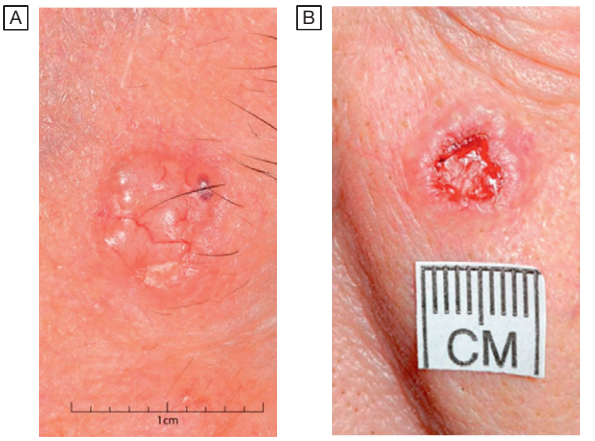

Fig. 28.9 Basal cell carcinoma. A A nodular BCC showing the translucent nature of the tumour and the abnormal arborising vessels. B An ulcerated BCC showing the raised rolled edge.

Management

Management involves early diagnosis and establishment of the correct treatment approach, taking into account patient and lesion factors (Box 28.16). Surgery is often the treatment of choice, although, increasingly, the place of non-surgical therapies is being recognised for low-risk BCC in patients in whom surgery is not appropriate. For example, an early nodular BCC in a fit patient is best excised surgically, whereas large, multiple, superficial BCCs on the trunk of a frail elderly patient with comorbidities may be best treated by a non-surgical approach, such as PDT or the immunomodulator

28.16 Management of non-melanoma skin cancer and pre-cancer

Basal cell carcinoma

- Excision results in the lowest recurrence rates
- Mohs' micrographic surgery is effective for high-risk BCC
- Medical treatments are often appropriate for low-risk superficial tumours in patients with comorbidities
- Cryotherapy and topical 5-fluorouracil can be used for superficial BCC
- Topical photodynamic therapy and topical imiquimod are both effective in superficial BCC
- BCC in patients with Gorlin's syndrome should not be treated with radiotherapy
- Hedgehog pathway inhibitors are being investigated for advanced inoperable BCC

Squamous cell carcinoma (and precursors actinic keratosis and Bowen's disease)

- Excision is the treatment of choice for invasive SCC
- Most recurrences or metastases occur within 5 years
- Medical management is not usually considered for invasive SCC
- There have been many advances in the medical management of field-change carcinogenesis, actinic keratoses and Bowen's disease, e.g. photodynamic therapy, imiquimod and other immunomodulators, new formulations of 5-fluorouracil, diclofenac in hyaluronic acid gel and ingenol mebutate

imiquimod (p. 426). Cryotherapy can be effective for BCC but can cause blistering and scarring, so is best suited to small, superficial lesions at low-risk sites. Curettage and cautery may also be effective for selected lesions. Management of infiltrative morphoeic BCC and/or lesions at difficult sites, such as around the eye, may require more complex surgical excision with margin control (Mohs'). If the primary tumour is not completely excised, re-excision or follow-up may be advised, as not all tumours that are incompletely excised recur. However, this is not recommended for tumours at high-risk sites or with infiltrative morphoeic BCC, where complete excision is advisable. Radiotherapy is less commonly used because of the risk of scarring, but can be invaluable for large lesions in frail patients. Clearance of more than 90% of tumours should be achieved. Non-surgical approaches are associated with higher recurrence rates than surgery (often up to 25% over 5 years) but may be most appropriate in some circumstances.

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignancy that arises from epidermal keratinocytes and is the second most common skin cancer, occurring more frequently in elderly males and smokers.

Clinical features

SCC usually occurs on chronically sun-exposed sites, such as bald scalp, tops of ears, face and back of hands. The clinical presentation may be diverse, ranging from rapid development of a painful keratotic nodule in a pre-existing area of dysplasia (Fig. 28.10) to the de novo presentation of an erythematous, infiltrated, often-warty nodule or plaque that may ulcerate. The clinical appearance depends on histological grading; well-differentiated tumours more often present as defined keratotic nodules (see Fig. 28.10), whereas poorly differentiated tumours tend to be ill-defined and infiltrative, and may ulcerate. SCC has metastatic potential; some tumours, such as those on lip and ears and in immunosuppressed patients, behave more aggressively and are more likely to metastasise to draining lymph nodes.

Management

Early diagnosis is important and complete surgical excision is the usual treatment of choice. Other options include curettage and cautery for small, low-risk lesions and radiotherapy if surgery is not feasible (see Box 28.16). Excision with a 3–4 mm margin has a cure rate of approximately 90–95% for most SCC. High-risk SCC, such as those with poorly differentiated histology or at high-risk sites, and metastatic disease require management via a multidisciplinary team. In patients who are at high risk for further SCC, systemic retinoids may have a role in reducing the rate of SCC development, but rapid appearance of tumours occurs on drug cessation.

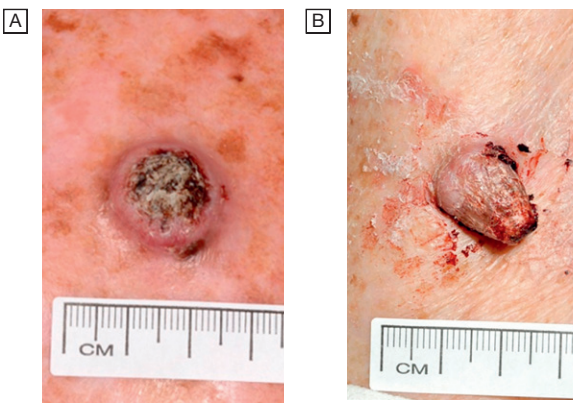

Fig. 28.10 Squamous cell carcinoma. A A centrally keratinous, symmetrical, well-differentiated SCC. Clinically, this could be confused with keratoacanthoma. B An SCC arising from an area of epidermal dysplasia.

Actinic keratosis

Actinic keratoses (AK) are hyperkeratotic erythematous lesions arising on chronically sun-exposed sites. Histology shows dysplasia, although the diagnosis of typical AK is usually made on clinical grounds (Fig. 28.11). They are very common in fair-skinned people who have had significant sun exposure, are often multiple and increase with age. Prevalence is much higher in Australia than in the UK and some surveys have shown a prevalence of more than 50% in those over 40 years old. The rate of progression to SCC is less than 0.1% and spontaneous resolution is possible. However, SCC can also arise de novo and without progression from AK. Increase in size, ulceration, bleeding, pain or tenderness can be indicative of transformation into SCC.

Management

A range of treatment options are available for AK (see Box 28.16). Emollients and photoprotection, including high-factor sunscreens, may suffice for mild disease. Single or low numbers of lesions of AK can be effectively treated with cryotherapy. Multiple lesions require field-directed therapy, such as 5-fluorouracil, imiquimod, diclofenac in hyaluronic acid, PDT or ingenol mebutate. Hyperkeratotic lesions may require curettage and cautery.

Fig. 28.11 Actinic keratosis. Close-up of a hyperkeratotic AK on the ear.

Intra-epidermal carcinoma (Bowen's disease)

Clinical features

Bowen's disease (BD) usually presents as a slowly enlarging, erythematous, scaly plaque on the lower legs of fair-skinned elderly women but may occur at other sites (Fig. 28.12). It can be confused with eczema or psoriasis, but is usually asymptomatic and does not respond to topical steroids. It may also be hard to distinguish from superficial BCC. Diagnostic biopsy shows intra-epidermal carcinoma but no invasion through the basement membrane. Transformation into SCC occurs in 3% or less.

Fig. 28.12 Intra-epidermal carcinoma (Bowen's disease). The lower leg is a common site and lesions are often treated non-surgically.

Management

Incisional biopsy is usually undertaken to confirm the diagnosis, although histology may be obtained by curettage. The latter also serves to treat the lesion but does not allow distinction from SCC to be made, due to loss of tissue architecture and orientation. Non-surgical therapies are commonly preferred (see Box 28.16), especially on the lower legs, as they are associated with improved healing and reduced risk of ulceration at this site.

Keratoacanthoma

Although benign, this squamous tumour is often difficult to distinguish from SCC and is thus included in this section. It has a striking clinical presentation of rapid growth over weeks to months and subsequent spontaneous resolution. It is thought to be associated with chronic sun exposure and most commonly occurs on the central face. The classical appearance is of an isolated dome-shaped nodule often of 5 cm or more in diameter, with a central keratin plug (Fig. 28.13). Clinically and histologically, the lesion often resembles SCC (see Fig. 28.10A); most are treated surgically, either by curettage and cautery or excision, to rule out SCC and to avoid the unsightly scar after spontaneous resolution.

Cutaneous lymphomas

The most common form of cutaneous T-cell lymphoma is mycosis fungoides (MF). This can persist for years in patch and plaque stages, often resembling eczema or psoriasis. Only sometimes does it progress through

Fig. 28.13 Keratoacanthoma.

to nodules and finally a systemic stage. B-cell lymphomas, on the other hand, usually present as nodules or plaque-like tumours. The diagnosis of cutaneous T-cell lymphoma requires a high index of suspicion, particularly in patients thought to have unusual recalcitrant forms of eczema or psoriasis.

Treatment is symptomatic and there is no evidence that it alters prognosis. In the early stages of cutaneous T-cell lymphoma, systemic or local corticosteroids may be indicated; alternatively, PUVA (for plaque stage MF) or narrowband UVB phototherapy (for patch stage MF) may be used. Once lesions have moved beyond plaque stage, localised radiotherapy, electron beam radiation or systemic anti-lymphoma regimens may be needed. Management often requires collaboration between dermatologists, pathologists and haematological oncologists.

Melanoma

Melanoma is a malignant tumour of epidermal melanocytes and has metastatic potential. There has been a steady rise in melanoma incidence in fair-skinned populations over recent decades, with the highest figures in Australasia. Primary prevention and early detection are essential, as, despite advances, therapy for advanced and metastatic disease is unsatisfactory. Most melanomas are sporadic and risk factors are genetic and environmental: fair skin, freckles, red hair, number of naevi and sunlight exposure. Thus, patients with multiple atypical naevi (dysplastic naevus syndrome) and fair-skinned subjects, often with variant alleles in the melanocortin-1 gene, are at increased risk of melanoma. The type of sunlight exposure is under debate but intermittent exposure, sunburn and sunbed use are implicated. Any family history of melanoma increases individual risk but a strong family history is rare. In familial cases, an autosomal dominant inheritance with incomplete penetrance can occur. Mutations in genes coding for the p16 (*CDKN2A*) tumour suppressor gene or its binding site are implicated and, in these patients, the lifetime risk of melanoma increases to more than 50%. Advances in molecular technology have identified

other susceptibility genes and potential genetic targets for therapeutic intervention in advanced disease.

Clinical features

Melanoma can occur at any age and site and in either sex, but typically affects the leg in females and back in males. It is rare before puberty. The classification of invasive malignant melanoma is shown in Box 28.17. Early lesions may be in situ and pre-invasive before becoming an invasive SSM.

Any change in naevi or development of new lesions should be assessed to exclude malignancy and, for this, the dermatoscope is invaluable (see Fig. 28.2, p. 1256). Real-time non-invasive imaging techniques are being investigated as tools to assist in diagnosis but are largely experimental. If in doubt, excision is advised.

Superficial spreading melanoma

Superficial spreading melanoma (SSM) is the most common type in Caucasians. It usually presents as a slowly enlarging, macular, pigmented lesion, with increasing irregularity in shape and pigment; this superficial, radial growth phase can last for approximately 2 years. Subsequently, the lesion becomes palpable and this is indicative of the development of vertical growth phase invasive disease in the dermis; this now has the potential to invade lymphatics and vessels and become metastatic (Fig. 28.14). Approximately 50% of melanomas arise from a pre-existing naevus.

Nodular melanoma

Nodular melanoma is most common in the fifth and sixth decades, particularly in men and on the trunk (see Fig. 28.14). This may account in part for the increased mortality rates from melanoma in men, as these are tumours with greater metastatic risk. They often present as a rapidly growing nodule that may bleed and ulcerate. Nodular melanomas may be heavily pigmented, or relatively amelanotic and erythematous, and be confused with benign vascular lesions. A rim of pigmentation may, however, be seen under the dermatoscope. Lesions may develop de novo or from a pre-existing naevus or SSM.

Lentigo maligna melanoma

This is biologically distinct and arises from a prolonged pre-invasive phase, lentigo maligna. It occurs as a very slowly expanding, pigmented, macular lesion, usually on photo-exposed head and neck sites of elderly patients; histology shows in situ changes only. This phase may last for several years before a nodule of invasive melanoma develops in a proportion of cases (lentigo maligna melanoma).

Acral lentiginous or palmoplantar melanoma

This accounts for only approximately 10% of melanoma in fair-skinned races but is more common in dark-skinned people, accounting for 50% of cases and indicating that UVR exposure may not be implicated in acral melanoma risk.

Subungual melanoma

This form of melanoma is rare. It may present as a painless, proximally expanding streak of pigmentation arising from the nail matrix, and progresses to nail dystrophy and involvement of the adjacent nail fold (Hutchinson's sign).

28.17 Classification of cutaneous malignant melanoma

Melanoma without metastatic potential (non-invasive)	
• Melanoma in situ	• Lentigo maligna
Melanoma with invasive potential	
• Superficial spreading melanoma • Nodular melanoma	• Acral lentiginous melanoma • Subungual melanoma • Lentigo maligna melanoma

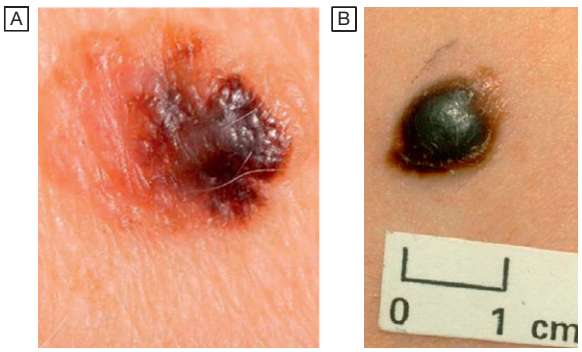

Fig. 28.14 Superficial spreading melanoma. A A superficial spreading malignant melanoma with a palpable area indicative of vertical growth phase (Breslow thickness 1.3 mm). B A nodular malignant melanoma arising de novo and with Breslow thickness 3.5 mm.

Management

Initial excision of a suspicious lesion should be performed with a 2 mm margin, where possible. Surgical excision is usually required, although radiotherapy or imiquimod may be used for lentigo maligna, if surgery is not feasible. The Breslow thickness of tumour (i.e. the maximal depth from granular cell layer to deepest tumour cells) is critical for management and prognosis. The clinical staging of extent of melanoma is essential, in order to establish whether disease is primary and localised, or if there is nodal or metastatic spread.

Wide excision of melanoma with a low risk of metastasis (i.e. stage 1 disease, Breslow thickness less than 1 mm) with a 1 cm clear margin is accepted practice. The margin of excision for more advanced disease is controversial, although a 2–3 cm margin for thicker tumours is common practice as an attempt to reduce risk of local recurrence (Box 28.18). The majority of tumours can be excised without the need for grafting. For tumours with a Breslow thickness of 1 mm or more, a sentinel lymph node biopsy may be offered. This is usually performed at the time of wider excision and involves injection of radio-labelled blue dye at the site of the primary melanoma, allowing identification of the draining 'sentinel' node by radioscintigraphy; this sentinel node is then removed and examined in detail by histology, immunohistochemistry and/or PCR of melanocyte gene products to look for tumour deposits. If the biopsy is positive, local lymphadenectomy is usually offered. This procedure may provide additional prognostic information but there is no evidence of improved survival rates in patients who have undergone this procedure. Local recurrence of disease and

EBM 28.18 Margin of excision of melanoma

'There is no evidence that radical surgery (4–6 cm excision margins) reduces the risk of local recurrence or survival compared with more conservative surgery.

Recommended surgical excision margins:
- Breslow thickness < 1 mm: 1 cm margin
- Breslow thickness 1.01–2 mm: 1–2 cm margin
- Breslow thickness 2.1–4 mm: 2–3 cm margin
- Breslow thickness > 4 mm: 3 cm margin.'

- Marsden JR, et al., British Association of Dermatologists. Br J Dermatol 2010; 163:238–256.

For further information: www.cochrane.org/cochrane-reviews

palpable local node involvement should be treated surgically.

Prognosis for metastatic disease is poor and chemotherapy is palliative. Melanoma is immunogenic and immunotherapy may be used in patients with advanced disease, although there is no evidence of improved overall survival. Other biological and gene therapies and vaccines are being investigated. Genetic advances have facilitated the introduction of tumour-targeted treatments for late-stage disease, such as *B-Raf* and *c-Kit* inhibitors for patients expressing these gene mutations, and this approach is under further investigation.

Prognosis

The Breslow thickness of the primary tumour is the most important prognostic factor in stage I disease, although other indices, including mitotic rate and presence/absence of ulceration, are also important. Patients with a primary tumour of less than 1 mm have more than a 95% chance of disease-free survival at 10 years, but this figure drops to approximately 50% for a tumour of greater than 3.5 mm thickness. Survival rates fall to less than 10% for those with advanced nodal or metastatic disease. In general, the prognosis is better in females and for tumours at certain sites, such as the leg.

Benign lesions that may be confused with skin cancers

In practice, it is often difficult to distinguish between skin cancer and a benign lesion on clinical grounds. Benign melanocytic naevi and basal cell papillomas can often be mistaken for melanoma, even by dermatologists. If there is any doubt, histology is required.

Freckle (ephelis)

Histologically, a freckle consists of normal numbers of melanocytes, but with focal increases in melanin in keratinocytes. They are most common on sun-exposed sites in fair-skinned individuals, particularly children and in those with red hair, and on the face. There is a familial tendency. Clinically, freckles are brown macules, which darken following UVR exposure.

Lentigines

A lentigo consists of increased numbers of melanocytes along the basement membrane, but without formation of the nests that occur in melanocytic naevi. These lesions usually occur at sites of chronic sun exposure (see the background skin changes in Fig. 28.10A), become more common with age, and are often referred to as 'liver spots' or 'age spots'. They can vary in colour from light to very dark brown. Distinction from melanoma is essential and histology may be required.

Haemangiomas

Benign vascular tumours or hamartomas are common and include Campbell de Morgan spots, which present as pink/red papules on the upper half of the body. They can sometimes be difficult to distinguish from melanocytic lesions, particularly if they are thrombosed or occur on particular sites, such as the lip or genitalia. The dermatoscope is helpful for this (see Fig. 28.2, p. 1256).

Basal cell papilloma (seborrhoeic wart)

Basal cell papillomas (seborrhoeic warts or keratoses) are common, benign epidermal tumours (Fig. 28.15). The name is misleading, as they do not involve sebaceous glands. They can be confused with melanoma and may be cosmetically troublesome. They may be flat, raised, pedunculated or warty-surfaced, and can appear to be 'stuck on'. They occur in both sexes and with increasing age, and are most common on the face and trunk. The colour may vary from yellow to almost black and the surface may seem 'greasy', with pinpoint keratin plugs visible, particularly with a magnifying lens. If there is no diagnostic doubt, they can be left alone or treated by cryotherapy or curettage. If the differential diagnosis includes melanoma, excision biopsy should be undertaken.

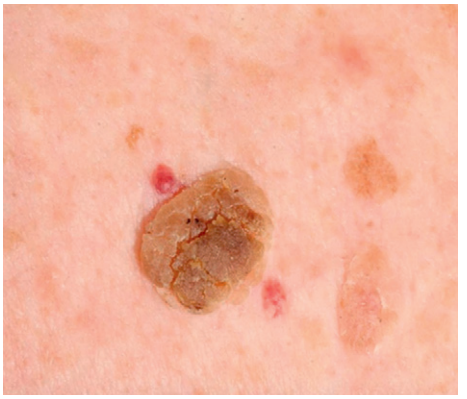

Fig. 28.15 A typical basal cell papilloma. Note the neighbouring basal cell papillomas and the coincidental benign angiomas (Campbell de Morgan spots).

Melanocytic naevi

Melanocytic naevi (moles) are localised benign clonal proliferations of melanocytes. Their cause is unknown but may relate to abnormalities of the normal migratory pattern of melanocytes during development. It is quite normal to have 20–50, although, interestingly, individuals with red hair have fewer. Genetic and environmental factors are implicated. Monozygotic twins have higher concordance in naevi numbers than dizygotic twins. Individuals who have had greater sun exposure have higher numbers of naevi. Most melanocytic naevi appear in childhood and early adult life, or during pregnancy

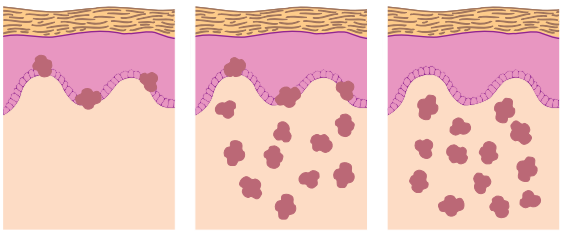

Fig. 28.16 Classification of melanocytic naevi. Classification is based on microscopic location of the nests of naevus cells.

or oestrogen therapy. The onset of a new mole is less common after the age of 25 years. Congenital melanocytic naevi occur at or shortly after birth.

Clinical features

Acquired melanocytic naevi are classified according to the microscopic location of the melanocyte nests (Fig. 28.16). Junctional naevi are usually macular, circular or oval, and mid- to dark brown. Compound and intradermal naevi are nodules, because of the dermal component, and may be hair-bearing. Intradermal naevi are usually less pigmented than compound naevi. Their surface may be smooth, cerebriform, hyperkeratotic or papillomatous.

Some individuals have large numbers of naevi, often at unusual sites, such as the scalp, palms or soles, and these may often appear 'atypical' in terms of variability in pigmentation, size and shape. Some may be very dark or pink and may show a depigmented or inflamed halo. If these naevi are removed, then 'dysplastic changes' are often seen. Such naevi are known to occur in some rare families with an inherited melanoma predisposition. However, the significance of such changes in non-familial cases is unclear and there is no consensus on management and follow-up.

Although approximately 50% of melanomas arise in pre-existing naevi, most naevi do not become malignant; although a changing naevus must be taken seriously, most will not be melanomas. Malignant change is most likely in large congenital melanocytic naevi (risk may correlate with the size of the lesion) and possibly in families who have been diagnosed as showing large numbers of atypical naevi with a history of melanoma.

Management

Melanocytic naevi are normal and do not require excision, unless malignancy is suspected or they become repeatedly inflamed or traumatised. Advice on photoprotection is important for fair-skinned individuals with multiple naevi.

Blue naevi

These are melanocytic naevi in which there is a proliferation of spindled melanocytes relatively deep within the dermis. Light scattering means that the pigment appears blue rather than brown. They may be difficult to distinguish from nodular melanoma and are therefore often excised.

Dermatofibroma

A dermatofibroma is a characteristically firm, often pigmented, raised lesion, most commonly found on the lower legs. Its aetiology is unclear, although a reactive process secondary to insect bites or trauma is one hypothesis. There is frequently a ring of pigment around the lesion and dimpling when the skin is pinched, reflecting epidermal tethering.

Acrochordon (skin tag)

Acrochordons are benign pedunculated lesions, most common in skin flexures. They may be confused with melanocytic naevi.

Lipoma

Lipomas are benign tumours of adipocytes, which are characteristically soft and lie more deeply in the skin than epidermal tumours. A variant, angiolipoma, is typically painful.

COMMON SKIN INFECTIONS AND INFESTATIONS

Bacterial infections

Impetigo

Impetigo is a common and highly contagious superficial bacterial skin infection. There are two main presentations: bullous impetigo, caused by a staphylococcal epidermolytic toxin, and non-bullous impetigo (Fig. 28.17), which can be caused by either *Staphylococcus aureus* or streptococcus, or both together. Staphylococcus is the most common agent in temperate climates, whereas streptococcal impetigo is more often seen in hot, humid areas. All ages can contract the infection but non-bullous disease particularly affects young children, often in late summer. It can be sporadic, although outbreaks can arise in conditions of overcrowding and poor hygiene or in institutions. A widespread form can occur in neonates. Predisposing factors are minor skin abrasions and the existence of other skin conditions, such as infestations or eczema.

In non-bullous impetigo, a thin-walled vesicle develops; it rapidly ruptures and is rarely seen intact. Dried

Fig. 28.17 Non-bullous impetigo.

exudate, forming golden crusting, arises on an erythematous base. In bullous disease, the toxins cleave desmoglein-1, causing a superficial epidermal split and the occurrence of intact blisters with clear to cloudy fluid, which last for 2–3 days. The face, scalp and limbs are commonly affected but other sites can also be involved, particularly if there are predisposing factors such as eczema. Lesions may be single or multiple and coalesce. Constitutional symptoms are uncommon. A bacterial swab should be taken from blister fluid or active lesion before treatment commences. Around one-third of the population are nasal carriers of *Staphylococcus*, so swabs from the nostrils should also be obtained.

In mild, localised disease, topical treatment with mupirocin or fusidic acid usually suffices and limits the spread of infection. The use of topical antiseptics and soap and water to remove infected crusts is also helpful. Staphylococcal carriage should be treated, with mupirocin topically to the nostrils if swabs are positive. In severe cases, an oral antibiotic, such as flucloxacillin or erythromycin, is indicated. If a nephritogenic streptococcus is suspected, then systemic antibiotics should be given, as post-streptococcal glomerulonephritis can occur (p. 498). Underlying disease, such as infestations, must be treated and cross-infection minimised. Scarring does not occur but there may be temporary dyspigmentation.

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS) is a potentially serious exfoliating condition occurring predominantly in children, particularly neonates (Fig. 28.18). It is caused by systemic circulation of epidermolytic toxins from a *Staph. aureus* infection. The same toxins are implicated in bullous impetigo, which is a localised form of SSSS. The focus of infection may be minor skin trauma, the umbilicus, urinary tract or nasopharynx. The child presents with fever, irritability and skin tenderness. Erythema usually begins in the groin, axillae and around the mouth. Blisters and superficial erosions develop over 1–2 days and can rapidly involve large areas, with severe systemic upset. Bacterial swabs should be obtained from possible primary sites of infection. A skin snip should also be taken for urgent histology. This is a sample of the superficial peeling skin removed by 'snipping with scissors', without the need for local anaesthetic. It shows a split beneath the stratum corneum, and differentiates SSSS from toxic epidermal necrolysis, in which the whole epidermis is affected (see Fig. 28.36, p. 1292). Systemic antibiotics (e.g. flucloxacillin) and intensive supportive measures should be commenced immediately. Bacterial swabs from nostrils, axillae and groins should be taken from family members to exclude staphylococcal carriage. Although the acute presentation of SSSS is often severe, rapid recovery and absence of scarring are usual, as the epidermal split is superficial.

Toxic shock syndrome

This condition is characterised by fever, desquamating rash, circulatory collapse and multi-organ involvement (p. 331). It is caused by staphylococcal toxins and early cases were thought to arise with tampon use. Intensive supportive care and systemic antibiotics are required.

Fig. 28.18 Staphylococcal scalded skin syndrome. A Extensive erythema and superficial peeling of the skin. From Savin, et al. 2002 – see p. 1305. B The condition was rapidly diagnosed by examination of a frozen section of skin snip.

Ecthyma

Ecthyma is caused by either staphylococcus or streptococcus, or both together and is characterised by adherent crusts overlying ulceration. It occurs worldwide but is more common in the tropics. In Europe, it occurs more frequently in children. Predisposing factors include poor hygiene, malnutrition and underlying skin disease, such as scabies. It is commonly seen in drug abusers, and minor trauma can predispose to lesion development.

Folliculitis, furuncles and carbuncles

Hair follicle inflammation can be superficial, involving just the ostium of the follicle (folliculitis) or deep (furuncles and carbuncles).

Superficial folliculitis

This is very common, usually minor and subacute or chronic. Primary lesions are follicular pustules and erythema. It is often infective, caused by *Staph. aureus*, but can also be sterile and caused by physical (e.g. traumatic epilation) or chemical (e.g. mineral oil) injury. Staphylococcal folliculitis is most common in children and often

Fig. 28.19 Staphylococcal carbuncle.

occurs on the scalp or limbs. Pustules usually resolve without scarring in 7–10 days but can become chronic. In older children and adults, they may progress to a deeper form of folliculitis. The condition is often self-limiting and may respond to irritant removal and antiseptics. More severe cases may require topical or systemic antibiotics and treatment of *Staph. aureus* carrier sites.

Deep folliculitis (furuncles and carbuncles)

A furuncle (boil) is an acute *Staph. aureus* infection of the hair follicle, usually with necrosis. It is most common in young adults and males. It is usually sporadic but epidemics occasionally occur. Malnutrition, diabetes and HIV predispose, although most cases arise in healthy subjects. Any body site can be involved but neck, buttocks and anogenital areas are common. Infection is often associated with chronic *Staph. aureus* carriage in the nostrils and perineum, and may be due to resistant strains, such as meticillin-resistant organisms (MRSA). Friction caused by tight clothing may be contributory. Initially, an inflammatory follicular nodule develops and becomes pustular, fluctuant and tender. Crops of lesions sometimes occur. There may be fever and mild constitutional upset. Lesions rupture over days to weeks, discharge pus, become necrotic and leave a scar.

If a deep *Staph. aureus* infection of a group of contiguous hair follicles occurs, this is termed a carbuncle and is associated with intense deep inflammation (Fig. 28.19). This usually occurs in middle-aged men, often with predisposing conditions such as diabetes or immunosuppression. A carbuncle is an exquisitely tender nodule, usually on the neck, shoulders or hips, associated with severe constitutional symptoms. Discharge, necrosis and scarring are usual. Bacterial swabs must be taken and treatment is with anti-staphylococcal antibiotics, e.g. flucloxacillin, and sometimes incision and drainage.

Other staphylococcal toxins may also be pathogenic. For example, Panton–Valentine leukocidin-producing *Staph. aureus* can cause recurrent abscesses and may be difficult to eradicate.

Cellulitis and erysipelas

Cellulitis is inflammation of subcutaneous tissue, due to bacterial infection (Fig. 28.20). In contrast, erysipelas is bacterial infection of the dermis and upper subcutaneous tissue (Fig. 28.21), although in practice it may be difficult to distinguish between them. These conditions are most commonly caused by group A streptococcus. However, culture of swabs from affected sites is often negative. There is frequently a source of organism entry, such as an ear infection, varicose eczema/ulcer or tinea pedis, and swabs should also be taken from these sites. Diabetes and immunosuppression are predisposing factors. The patient usually has malaise, fever and leucocytosis, and streptococcal serology will often be positive. The face (erysipelas) and legs (cellulitis) are most often affected and the site is hot, painful, erythematous and oedematous. Blistering often occurs and may be haemorrhagic. Regional lymphadenopathy is common. Erysipelas typically has a well-defined edge due to its more superficial level of involvement, whereas cellulitis is typically ill-defined. Treatment is usually with intravenous anti-streptococcal antibiotics, such as benzylpenicillin, with erythromycin or ciprofloxacin as an alternative for penicillin-allergic patients. Milder cases may be treated with oral antibiotics. If cases are untreated, sequelae include lymphoedema, cavernous sinus thrombosis, septicaemia and glomerulonephritis.

Fig. 28.20 **Acute cellulitis of the leg.** Note the chronic lymphoedema and the haemorrhagic blistering. Blister fluid was positive for group G streptococci.

Fig. 28.21 **Erysipelas.** Note the blistering and the crusted rash with raised, erythematous edge. The yellow discoloration is due to topical iodine treatment.

Necrotising soft tissue infections and anthrax

See pages 305 and 347, respectively.

Erythrasma

Erythrasma is a mild, chronic, localised, superficial skin infection caused by *Corynebacterium minutissimum*, which is part of the normal skin flora. Warmth and humidity predispose to this infection, which usually occurs in flexures and toe clefts. It is asymptomatic or mildly itchy and lesions are well defined, red/brown and scaly. *C. minutissimum* has characteristic coral-pink fluorescence under Wood's light. Microscopy and culture of skin scrapings can confirm the diagnosis but are not usually needed if Wood's light examination is positive. A topical azole (clotrimazole or miconazole) or fusidic acid is usually effective. Oral erythromycin can be used for extensive or resistant disease. Antiseptics can be used to prevent disease recurrence.

Pitted keratolysis

This is another superficial skin infection with *Corynebacterium*, producing characteristic circular erosions ('pits') on the soles. It is usually asymptomatic. The bacterium can be identified in skin scrapings and typically occurs in association with hyperhidrosis, which must be treated to prevent recurrence. Treatment is as for erythrasma.

Other skin infections

Syphilis and the non-venereal treponematoses are described on pages 419 and 332. Lyme disease is described on page 334.

Viral infections

Herpesvirus infections

The cutaneous manifestations of the human herpesviruses are described on page 325.

Papillomaviruses and viral warts

Viral warts are extremely common and are caused by the DNA human papillomavirus (HPV). There are over 90 subtypes, based on DNA sequence analysis, causing different clinical presentations. Transmission is by direct virus contact, in living or shed skin, and is encouraged by trauma and moisture (e.g. swimming pools). Genital warts are spread by sexual activity and show a clear relationship with cervical and intra-epithelial cancers of the genital area. HPV-16 and 18 appear to inactivate tumour suppressor gene pathways and lead to squamous cell carcinoma of the cervix or intra-epithelial carcinoma of the genital skin (p. 425). Vaccinations are now available against HPV-16 and 18 and are recommended for adolescent females before they become sexually active. The relationship between skin HPV and skin cancer is unclear. Individuals who are systemically immunosuppressed, e.g. after organ transplantation, have greatly increased risks of skin cancer and HPV infection, but a causal link is not certain.

Clinical features

Common warts are initially smooth, skin-coloured papules, which become hyperkeratotic and 'warty'.

Fig. 28.22 Viral wart on the finger. The capillary loops are evident within the warty hyperkeratosis. Periungual sites are common and more difficult to treat.

They are most common on the hands (Fig. 28.22) but can occur on the face, genitalia and limbs, and are often multiple. Plantar warts (verrucae) have a slightly protruding rough surface and horny rim and are often painful on walking. Paring reveals capillary loops that distinguish plantar warts from corns.

Other varieties of wart include:

- *mosaic warts*: mosaic-like sheets of warts
- *plane warts*: smooth, flat-topped papules, usually on the face and backs of hands; they may be pigmented and therefore misdiagnosed
- *facial warts*: often filiform
- *genital warts*: may be papillomatous and exuberant.

Management

Most viral warts resolve spontaneously, although this may take years and active treatment is therefore often sought. However, asymptomatic warts generally should not be treated. Viral warts are particularly problematic and more recalcitrant to treatment in immunosuppressed patients following organ transplantation.

Treatments are destructive. Salicylic acid or salicylic/lactic acid combinations and regular wart paring for several months is the first approach (Box 28.19). Cryotherapy is usually the next step and is repeated 2–4-weekly. However, caution is required, particularly on the hands, as over-vigorous cryotherapy can lead to scarring, nail dystrophy and even tendon rupture. Periungual and subungual warts can be problematic, and nail cutting and electrodessication may help. Several other therapies have been used for recalcitrant warts,

EBM 28.19 Treatment of viral skin warts

'Salicylic acid is the most consistently effective treatment. For certain types (such as filiform warts on the face), cryotherapy is generally the treatment of choice but, for common hand and foot warts, a salicylic acid wart paint should be used first.'

- Kwok CS, et al. Topical treatments for cutaneous warts. Cochrane Database of Systematic Reviews, 2012, issue 9. Art. no.: CD001781.

For further information: www.cochrane.org/cochrane-reviews

including systemic retinoids, intralesional bleomycin or interferon injections, and contact sensitisation with, for example, diphencyprone. Imiquimod and PDT may also be beneficial, particularly for multiple warts in immunosuppressed patients.

Molluscum contagiosum

Molluscum contagiosum is caused by a DNA poxvirus skin infection. It is most common in children over the age of 1 year, particularly those with atopic dermatitis. It also frequently occurs in immunosuppressed patients, including those with HIV (p. 388). Lesions are dome-shaped, 'umbilicated', skin-coloured papules with central punctum (Fig. 28.23). They are often multiple and found at sites of apposition, such as the side of the chest and the inner arm. Spontaneous resolution occurs but can take months. Prior to resolution, they often become inflamed and may leave small, atrophic scars. Destructive therapies may be painful and risk scarring, and the decision not to treat is often sensible. Gentle squeezing with forceps after bathing can hasten resolution. Topical salicylic acid, podophyllin, trichloroacetic acid, cryotherapy or curettage is an alternative. Efficacy with imiquimod has recently been reported.

Fig. 28.23 Molluscum contagiosum. Note the central umbilication.

Orf

Orf is a parapoxvirus skin infection and is an occupational risk for those who work with sheep and goats. Inoculation of virus, usually into finger skin, causes significant inflammation and necrosis, which typically resolves within 2–6 weeks. No specific treatment is required, unless there is secondary infection. Erythema multiforme (p. 1302) can be provoked by orf.

Other viral exanthems

See page 313.

Fungal infections

Fungal skin infections can be superficial (dermatophytes and yeasts) or, less commonly, deep (chromomycosis or sporotrichosis); the latter are more often seen in tropical climates or in the immunocompromised. Dermatophyte infections (ringworm) are extremely common and usually caused by fungi of the *Microsporum*, *Trichophyton* and *Epidermophyton* species. The fungi can originate from soil (geophilic) or animals (zoophilic), or be confined to human skin (anthropophilic). Dermatophyte infections usually present with skin (tinea corporis), scalp (tinea capitis), groin (tinea cruris), foot (tinea pedis) and/or nail (onychomycosis) involvement (Fig. 28.24).

Tinea corporis

Tinea corporis should feature in the differential diagnosis of a red, scaly rash (p. 1257). Typically, lesions are erythematous, annular and scaly, with well-defined edge and central clearing. There may also be pustules at the active edge. Lesions are usually asymmetrical and may be single or multiple. The degree of inflammation is dependent on the organism involved and the host immune response. *Microsporum canis* (from dogs) and *Trichophyton verrucosum* (from cats) are common culprits. Ill-advised use of topical steroids can modify the clinical presentation and increase disease extension (tinea incognito).

Tinea cruris

This is extremely common worldwide and is usually caused by *Trichophyton rubrum*. Itchy, erythematous plaques develop in the groins and extend on to the thighs, with a raised active edge (Fig. 28.24A).

Tinea pedis (athlete's foot)

This is the most common fungal infection in the UK and USA, and is usually caused by anthropophilic fungi, such as *T. rubrum*, *T. interdigitale* and *Epidermophyton*

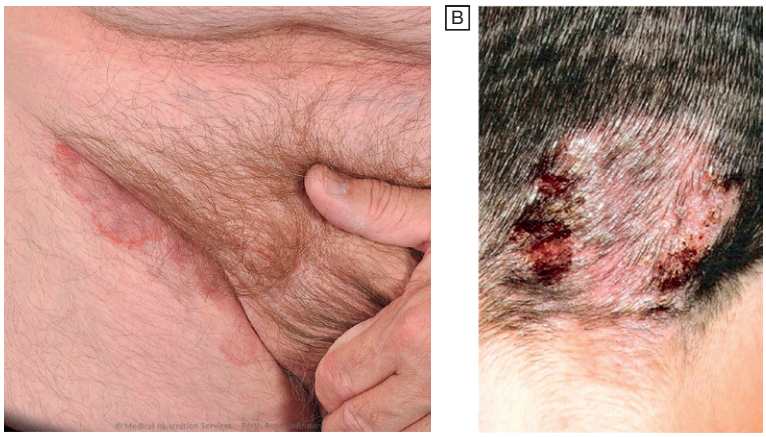

Fig. 28.24 Dermatophyte infections. A *Trichophyton rubrum* infection of the groin (tinea cruris). B *Microsporum canis* infection of the scalp (tinea capitis).

floccosum. It typically presents as an itchy rash between the toes, with peeling, fissuring and maceration. Involvement of one sole or palm (tinea manuum) with fine scaling is characteristic of *T. rubrum* infection. Vesiculation or blistering is more often seen with *T. mentagrophytes*.

Tinea capitis

This is a dermatophyte infection of scalp hair shafts and is most common in children (Fig. 28.24B). It typically presents as an area of scalp inflammation and scaling, often with pustules and partial hair loss. Infection may be within the shaft (endothrix, e.g. *T. tonsurans*), causing patchy hair loss, with broken hairs at the surface ('black dot'), little inflammation and no fluorescence with Wood's light. Infection outside the hair shaft (ectothrix, e.g. *Microsporum audouinii* (anthropophilic)) shows minimal inflammation; *M. canis* (from dogs and cats) infections are more inflammatory and can be identified by green fluorescence with Wood's light. Kerion is a boggy, inflammatory area of tinea capitis, usually caused by zoophilic fungi (e.g. cattle ringworm; *T. verrucosum*).

Onychomycosis

This is a fungal infection of the nail plate and the species involved are generally those that cause tinea capitis or tinea pedis. Onychomycosis usually presents with yellow/brown nail discoloration, crumbling, thickening and subungual hyperkeratosis. Usually, some nails are spared, there is asymmetry and toenails are more commonly involved.

Diagnosis and management

Skin scrapings, hair pluckings or nail clippings must be taken from areas of disease activity, typically the advancing lesion edge, in order to confirm the diagnosis by microscopy and culture (p. 1255). Topical antifungals (e.g. terbinafine or miconazole) may suffice, although systemic treatment (terbinafine, griseofulvin or itraconazole) may be required for stubborn or extensive disease and scalp or nail involvement. In addition to systemic antifungals, a short course of systemic corticosteroid may be required for kerion to limit hair loss.

Candidiasis

This is a superficial skin or mucosal infection caused by a yeast-like fungus, *Candida albicans* (p. 381). Infections are usually not serious, unless the patient is immunocompromised, when deeper tissues can be involved (p. 389). The organism has a predilection for warm, moist environments and typical presentations are napkin candidiasis in babies, genital and perineal candidiasis, intertrigo and oral candidiasis. Diagnosis can be confirmed by microscopy and culture of skin swabs, and treatment is with topical or systemic antifungals, such as azoles.

Pityriasis versicolor

Pityriasis versicolor is a persistent, superficial skin condition caused by a common commensal yeast, *Malassezia furfur*. It occurs in men and women and in different races. It is found more frequently in warmer, humid climates, and is usually more severe and persistent in the immunocompromised. It is characterised by scaly, oval macules on the upper trunk, usually hypopigmented but occasionally hyperpigmented. Hypopigmentation is more obvious after sun exposure and tanning. The diagnosis can be confirmed by microscopy of skin scrapings, showing 'spaghetti and meatballs' hyphae. Treatment with selenium sulphide or ketoconazole shampoos, and topical or systemic azole antifungal agents is usually effective, although, because these yeasts are skin commensals, recurrence is common and maintenance topical therapy may be required. Altered pigmentation can persist for months after treatment.

Scabies

Scabies is caused by the mite, *Sarcoptes scabiei*. It can lead to secondary infection, sometimes with complications, such as glomerulonephritis due to nephritogenic streptococci. It spreads in households and environments where there is intimate personal contact. The diagnosis is made by identifying the scabietic burrow (p. 312 and Fig. 28.25) and visualising the mite (by extracting with a needle or using a dermatoscope). In small children, the palms and soles can be involved, with pustules. Pruritus is prominent. The clinical features include secondary eczematisation elsewhere on the body; the face and scalp are rarely affected, except in infants. Involvement of the genitals in males and of the nipples commonly occurs. Even after successful treatment, itch can continue and occasionally nodular lesions persist.

Topical treatment of the affected individual and all asymptomatic family members/physical contacts is required to ensure eradication. Two applications 1 week apart of an aqueous solution of permethrin or malathion

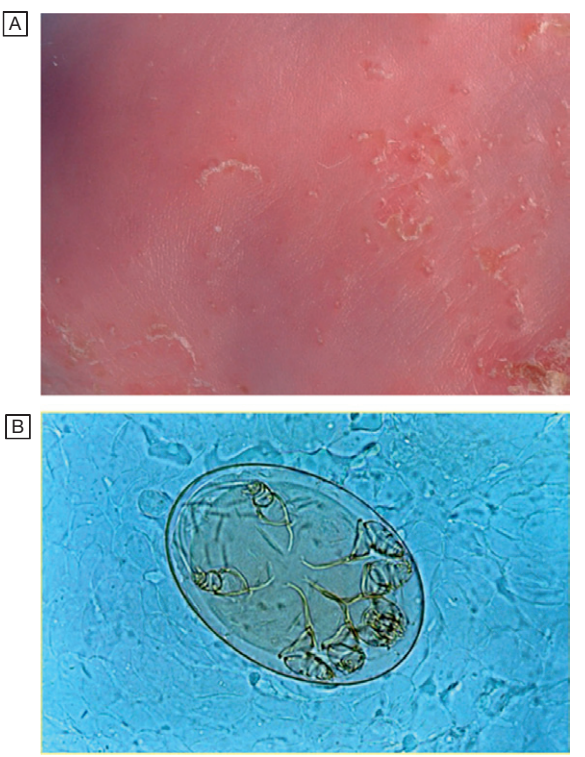

Fig. 28.25 Scabies. A Burrows evident on the palm of the hand. B A mite still in its egg, seen on light microscopy of scrapings over a burrow. Note that the mite has only six legs, unlike adult mites, which have eight.

to the whole body, excluding the head, are usually successful. If there is poor compliance, immunosuppression or heavy infestation (crusted 'Norwegian' scabies), systemic treatment with a single dose of ivermectin is sometimes appropriate.

Lice

Head lice

Infestation with the head louse, *Pediculus humanus capitis*, is common. It is highly contagious and spread by direct head-to-head contact. Scalp itch leads to scratching, secondary infection and cervical lymphadenopathy. The diagnosis is confirmed by identifying the living louse or nymph on the scalp or on a black sheet of paper after careful fine-toothed combing of wet hair following conditioner application. The empty egg cases ('nits') are easily seen on the hair shaft (p. 1250) and are hard to dislodge.

Treatment is recommended for the affected individual and any infected household/school contacts. Eradication in school populations is difficult because of poor compliance and treatment resistance. Malathion, permethrin or carbaryl, in lotion or aqueous formulations, should be applied twice at an interval of 7–10 days. Rotational treatments within a community may avoid resistance. Regular 'wet-combing' (physical removal of live lice by regular combing of conditioned wet hair) may be less effective than pharmacological treatments. Vaseline should be applied to eyelashes/brows twice daily for at least a fortnight.

Body lice

These are similar to head lice but live on clothing, particularly in seams, and feed on the skin. Poor hygiene and overcrowded conditions predispose. Itch, excoriation and secondary infection occur. Dry cleaning and high-temperature washing or insecticide treatment of clothes are required.

Pubic (crab) lice

Usually, these are sexually acquired and very itchy. Malathion or carbaryl in an aqueous base is the treatment of choice, applied on two occasions to the whole body, as body hair can also be infested. Contacts should also be treated.

ACNE AND ROSACEA

Acne vulgaris

Acne is chronic inflammation of the pilosebaceous units. The condition is extremely common; it generally starts after puberty and there are reports of it affecting over 90% of adolescents. It is usually most severe in the late teenage years but can persist into the thirties and forties, particularly in females (Box 28.20).

Aetiology

The key components are increased sebum production; colonisation of pilosebaceous ducts by *Propionibacterium acnes*, which in turn causes inflammation; and hypercornification and occlusion of pilosebaceous ducts

28.20 Acne in adolescence

- **Epidemiology**: acne vulgaris is most common between the ages of 12 and 20. It often begins around 10–13 years of age, lasts 5–10 years and usually resolves by age 20–25.
- **Emotional effects**: at all ages acne can have negative effects on self-esteem, but it is especially important to assess how it affects an adolescent. The consequences (whether acne is objectively severe or not) can be devastating, leading to embarrassment, school avoidance, life-long effects on ability to form friendships, attract partners, and acquire and keep employment.
- **Treatment**: effective treatments aim to improve the condition and prevent worsening (including later scarring), and to restore emotional well-being and self-esteem.

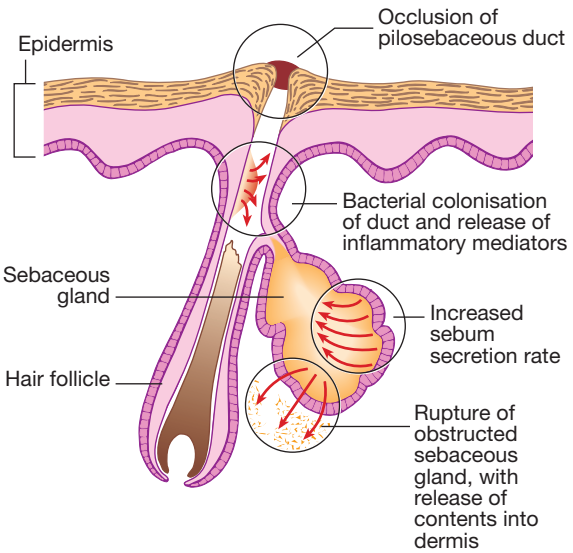

Fig. 28.26 Pathogenesis of acne.

(Fig. 28.26). Severity of acne is associated with sebum excretion rate, which increases at puberty. Both androgens and progestogens increase sebum excretion and oestrogens reduce it, although the hormonal effects may also reflect end-organ sensitivity, as most patients have normal hormone profiles. There may be a positive family history; there is high concordance in monozygotic twins and it is likely that genetic factors are important in some families, but candidate genes have not been confirmed.

Clinical features

Acne usually affects the face and often the trunk. Greasiness of the skin may be obvious (seborrhoea). The hallmark is the comedone: open comedones (blackheads) are dilated keratin-filled follicles, which appear as black papules due to the keratin debris; closed comedones (whiteheads) usually have no visible follicular opening and are caused by accumulation of sebum and keratin deeper in the pilosebaceous ducts. Inflammatory papules, nodules and cysts occur and may arise from comedones (Fig. 28.27). Scarring may follow deep-seated or superficial acne and may be keloidal.

There are distinct clinical variants:

- *Acne conglobata*: characterised by comedones, nodules, abscesses, sinuses and cysts, usually with

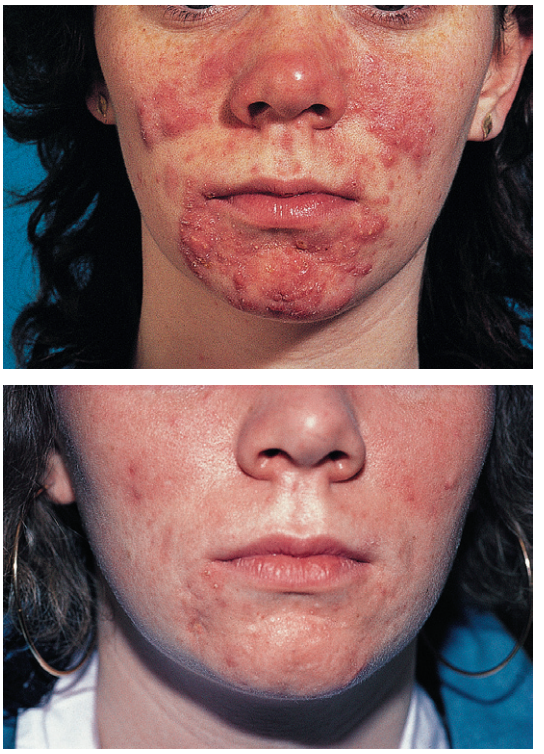

Fig. 28.27 Cystic acne in a teenager. A Before treatment. B After prolonged systemic antibiotic treatment.

marked scarring. It is rare, usually affecting adult males, and most commonly occurs on trunk and upper limbs. It may be associated with hidradenitis suppurativa (a chronic, inflammatory disorder of apocrine glands, predominantly affecting axillae and groins), scalp folliculitis and pilonidal sinus.

- *Acne fulminans*: a rare but severe presentation of acne, associated with fever, arthralgias and systemic inflammation, with raised neutrophil count and plasma viscosity. It is usually found on the trunk in adolescent males. Costochondritis can occur.
- *Acne excoriée*: describes self-inflicted excoriations due to compulsive picking of pre-existing or imagined acne lesions. It usually affects teenage girls and underlying psychological problems are common.
- *Secondary acne*: comedonal acne can be caused by greasy cosmetics or occupational exposure to oils, tars or chlorinated aromatic hydrocarbons. Predominantly pustular acne can occur in patients using systemic or topical corticosteroids, oral contraceptives, anticonvulsants, lithium or antineoplastic drugs, such as the epidermal growth factor receptor (EGFR) inhibitor, cetuximab. Most patients with acne do not have an underlying endocrine disorder. However, acne is a common feature of polycystic ovary syndrome (p. 764), which should be suspected if acne is moderate to severe and associated with hirsutism and menstrual irregularities. Virilisation should also raise suspicion of an androgen-secreting tumour.

Investigations

Investigations are not required in typical acne vulgaris. Secondary causes and suspected underlying endocrine disease or virilisation should be investigated (p. 763).

Management

Mild to moderate disease

Mild disease is usually managed with topical therapy (p. 1264). If comedones predominate, then topical benzoyl peroxide or retinoids should be used. Treatment should initially be applied at low concentrations for short duration and increased as tolerated. Azelaic acid may also be useful for mild acne. Patients with mild inflammatory acne should respond to topical antibiotics, such as erythromycin or clindamycin, which can be used in combination with other treatments.

For moderate inflammatory acne, a systemic tetracycline, such as oxytetracycline or lymecycline, should be used at adequate dose for 3–6 months in the first instance (p. 1267; Fig. 28.27B). If the case fails to respond, then alternatives include erythromycin or trimethoprim.

Oestrogen-containing oral contraceptives or a combined oestrogen/anti-androgen (such as cyproterone acetate) contraceptive may provide additional benefit in women. Patients should be referred for consideration of isotretinoin (13 *cis*-retinoic acid) if there is a failure to respond adequately to 6 months of therapy with these combined systemic and topical approaches (p. 1267).

Moderate to severe disease

Isotretinoin has revolutionised the treatment of moderate to severe acne that has not responded adequately to other therapies. It has a multifactorial mechanism of action, with reduction in sebum excretion by over 90%, follicular hypercornification and *P. acnes* colonisation. A typical course lasts for 4 months. Sebum excretion usually returns to baseline over the space of a year after treatment is stopped, although clinical benefit is usually longer-lasting. Many patients will not require further treatment, although a second or third course of isotretinoin may be required. A low-dose continuous or intermittent-dose regimen may be considered for a longer duration, in patients who relapse after a higher-dose regimen. Combination with systemic steroid may be required in the short term for severe acne, in order to minimise the risk of disease flare early in the treatment course. Thorough screening and monitoring are required, given the side-effect profile of isotretinoin (p. 1267).

Other treatments and physical measures

Intralesional injections of triamcinolone acetonide may be required for inflamed acne nodules or cysts, which can also be incised and drained, or excised under local anaesthetic. Scarring may be prevented by adequate treatment of active acne. Keloid scars may respond to intralesional steroid and/or silicone dressings. Carbon dioxide laser, microdermabrasion, chemical peeling or localised excision can also be considered for scarring. UVB phototherapy or PDT can occasionally be used in patients with inflammatory acne who are unable to use conventional therapy, such as isotretinoin. There is no convincing evidence to support a causal association between diet and acne. The psychological impact of acne must not be underestimated and should be considered in management decisions (see Box 28.20).

Rosacea

This chronic inflammatory condition affects the central face and consists of flushing, erythema, papules, pustules and telangiectasiae. The cause is unknown. Rosacea is distinct from acne vulgaris; sebum excretion is normal and comedones are absent. The relative contribution of *Demodex* mite and cutaneous vasomotor instability to the pathogenesis of rosacea remains poorly defined.

Clinical features and diagnosis

Rosacea most commonly affects fair-skinned, middle-aged females and can be exacerbated by heat, sunlight and alcohol. The convexities of nose, forehead, cheeks and chin are typically involved (Fig. 28.28). The condition is heterogeneous and, in some, intermittent flushing, followed by fixed erythema and telangiectasiae, predominate; in others, papules and pustules are prominent. Sebaceous gland hyperplasia and soft tissue overgrowth of the nose (rhinophyma) can occur, particularly in males. Conjunctivitis and blepharitis may also occur. Facial lymphoedema can be an added complication. Usually, no investigations are required and the diagnosis is obvious clinically. However, it must be distinguished from acne vulgaris, systemic lupus erythematosus, photosensitivity disorders and seborrhoeic dermatitis (the latter may coexist with rosacea).

Management

Mild disease may respond to topical antimicrobials, such as metronidazole or azelaic acid. Tetracycline or erythromycin for 3–6 months is usually effective in inflammatory pustular disease resistant to topical therapy (p. 1264). Relapse may require intermittent or chronic antibiotic use. Erythema and telangiectasiae do not respond well to antibiotics but laser therapy can be effective. Systemic isotretinoin may be helpful in severe resistant disease and rhinophyma may need laser therapy or surgery.

Fig. 28.28 Rosacea. Typical erythematous papulopustular rosacea affecting the mid-face.

ECZEMAS

The terms 'eczema' and 'dermatitis' are synonymous. Eczema can be acute or chronic and there are several causes. Acutely, epidermal oedema (spongiosis) and intra-epidermal vesiculation (producing multilocular blisters) predominate, whereas with chronicity there is more epidermal thickening (acanthosis). Vasodilatation and T-cell lymphocytic infiltration of the upper dermis also occur.

Clinical features

There are several patterns of eczema (Box 28.21) and environmental causes may be identifiable. The clinical features are similar, irrespective of the cause (Box 28.22).

Atopic eczema

Generalised, prolonged hypersensitivity to common environmental antigens, such as pollen and house dust mite, is the hallmark of atopy, in which there is a genetic predisposition to produce excess IgE. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. There are strong familial associations with atopic diseases. The diagnosis of atopic eczema is made using clinical criteria (Box 28.23). Its prevalence has increased 2–5-fold since the early 1980s, and the disease now affects 1 in 10 schoolchildren.

Aetiology

Genetic factors are important. Epidermal barrier impairment is a major, and perhaps primary, factor in this form of eczema. Mutations in the filaggrin gene have been identified as important in some. Environmental factors, such as exposure to allergens in utero or during childhood, may also have an aetiological role and 60–80% of

28.21 Classification of eczema

Endogenous
• Atopic, seborrhoeic
Exogenous
• Irritant, allergic, photoallergic, chronic actinic dermatitis
Characteristic patterns and morphology
• Asteatotic, discoid, gravitational, lichen simplex, pompholyx

28.22 The clinical morphology of eczema

Acute
• Erythema, oedema, usually typically ill-defined • Papules, vesicles and occasionally bullae • Exudation, fissuring • Scaling
Chronic
• May be as above but less oedema, vesiculation and exudate • Lichenification: skin thickening with pronounced skin markings, secondary to chronic rubbing and scratching • Fissures, excoriations • Dyspigmentation: hyper- and hypopigmentation can occur

28.23 Diagnostic criteria for atopic eczema

Pruritus and at least three of the following are required:
- History of itch in skin creases (or cheeks if < 4 yrs)
- History of asthma/hay fever (or in a first-degree relative if < 4 yrs)
- Dry skin (xeroderma)
- Visible flexural eczema (cheeks, forehead, outer limbs if < 4 yrs)
- Onset in first 2 yrs of life

individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair. Decreased skin barrier function may also allow greater penetration of allergens through the epidermis, and thus cause immune stimulation and subsequent inflammation.

Clinical features

Atopic eczema is extremely itchy and scratching accounts for many of the signs (Fig. 28.29). Widespread cutaneous dryness (roughness) is another feature. The distribution and character of the rash vary with age (Box 28.24). Complications are listed in Box 28.25.

28.24 Atopic eczema: distribution and character of rash

Babies and infants
- Often acute and facial involvement prominent
- Trunk involved but nappy area usually spared

Children
- Flexures: behind knees, antecubital fossae, wrists and ankles

Adults
- Face and trunk usually involved, limb involvement not restricted to flexures
- Lichenification common

Fig. 28.29 Atopic eczema. A This patient had life-long chronic atopic eczema and experienced a generalised flare of disease triggered by infection. B Lichenification of chronic flexural eczema secondary to rubbing and scratching.

28.25 Complications of atopic eczema

Secondary infection

Bacterial
- *Staph. aureus* most common

Viral
- Herpes simplex virus can cause a widespread severe eruption – eczema herpeticum
- Papillomavirus and molluscum contagiosum are more common in atopic eczema, especially if treated with topical corticosteroids

Increased susceptibility to irritants
- Defective barrier function

Increased susceptibility to allergy
- Food allergy – mainly relevant in infants. Eggs, cow's milk, protein, fish, wheat and soya may cause an immediate urticarial eruption rather than exacerbation of eczema
- Increased risk of sensitisation to type IV allergens because of impaired barrier function

Impact on life and health
- Poor sleep, loss of schooling, behavioural difficulties, failure to thrive in children
- Impact on sleep, work, relationships, hobbies, psychology and quality of life in adults

Seborrhoeic eczema

This is an erythematous scaly rash affecting the scalp (dandruff), central face, nasolabial folds, eyebrows, central chest and upper back. It is associated with, and may be due to, overgrowth of *Pityrosporum* yeasts. When severe, it may resemble psoriasis. Severe or recalcitrant seborrhoeic eczema can be a marker of immunodeficiency, including HIV infection (p. 397).

Discoid eczema

This is common and characteristically consists of discrete coin-shaped eczematous lesions, which are often impetiginised and most commonly occur on the limbs of men. It is an eczema type that can be due to any chronic itchy condition, whether primarily of skin (e.g. atopic eczema) or another system (e.g. renal failure).

Irritant eczema

Detergents, alkalis, acids, solvents and abrasives are common irritants. Strong irritants have acute effects, whereas weaker irritants commonly cause chronic eczema, especially of the hands, after prolonged exposure. Individual susceptibility varies and the elderly, atopic and fair-skinned are predisposed. Irritant eczema accounts for most occupational cases of eczema and is a significant cause of time off work.

Allergic contact eczema

This occurs due to a delayed hypersensitivity reaction following contact with antigens or haptens. Previous allergen exposure is required for sensitisation and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 28.26.

Allergy persists indefinitely and eczema occurs at sites of allergen contact and can secondarily spread

28.26 Common type IV delayed hypersensitivity allergens

Allergen	Source
Nickel	Jewellery, jean studs, bra clips, watches
Dichromate	Cement, leather, matches
Rubber chemicals	Clothing, shoes, rubber gloves, tyres
Colophony	Sticking plaster, collodion, nail varnish
Paraphenylenediamine	Hair dye, clothing, tattoos
Balsam of Peru	Perfumes, citrus fruits, shower/bath products
Neomycin, benzocaine	Topical medications
Parabens	Preservative in cosmetics and creams
Wool alcohols	Lanolin, cosmetics, creams
Epoxy resin	Resin adhesives, glues

Fig. 28.30 Allergic contact eczema. This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral periorbital oedema are typical.

beyond this. There are many recognisable patterns, e.g. eczema of the earlobes, wrists and umbilicus due to contact with nickel in earrings, watches and jeans studs, or eczema of the hands and wrists due to rubber gloves. Oedema may also be a feature (Fig. 28.30).

Asteatotic eczema

This occurs in dry skin and is common in the elderly. Low humidity caused by central heating, over-washing, diuretics and cholesterol-lowering drugs predispose. The most common site is the lower legs and a 'crazy paving' pattern of fine fissuring on an erythematous background is seen.

Gravitational (stasis) eczema

This occurs on the lower legs and is often associated with signs of venous insufficiency: oedema, loss of hair, induration, lipodermatosclerosis and ulceration.

Lichen simplex

Lichenification of eczema occurs secondary to chronic rubbing and scratching, and lichen simplex is a localised form. Common sites include the neck, lower legs and the anogenital region.

Pompholyx

Intensely itchy vesicles and bullae occur on the palms, palmar surface and sides of the fingers and soles. Pompholyx may have several causes, which include atopic eczema, irritant and contact allergic dermatitis and fungal infection.

Investigation of eczema

Patch tests are performed if contact allergic dermatitis is suspected (see Box 28.26). IgE and specific IgE tests are not routinely undertaken in atopic eczema and, similarly, prick tests are not usually helpful. Bacterial and viral swabs for microscopy and culture are useful in suspected secondary infection. Individuals with atopic eczema have an increased susceptibility to herpes simplex virus (HSV), and are at risk of developing a widespread infection, eczema herpeticum. The presence of small, punched-out lesions on a background of worsening eczema suggests the possibility of secondary HSV infection. Skin scrapings to rule out secondary fungal infection should be considered. Skin biopsy is not usually required unless there is diagnostic doubt, e.g. of a drug adverse effect or cutaneous lymphoma.

General management of eczema

Regular use of emollients (e.g. emulsifying ointment) is the mainstay treatment in all eczema types, as they limit water loss and help reduce the amount of topical corticosteroid used. Emollients are used as bath additives and soap substitutes, and directly on to the skin, and are often combined with antiseptics. Sedative antihistamines are useful if sleep is interrupted, but non-sedating antihistamines are ineffective (Box 28.27).

Topical corticosteroids

Topical corticosteroid ointments are preferred for chronic eczema, whereas cream or lotion-based treatment may be more appropriate for acute eczema. Treatment is once to twice daily (p. 1264). Hydrocortisone (1%) or clobetasone butyrate is generally used on the face, with potent or very potent corticosteroid use restricted to trunk and limbs. It is preferable to use a more potent intensive regime initially and taper according to response. As a rough guide, 200 g of a mildly

EBM 28.27 Antihistamines and itch in atopic eczema

'There is currently no high-level evidence to support or refute the efficacy or safety of oral H_1 antihistamines used as monotherapy for eczema. As for various causes of itch not mediated primarily by histamine in the skin, however, sedative (but not non-sedating) antihistamines may offer symptomatic relief.'

Apfelbacher CJ, et al. Cochrane Database of Systematic Reviews, 2013, issue 2. Art. no.: CD007770.

For further information: www.cochrane.org/cochrane-reviews

potent, 50 g of a moderately potent or 30 g of a potent corticosteroid per week would be appropriate (see Box 28.11). Very potent topical corticosteroids should not be used long-term. The side-effects of topical corticosteroid therapy need to be considered when patients are using them for a long period of time, although 'steroid phobia' and under-treatment of eczema are often more of a problem. Particular care should be taken on certain sites, such as the face and flexures, and in children and the elderly (see Box 28.2 and Fig. 28.8, p. 1265). The least potent corticosteroid that is effective should be used for the shortest possible time. The topical calcineurin inhibitors, tacrolimus and pimecrolimus, may be useful steroid-sparing agents, particularly on the face.

Atopic eczema

The impact of atopic eczema on the quality of life of the patient and parents must not be under-estimated. Information and ongoing support from health-care systems and patient support groups, such as the National Eczema Society in the UK, are essential. Mainstays of treatment are emollients and topical steroids, and tar and ichthammol paste bandages may be required. Secondary infection should be treated. Identification and avoidance of allergens are important. Phototherapy, usually with narrowband UVB, is generally the next step, if topical therapies are insufficient. PUVA or UVA1 is sometimes used. Topical calcineurin inhibitors may be applied, and systemic immunosuppression with intermittent ciclosporin, oral corticosteroids, azathioprine or methotrexate may be needed.

Seborrhoeic eczema

Topical azoles, such as ketoconazole shampoo and cream, often combined with mild corticosteroid, are mainstays. Treatment often needs to be repeated.

Irritant eczema

Irritant avoidance, including protective clothing (e.g. gloves), is essential. Emollients and topical corticosteroids are indicated.

Contact allergic eczema

Allergen avoidance is key and may involve a change of occupation or hobbies. Treatment with emollients and topical corticosteroids helps.

Gravitational eczema

Topical corticosteroids should be applied to eczematous areas but not ulcers. There is a high risk of sensitisation to topical preservatives (e.g. chlorocresol), antibiotics (e.g. neomycin) and bandages (e.g. rubber additives). Oedema and ulceration are treated by leg elevation and compression bandages (p. 1263).

PSORIASIS AND OTHER ERYTHEMATOUS SCALY ERUPTIONS

Psoriasis

Psoriasis is a chronic inflammatory, hyperproliferative skin disease. It is characterised by well-defined, erythematous scaly plaques, particularly affecting extensor surfaces and scalp, and usually follows a relapsing and remitting course. Psoriasis affects approximately 1.5–3% of Caucasians and is less common in Asian, South American and African populations. It occurs equally in both sexes and at any age; although it is uncommon under the age of 5 years, more than 50% present before the age of 30 years. The age of onset follows a bimodal distribution, with an early-onset type in the teenage or early adult years, often with a family history of psoriasis and more severe disease course. The later-onset type is typically seen between 50 and 60 years, usually without a family history and a less severe disease course.

Aetiology and pathogenesis

The pathogenesis of psoriasis is multifactorial and genetic and environmental factors are important. The genetic component is complex and polygenic. Twin studies indicate concordance rates of 60–75% and 15–20% for psoriasis arising in monozygotic and dizygotic twins, respectively, with similarities in age of onset, nature and severity of disease in familial cases. If one parent has psoriasis, the chance of a child being affected is about 15–20%; if both parents have the disease, this rises to 50% and the risk is increased further if a sibling has the disease. Advances in molecular biology have facilitated the identification of several genes with significant linkage to psoriasis. The most replicated gene is *PSORS1*, located within the major histocompatibility complex (MHC) on chromosome 6 (human leucocyte antigen (HLA) Cw6) and encoding an epidermal protein, corneodesmosin. It is thought that this gene accounts for almost half of the heritability of psoriasis.

There are several environmental triggers for psoriasis becoming manifest in a genetically predisposed subject (Box 28.28). Although the theory is controversial, stress

28.28 Exacerbating factors in psoriasis

Trauma

- Psoriatic lesions can appear at sites of skin trauma, such as scratches or surgical wounds (Köbner isomorphic phenomenon)

Infection

- β-haemolytic streptococcal throat infections often precede guttate psoriasis (see Fig. 28.32B)
- Severe psoriasis may be the initial presentation of HIV infection

Sunlight

- A minority of patients experience exacerbation of psoriasis after sun exposure, mainly due to Köbnerisation at sites of sunburn or polymorphic light eruption

Drugs

- Antimalarials, β-adrenoceptor antagonists (β-blockers), lithium, NSAIDs and anti-TNF-α drugs, such as infliximab, are examples of drugs that can exacerbate psoriasis
- 'Rebound' flare of psoriasis may occur after withdrawal of systemic corticosteroids or potent topical corticosteroids. Rebound psoriasis is often unstable and may be pustular

Psychological factors

- Anxiety and stress may exacerbate psoriasis in predisposed individuals

(NSAID = non-steroidal anti-inflammatory drug; TNF-α = tumour necrosis factor alpha)

may exacerbate psoriasis in susceptible individuals and psoriasis is itself a cause of psychological stress. Likewise, there is a higher incidence of smoking and heavy alcohol consumption in patients with psoriasis but it is unclear whether this is cause or effect.

The histological changes of psoriasis are shown in Figure 28.31. The main features are:

- keratinocyte hyperproliferation and abnormal differentiation, leading to retention of nuclei in the stratum corneum
- inflammation, with a T-cell lymphocytic infiltrate and release of cytokines and adhesion molecules, such as interleukins, TNF-α and intercellular adhesion molecule (ICAM)-1
- vascular changes, with tortuosity of dermal capillary loop vessels and release of mediators, such as vascular endothelial growth factor (VEGF).

The initiating event is unknown; whilst hyperproliferation was considered the primary step, this has not been confirmed and may, in fact, be secondary to inflammation or vascular changes.

Disordered cell proliferation is reflected by an increase in the mitotic index and in keratinocyte and T-lymphocyte apoptosis in psoriatic plaques. The transit time for keratinocyte migration, from basal layer to shedding from stratum corneum, is shortened from approximately 28 to 5 days, so that immature cells reach the stratum corneum prematurely. Proliferation rate is also less markedly increased in non-lesional skin. Similarly, even the clinically unaffected nails of patients with psoriasis grow more quickly than those of controls.

Interestingly, the HLA association, efficacy of immunosuppressants and development of psoriasis in haematopoietic stem cell transplant recipients from donors with psoriasis support an immune pathogenesis, but the mechanisms and sequence of events are unclear.

Clinical features

Psoriasis has several different presentations (Fig. 28.32).

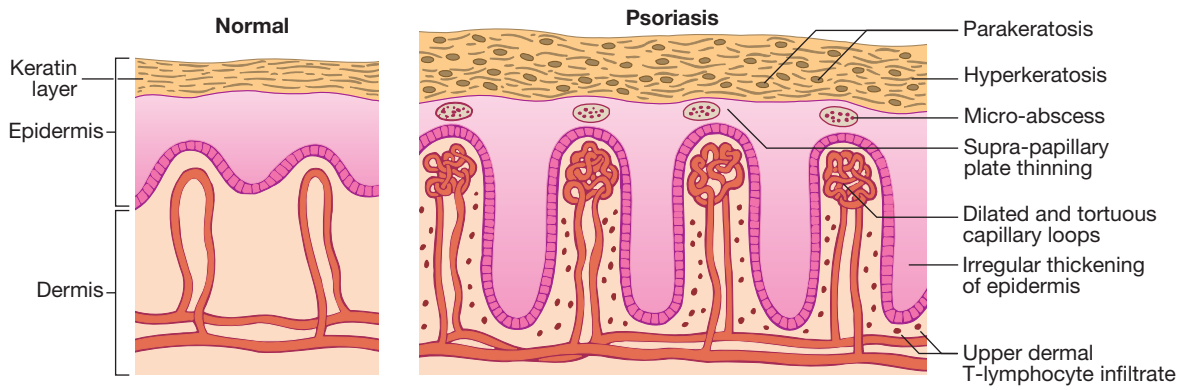

Fig. 28.31 The histology of psoriasis.

Fig. 28.32 **Psoriasis.** A Chronic plaque psoriasis, most prominent on extensor surfaces. B Nail involvement, with coarse pitting and separation from the nail plate (onycholysis). C Guttate psoriasis following a streptococcal throat infection. D Erythrodermic psoriasis.

Plaque psoriasis

This is the most common presentation and usually represents more stable disease. The typical lesion is a raised, well-demarcated erythematous plaque of variable size (Fig. 28.32A). In untreated disease, silver/white scale is evident and more obvious on scraping the surface. The most common sites are the extensor surfaces, notably elbows and knees, and the lower back. Others include:

- *Scalp*: involvement is seen in approximately 60% of patients. Typically, easily palpable, erythematous scaly plaques are evident within hair-bearing scalp and there is clear demarcation at or beyond the hair margin. Occipital involvement is common and difficult to treat. Less often, fine diffuse scaling may be present and difficult to distinguish from seborrhoeic dermatitis. Involvement of other 'seborrhoeic sites', such as eyebrows, nasolabial folds and the pre-sternal area, is not uncommon and again may be confused with seborrhoeic dermatitis. Temporary hair loss can occur but permanent loss is unusual.
- *Nails*: involvement is common, with 'thimble pitting', onycholysis (separation of the nail from the nail bed, Fig. 28.32B), subungual hyperkeratosis and periungual involvement (p. 1250).
- *Flexures*: psoriasis of the natal cleft and submammary and axillary folds is usually symmetrical, erythematous and smooth, without scale.
- *Palms*: psoriasis of the palms can be difficult to distinguish from eczema.

Guttate psoriasis

This is most common in children and adolescents and is often the initial presentation (Fig. 28.32C). It is commonly associated with HLA Cw6. It may present shortly after a streptococcal throat infection and rapidly evolves. Individual lesions are droplet-shaped, small (usually less than 1 cm in diameter), erythematous, scaly and numerous. An episode of guttate psoriasis may clear spontaneously or with topical treatment within a few months, but UVB phototherapy is often required and is highly effective. Guttate psoriasis often heralds the onset of plaque psoriasis in adulthood.

Erythrodermic psoriasis

Generalised erythrodermic psoriasis is a medical emergency (Fig. 28.32D).

Pustular psoriasis

Pustular psoriasis may be generalised or localised. Generalised pustular psoriasis is uncommon, unstable and life-threatening. It will often emerge in the context of plaque disease and the onset is usually sudden, with large numbers of small sterile pustules on an erythematous background, often merging into sheets, with waves of new pustules in subsequent days. The patient is usually febrile and systemically unwell, and this must be dealt with as a medical emergency (p. 1264). Localised pustular psoriasis of the palms and soles (palmoplantar pustulosis) is more common, chronic and closely associated with smoking; small, sterile pustules and erythema develop and resolve with pigmentation and scaling (p. 1250). A localised form of sterile pustulosis of a few digits (acropustulosis) can also occur. It is unclear whether these localised forms of pustulosis are truly psoriatic.

Arthropathy

Between 5% and 10% of individuals with psoriasis develop an inflammatory arthropathy, which can take on a number of patterns (pp. 1250 and 1109).

Assessment and investigations

Biopsy is not required in typical cases but may be performed if there is diagnostic doubt. An infection screen, particularly throat swab for streptococcus, may be informative in guttate psoriasis. Assessment of impact on life (e.g. using the Dermatology Life Quality Index, or DLQI) and psoriasis severity (e.g. using the Psoriasis Area and Severity Index, or PASI) (p. 1251) is essential. Rheumatology assessment should be performed if the patient has joint symptoms or signs. Due to the association of psoriasis with insulin resistance, cardiovascular risk factors should be assessed (p. 805). HIV testing should be considered in severe or recalcitrant psoriasis.

Management

Patient counselling about diagnosis and management is paramount. Psoriasis can have a major impact on all aspects of life (work, school, leisure, personal relationships and self-esteem) and this must not be underestimated. Reassurance is also needed, as the condition is generally not life-threatening. Advice regarding reduction in risk factors for cardiovascular disease should be given (smoking cessation, reduction of alcohol intake, adequate exercise and a normal body mass index). Patients need to be involved in their own management, as the disease is usually chronic and the benefit/risk profile of treatments needs to be discussed and tailored to individuals. The end-point for treatment also needs to be discussed because complete disease clearance may not be practical or appropriate and patients vary considerably in their treatment requirements. Extent of disease and impact on quality of life must be taken into account. Patient compliance with topical and systemic therapies is essential and dependent on the treatment practicalities.

The treatment approach generally follows a stepwise progression, as summarised in Box 28.29. Treatment categories are outlined in Box 28.30. If topical treatment is insufficient, then UVB phototherapy or PUVA should usually be the next step. If the patient continues to have active disease or early recurrence, then the addition of systemic retinoid (usually acitretin) or use of immunosuppressants, such as methotrexate as first choice, then

EBM 28.29 Assessment and management of psoriasis

- 'Access to appropriate information and services must be facilitated for patients with psoriasis.
- Disease severity and impact must be assessed.
- Associated arthritis must be assessed and managed.
- Comorbidities, such as cardiovascular risk, must be addressed.
- Topical therapies are first-line, followed by second- and third-line treatments (see below).
- Topical corticosteroids must be used safely.'

For further information: www.nice.org.uk
www.sign.ac.uk

28.30 Treatment categories in psoriasis

Topical agents
• Emollients, tars, dithranol, vitamin D agonists, retinoids, corticosteroids
Photo(chemo)therapies
• UVB, PUVA, (excimer laser)
Systemic agents
• Retinoids • Immunosuppressants, e.g. methotrexate, ciclosporin, mycophenolate, hydroxycarbamide • Immunomodulators, e.g. fumaric acid esters • Biological immunosuppressants, e.g. infliximab, etanercept, adalimumab
Intensive inpatient or day-patient care
• Topical agents and photo(chemo)therapies under medical supervision

ciclosporin, mycophenolate mofetil or hydroxycarbamide, may be considered. In severe, unresponsive disease, fumaric acid esters or biological therapies, such as TNF-α, interleukin (IL)-12 or IL-23 antagonists, may be required (p. 1102).

Individualised management is essential. For example, a patient with localised plaque psoriasis on elbows, knees and sacrum should respond to topical treatment only, whereas a patient with guttate psoriasis is likely to need phototherapy as a first-line approach because of difficulties in topical drug application in extensive disease. A patient with extensive chronic plaque psoriasis and significant arthropathy would be better suited to a systemic drug, such as methotrexate, than phototherapy, which would be unlikely to improve joint symptoms.

Pityriasis rosea

This is an acute, self-limiting exanthem that particularly affects young adults and occurs worldwide, with a slight female predominance. It usually occurs in spring and summer, although no infective agent has been identified and its aetiology is unknown.

Clinical features and management

Pityriasis rosea is characterised by the appearance of a 'herald patch', an oval lesion (1–2 cm) with a central pinkish (salmon-coloured) centre, a darker periphery and a characteristic collarette of scale. It is followed 1–2 weeks later by a widespread papulosquamous eruption, which is typically arranged in a symmetrical 'Christmas tree' pattern on the trunk. Individual lesions also have a collarette of scale. An inverse variant with flexural involvement can occur. Mucosal involvement is rare. There is a small risk of recurrence. Symptomatic relief can be achieved with emollients and mild topical steroids. Post-inflammatory hyperpigmentation can supervene, particularly in darker skin types.

Other causes of an erythematous papulosquamous rash

Secondary syphilis (p. 419), pityriasis versicolor (p. 1280) and fungal infection with *Tinea corporis* (p. 1279) can all cause an erythematous papulosquamous rash and must be considered in the differential diagnosis.

Pityriasis lichenoides chronica

This is rare but typically presents within the first three decades of life. The aetiology is unclear but the condition is part of a spectrum and remits spontaneously. The more acute variety (pityriasis lichenoides et varioliformis acuta, PLEVA) presents as crops of papules that rapidly evolve with central necrosis, each attack lasting up to 3 months. The more chronic variety presents as a persistent, widespread, scaly eruption. Characteristically, lesions are brown papules with a mica-like scale ('cornflake'). The condition fluctuates but can persist for months or years. Emollients, topical steroids and long-term oral erythromycin can occasionally be helpful. UVB phototherapy or PUVA is usually effective, although recurrences are high.

Drug eruptions

It is essential to consider a drug cause in anyone presenting with an erythematous maculopapular or papulosquamous eruption, and a careful drug history is critical (p. 1303). Exfoliation ('peeling') and post-inflammatory hyper- or, less commonly, hypopigmentation, can occur.

LICHEN PLANUS AND LICHENOID ERUPTIONS

Lichen planus

Lichen planus occurs worldwide; it typically presents as a pruritic rash and the mucosae, hair and nails may be involved.

Aetiology and pathology

The cause is unknown; a viral trigger was considered but has not been substantiated. An autoimmune pathogenesis is suspected, as there is an association with inflammatory bowel disease, primary biliary cirrhosis, autoimmune hepatitis, hepatitis B and C, alopecia areata, myasthenia gravis (p. 1226) and thymoma, and there are similarities with graft-versus-host disease (GVHD, p. 1017). An immune reaction to unknown antigen is plausible. Lichen planus can occasionally occur in families and possible HLA associations have been proposed, although there is no clear inheritance pattern. There are characteristic histological changes, with hyperkeratosis, basal cell degeneration and a heavy, band-like T-lymphocyte infiltrate in the papillary dermis, with affinity for the epidermis (epidermotropism). The dermo-epidermal junction has a 'sawtooth' appearance.

Clinical features

Lichen planus occurs in both sexes and at any age, although usually between 30 and 60 years. It generally presents on the distal limbs, most commonly on the flexural aspects of the wrists and forearms (Fig. 28.33), and on the lower back. It is intensely itchy and lesions are violaceous, shiny, flat-topped, polygonal papules, with a characteristic fine lacy, white network on the surface (Wickham's striae). New lesions may appear at sites of skin trauma (Köbner phenomenon) and the

Fig. 28.33 Lichen planus. Violaceous papules on the flexural aspect of forearm, arising at a site of minor linear trauma (Köbner phenomenon).

rash may become generalised. Individual lesions may last for many months and can become hypertrophic and modified by scratching, particularly on the lower legs. The eruption usually remits over months, but can become chronic, particularly with hypertrophic disease. Post-inflammatory pigmentary change is common, particularly in darker skin types. Mucous membrane involvement occurs in 30–70% of patients, usually as a network of white, lacy striae on the buccal mucosae (p. 1250) and tongue. These oral changes are often asymptomatic and should be sought on examination. Genital and other mucosal surfaces can also be affected (pp. 416 and 418). Nail involvement occurs in about 10% and can range from longitudinal ridging to a destructive nail dystrophy, scarring (pterygium) and nail loss (p. 1298). Scalp involvement usually presents as an inflammatory scarring alopecia, often with tufting of residual hairs. The classical presentation of lichen planus is unmistakable but less common, atypical variants, which include annular, atrophic, actinic, linear, bullous, follicular, pigmented and ulcerative types, can be a diagnostic challenge.

Diagnosis

A skin biopsy should be performed if there is diagnostic doubt. A careful drug history must be taken as, although the classical presentation of lichen planus is usually 'idiopathic', the main differential is a drug-induced lichenoid reaction (see below). Other differential diagnoses include psoriasis, pityriasis rosea, pityriasis lichenoides chronica and secondary syphilis. Screening for underlying disease, such as hepatitis, must be considered.

Management

The condition is usually self-limiting, although rarely, particularly with oral lichen planus, it may persist for years. Treatment is symptomatic and potent local corticosteroids (topical, with occlusion or by injection for hypertrophic disease, or as oral rinse for oral involvement) may help the intense itch; short courses of systemic corticosteroids are sometimes required for extensive disease. UVB, PUVA or UVA1 can be beneficial and, for recalcitrant disease, retinoids or immunosuppressants such as ciclosporin may be needed. A low but significant risk of malignant transformation exists with persistent oral and genital disease, so active treatment, surveillance and smoking cessation are important.

Lichenoid eruptions

Drug-induced lichenoid reactions that are clinically and histologically difficult to distinguish from idiopathic lichen planus are important to identify. The culprits are gold, quinine, proton pump inhibitors, sulphonamides, penicillamine, antimalarials, antituberculous drugs, thiazide diuretics, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, NSAIDs, sulphonylureas, lithium and dyes in colour developers (Box 28.44, p. 1304).

Graft-versus-host disease

In the acute stage of graft-versus-host disease (GVHD, p. 1017), there is a distinctive dermatitis associated with hepatitis. After about 3 months, chronic GVHD can present with a lichenoid eruption on the palms, soles, face and upper trunk. Progressive sclerodermatous skin thickening may lead to contractures and limited mobility.

URTICARIA

Urticaria ('hives') is caused by localised dermal oedema secondary to a temporary increase in capillary permeability. If oedema involves subcutaneous or submucosal layers, the term angioedema is used. Acute urticaria may be associated with angioedema of the lips, face, tongue, throat and, rarely, wheezing, abdominal pain, headaches and even anaphylaxis (p. 91).

Urticaria present for less than 6 weeks is considered to be acute, and chronic if it continues for more than 6 weeks. Individual weals last for less than 24 hours; if they persist, urticarial vasculitis needs to be considered. Clarification of duration can be achieved by drawing around the weal and re-assessing 24 hours later.

History-taking should probe for possible causes (Box 28.31). Physical triggers can also be assessed in challenge testing, such as eliciting dermographism or pressure testing. Enquiry about family history is important in angioedema. Examination may be unremarkable or weals may be evident (Fig. 28.34).

Mast cell degranulation and release of histamine and other vasoactive mediators is the basis of urticaria (Fig. 28.35). Chronic spontaneous urticaria (previously called 'chronic idiopathic' or 'chronic ordinary'

28.31 Causes of urticaria

Acute and chronic urticaria

- Autoimmune: due to antibodies that cross-link the IgE receptor on mast cells
- Allergens: in foods, medications and inhalants
- Drugs: (see Box 28.44, p. 1304)
- Contact: e.g. latex, animal saliva
- Physical: e.g. heat, cold, pressure, sun, sweat, water
- Infection: e.g. intestinal parasites
- Others: e.g. systemic lupus erythematosus (SLE), pregnancy
- Idiopathic: Chronic spontaneous urticaria and angioedema

Urticarial vasculitis

- Hepatitis B
- SLE
- Idiopathic

urticaria) is the most common chronic urticaria and has an autoimmune pathogenesis in some cases.

Investigations

Investigations should be guided by the history and possible causes but are often negative, particularly in acute urticaria. Some or all of the following may be appropriate:

- *full blood count*: eosinophilia in parasitic infection or drug cause
- *erythrocyte sedimentation rate (ESR) or plasma viscosity*: elevated in vasculitis
- *urea and electrolytes, thyroid and liver function tests, iron studies*: may reveal an underlying systemic disorder
- *total IgE and specific IgE to possible allergens*: e.g. shellfish, peanut, house dust mite
- *antinuclear factor*: positive in systemic lupus erythematosus (SLE) and often positive in urticarial vasculitis
- *complement C_3 and C_4 levels*: if these are low due to complement consumption, *C_1 esterase inhibitor* activity should be measured
- *skin biopsy*: if urticarial vasculitis is suspected
- *challenge tests*: to confirm physical urticarias.

Fig. 28.34 Urticaria. Erythema, reflecting dilated dermal vessels, and oedema (with upper dermal oedema obscuring the erythema centrally) are evident. Note the absence of epidermal changes.

Management

Removal or treatment of any trigger is essential, although this may not be identified in the majority of cases. Urticaria may be precipitated by aspirin, NSAIDs, codeine and opioids, and it is advisable to suggest alternatives such as paracetamol. In chronic urticaria, non-sedating antihistamines, such as fexofenadine, loratadine or cetirizine, are usually beneficial. If, after 2 weeks, there is lack of response, an alternative non-sedating antihistamine should be used and an H_2-blocker, such as cimetidine or ranitidine, is often added. Mast cell stabilisers or leukotriene receptor antagonists, such as montelukast, may be added for more recalcitrant disease. For chronic urticaria, narrowband UVB phototherapy is valuable. Systemic corticosteroids are widely prescribed for urticaria, but often need to be used at high doses and are only appropriate for occasional short courses. Patients with a history of life-threatening anaphylaxis, as in peanut or wasp sting allergy, should carry a self-administered adrenaline (epinephrine) injection kit. The management of anaphylaxis and hereditary angioedema is discussed on pages 92 and 94.

BULLOUS DISEASES

Blistering can occur at any level in the skin and, as such, there are a variety of different presentations, depending on the underlying defect and level of involvement. Our knowledge of the molecular basis of many blistering disorders has considerably advanced as we come to understand the processes of cutaneous cell

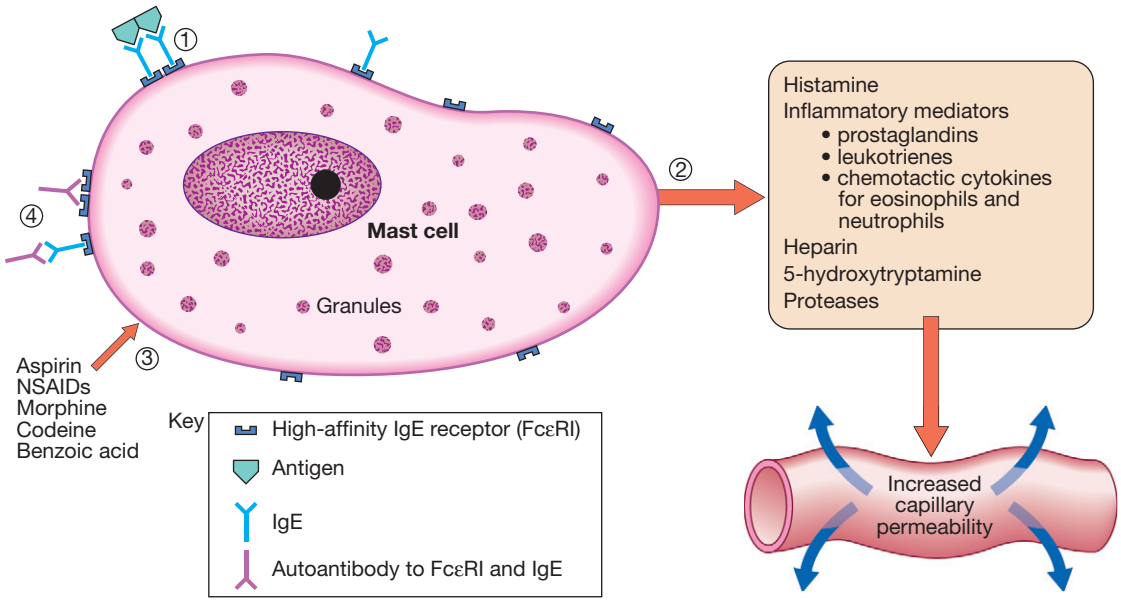

Fig. 28.35 Pathogenesis of urticaria. Mast cell degranulation occurs in a variety of ways. (1) Type I hypersensitivity causes degranulation. (2) Spontaneous mast cell degranulation in chronic urticaria. (3) Chemical mast cell degranulation. (4) Autoimmunity, with IgE antibodies directed against IgE receptors or IgE itself. Histamine and the leukotrienes are especially relevant mediators in urticaria. Heparin release is probably not a major factor in urticaria, but plays a role in the osteoporosis frequent in the mastocytoses (conditions of excess mast cells).

28.32 Classification of epidermolysis bullosa

Type	Mode of inheritance	Level of blister*	Abnormality
Simple	Autosomal dominant	Epidermal basal cell	Keratins 5 and 14
Junctional	Autosomal recessive	Lamina lucida	Laminin-5 and α_6 β_4 integrin
Dystrophic	Autosomal dominant and recessive	Dermis below lamina densa	Collagen VII

*See Fig. 28.1, p. 1253.

adhesion. Studies of the rare genetic blistering disorders, particularly epidermolysis bullosa, which present at birth (Box 28.32) have facilitated this. This section concentrates on primary blistering skin diseases.

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is a medical emergency, as the extensive mucocutaneous blistering is associated with a high mortality rate. It is usually drug-induced (see Box 28.44, p. 1304), particularly by anticonvulsants, sulphonamides, sulphonylureas, NSAIDs, allopurinol and antiretroviral therapy. Usually 1–4 weeks after drug commencement, the patient becomes systemically unwell and often pyrexial, and erythema and blistering develop, initially on the trunk but rapidly involving all skin. Sheets of blisters coalesce and denude, and the underlying skin is painful and erythematous (Fig. 28.36). Mucous membrane involvement and blistering are usual. A disease severity score (Box 28.33) is used to predict outcome. The main differential diagnosis is SSSS (p. 1276), although the diagnosis is usually obvious in an adult patient with a culprit drug. Skin snip allows early diagnosis and is preferred to full-thickness skin biopsy in the acute stage.

Identification and discontinuation of the causative drug are essential. Intensive care in a dedicated dermatology ward or intensive care or burns unit is of paramount importance. Treatment is supportive, with regular sterile dressings and emollients, careful attention to fluid balance and monitoring for infection. Urethral and ocular involvement is common and must be looked for and treated symptomatically, as ocular and urethral scarring in survivors can be problematic. Sepsis and multi-organ failure are major risks. Systemic corticosteroids are contraindicated, as they are associated with increased mortality. Intravenous immunoglobulins have been studied but there is no good evidence for improved outcomes (Box 28.34).

Fig. 28.36 Toxic epidermolytic necrolysis. Note the extensive erythema, oedema and epidermal loss secondary to carbamazepine.

28.33 Disease severity score for toxic epidermal necrolysis (TEN): SCORTEN

Factor

- Age > 40 yrs
- Heart rate > 120 beats/min
- Cancer or haematological malignancy
- Involved body surface area > 10%
- Blood urea > 10 mmol/L (28 mg/dL)
- Serum bicarbonate < 20 mmol/L (20 meq/L)
- Blood glucose ≥ 14 mmol/L (252 mg/dL)

Mortality rates

- 0–1 factor present = 3%
- 2 factors = 12%
- 3 factors = 35%
- 4 factors = 58%
- ≥ 5 factors = 90%

Bastuji-Garin S, et al. J Invest Dermatol 2000; 115:149–153.

EBM 28.34 Intravenous immunoglobulin (IVIg) for toxic epidermal necrolysis

'The treatment of TEN involves stopping likely drug causes and supportive management. Although it is sometimes used, there is no good evidence of benefit from IVIg. Randomised studies of such interventions are needed.'

- Huang YC, et al. Br J Dermatol 2012; 167:424–432.

Immunobullous diseases

The age of the patient may be informative in suspected immunobullous disease (Box 28.35). The key investigation is an elliptical biopsy taken from the edge of a recent blister (Box 28.36). The sample is halved and one half put in formalin for subsequent histology, whilst the other is sent fresh for direct immunofluorescence. Serum should also be sent for indirect immunofluorescence in suspected immunobullous disease (p. 1255). Several of these blistering disorders are associated with underlying diseases, which should be considered. Many patients will require immunosuppression. Blister fluid should always be sent for culture to exclude viral or bacterial infection.

Bullous pemphigoid

Bullous pemphigoid (BP) is the most common immunobullous disease and occurs worldwide. It is a disease of the elderly, with an average age of onset of 65 years; males and females are equally affected. A range of

autoantibodies develop, the best characterised being antibodies BP-230 and BP-180, directed against the hemi-desmosomal BP antigens, BPAg-1 (intracellular) and BPAg-2 (transmembranous type XVII collagen), respectively. Antibody–antigen binding initiates complement activation and inflammation, hemi-desmosomal damage and consequent subepidermal blistering.

28.35 Age of onset in immunobullous skin disorders

Disease	Age
Pemphigus vulgaris	40–60 yrs
Pemphigus foliaceus	Any age (endemic form, e.g. in parts of Brazil and South Africa, from teenage years on)
Bullous pemphigoid	60s and over
Dermatitis herpetiformis	Young, associated with coeliac disease
Linear IgA disease	Any age
Pemphigoid gestationis	Pregnant females
Epidermolysis bullosa acquisita	Any age
Bullous lupus erythematosus	Young black female

Clinical features and diagnosis

There is often a lengthy prodrome of an itchy, urticated, erythematous rash prior to the development of tense bullae (Fig. 28.37A). Milia may develop due to basement membrane disruption. Mucosal involvement is uncommon. Histology shows subepidermal blistering with an eosinophil-rich inflammatory infiltrate. Direct immunofluorescence demonstrates the presence of IgG and C3 at the basement membrane (Fig. 28.37B). Indirect immunofluorescence may show positive titres of circulating anti-epidermal antibodies. Distinction from epidermolysis bullosa acquisita requires immunofluorescence studies using the patient's serum on salt-split skin. In BP, the immunoreactants localise to the epidermal side (hemi-desmosome) of split skin, whereas in epidermolysis bullosa acquisita they localise to the base of the split (type VII collagen/anchoring fibrils).

Management

Very potent topical steroids to all sites may be sufficient in frail elderly patients (Box 28.37). Tetracyclines, such as doxycycline, have an important role and may limit the use of systemic corticosteroids. However, most require systemic corticosteroids, often combined with azathioprine. There is evidence to support the use of intravenous immunoglobulin as a steroid-sparing therapy in BP. The condition often burns out over a few years.

28.36 Clinical and investigation findings in the immunobullous disorders

Disease	Site of blisters	Nature of blisters	Mucous membrane involvement	Antigen	Circulating antibody (indirect IF)	Fixed antibody (direct IF)
Pemphigus vulgaris	Trunk, head	Flaccid, fragile, many erosions	100%	Desmoglein-1 and 3 (120 kD)	IgG	IgG, C_3 intercellular (epidermal)
Pemphigus foliaceus	Trunk	Often not present, multiple erosions, may mimic dermatitis	No	Desmoglein-1	IgG	IgG, C_3 intercellular (epidermal)
Bullous pemphigoid	Trunk, flexures and limbs	Tense, milia as resolve	Occasional	BP-230 and 180	IgG (70%)	IgG, C_3 at BMZ
Dermatitis herpetiformis	Elbows, lower back, buttocks	Excoriated and often not present	No	Unknown	Anti-endomysial and tissue transglutaminase	Granular IgA in papillary dermis
Linear IgA disease	Widespread	Tense, often annular configuration, 'string of beads'	Frequent	Unknown	50% have low titres of circulating antibody	Linear IgA at BMZ
Pemphigoid gestationis	Periumbilical and limbs	Tense, milia as resolve	Rare	Collagen XVII (part of hemi-desmosome, BP-180)	Circulating antibodies to BP-180 (type XVII collagen) (and BP-230)	C_3 at BMZ
Epidermolysis bullosa acquisita	Widespread	Tense, scarring, milia	Common (50%)	Type VII collagen	IgG (anti-type VII collagen)	IgG at BMZ
Bullous lupus erythematosus	Widespread	Tense	Rare	Type VII collagen	Anti-type VII collagen	IgG, IgA, IgM at BMZ

(BMZ = basement membrane zone; IF = immunofluorescence)

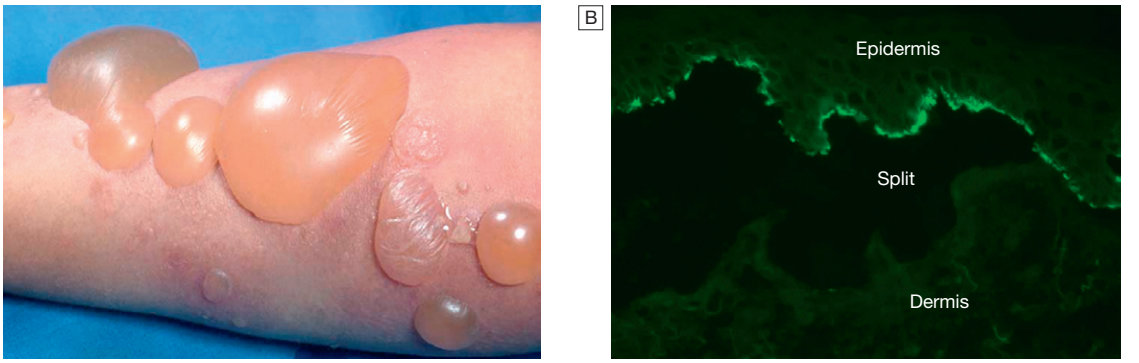

Fig. 28.37 Bullous pemphigoid. A Large, tense, unilocular blisters. B Immunofluorescence on salt-split skin, showing a subepidermal blister and linear IgG and C3 deposition at the basement membrane zone.

EBM 28.37 Treatment of bullous pemphigoid

'Very potent topical corticosteroids are effective. However, in extensive disease, applications by patients or carers may be difficult. If systemic corticosteroids are needed, there is generally no advantage in using doses greater than 0.75 mg/kg/day of prednisolone.'

- Kirtschig G, et al. Interventions for bullous pemphigoid. Cochrane Database of Systematic Reviews, 2010, issue 10. Art. no.: CD002292.

Pemphigus

Pemphigus is less common than BP and patients are usually younger. Typically, IgG1 and IgG4 autoantibodies, directed against desmogleins-1 and 3, develop, resulting in intra-epidermal blistering. Secondary causes are drugs (e.g. penicillamine or captopril) and underlying malignancy ('paraneoplastic pemphigus'). Pemphigus foliaceus is a very superficial form, in which antibodies are directed against desmoglein-1 only and affect just the most superficial epidermis.

Clinical features and diagnosis

Skin and mucosae are usually involved, although disease may be restricted to mucosae only, which may be severely affected. Due to the higher level of split within the epidermis, the blisters are flaccid, easily ruptured and often not seen intact. Erosions are common and the Nikolsky sign is positive. The trunk is usually affected. The condition is associated with significant morbidity and mortality. Histology shows intra-epidermal blistering and acantholysis, with positive direct immunofluorescence. The titres of circulating epidermal autoantibodies can also be used to monitor disease activity. Investigations should screen for associated autoimmune disease or malignancy if paraneoplastic pemphigus is suspected.

Management

Pemphigus is more difficult to control than BP and high-dose systemic corticosteroids are usually required. Azathioprine, cyclophosphamide and intravenous immunoglobulins may be used as steroid-sparing agents. Often, long-term treatment is required to prevent relapse.

Dermatitis herpetiformis

Dermatitis herpetiformis (DH) is an autoimmune blistering disorder that is strongly associated with gluten intolerance. Fewer than 10% of individuals with coeliac disease develop DH, although almost all patients with DH have evidence of partial villous atrophy on investigation, even if asymptomatic (p. 881). The pathogenesis is unknown.

Intact vesicles or blisters are often not seen, as the condition is so pruritic that excoriations on extensor surfaces of arms, knees, buttocks, shoulders and scalp may be the only signs.

Subepidermal vesiculation in the dermal papillae and a neutrophil- and eosinophil-rich infiltrate is seen histologically. Direct immunofluorescence shows granular IgA in the papillary dermis. Anti-endomysial antibodies and tissue transglutaminase should be assessed, and jejunal biopsy undertaken if indicated. A gluten-free diet may suffice but, if not, the condition is usually highly responsive to dapsone.

Linear IgA disease

This occurs in children (chronic bullous disease of childhood) and adults, and is usually self-limiting, although it can be active for a few years. Drugs, notably vancomycin, are a secondary cause. Blisters can arise on erythematous, urticated or otherwise normal-looking skin and often form an annular configuration at the edge of the lesion: 'clusters of jewels' (herpetiform) and 'string of beads' (annular/polycyclic). Mucosal involvement is common and ophthalmology input important, as long-term scarring is a risk. Linear IgA is seen at the basement membrane on direct immunofluorescence and localises to either roof or floor of salt-split skin. Dapsone, sulfapyridine, prednisolone, colchicine or intravenous immunoglobulin may be effective.

Epidermolysis bullosa acquisita

This chronic blistering disease affects skin and mucosae, and may be difficult to distinguish from other immunobullous blistering diseases. It is caused by an IgG antibody to type VII collagen, which provokes subepidermal blistering and a mixed inflammatory infiltrate. Blisters often follow trauma, and milia develop. The condition may be associated with inflammatory bowel disease, rheumatoid arthritis, multiple myeloma and

lymphoma. It is difficult to treat, as it often does not respond to immunosuppressants.

Porphyria cutanea tarda and pseudoporphyria

These conditions may also cause blistering (see Boxes 28.9 and 28.44, pp. 1260 and 1304).

PIGMENTATION DISORDERS

Decreased pigmentation

Disorders causing hypopigmentation and/or depigmentation include:

- vitiligo
- albinism
- pityriasis alba: depigmented areas on the face, particularly in children, with or without scale and usually considered to be eczematous
- pityriasis versicolor (p. 1280): hypopigmentation or, less commonly, hyperpigmentation can occur
- idiopathic guttate hypomelanosis: multiple small areas of depigmentation arising in chronically sun-exposed skin
- rarely, phenylketonuria (p. 449) and hypopituitarism.

Vitiligo

Vitiligo is an acquired condition affecting 1% of the population worldwide. Focal loss of melanocytes results in the development of patches of hypopigmentation. A positive family history of vitiligo is relatively common in those with extensive disease, and this type is also associated with other autoimmune diseases. Trauma and sunburn may (through the Köbner phenomenon) precipitate the appearance of vitiligo. The pathogenesis is unclear and, whilst melanocytes may be the target of a cell-mediated autoimmune attack, it is not known why only focal areas are affected.

Clinical features

Generalised vitiligo is often symmetrical and involves hands, wrists, knees and neck, as well as areas around body orifices (Fig. 28.38). The hair of the scalp, beard, eyebrows and lashes may also depigment. Segmental vitiligo is restricted to one part of the body but not necessarily a dermatome. The patches of depigmentation are sharply defined, and in Caucasians may be surrounded by hyperpigmentation. Spotty perifollicular pigment may be seen within the depigmentation and is often the first sign of repigmentation. Sensation in the depigmented patches is normal (unlike in tuberculoid leprosy, p. 347). Wood's light examination enhances the contrast between pigmented and non-pigmented skin. The course is unpredictable but most patches remain static or enlarge; a few repigment spontaneously.

Fig. 28.38 Vitiligo. Symmetrical localised patches of depigmented skin.

Management

Protecting the patches from excessive sun exposure with clothing or sunscreen may be helpful to avoid sunburn. Camouflage cosmetics may be beneficial, particularly in those with dark skin, as can potent topical corticosteroids. Phototherapy with narrowband UVB or PUVA can be used. Narrowband UVB is the most effective repigmentary treatment available for generalised vitiligo, but even very prolonged courses often do not produce a satisfactory outcome. The absence of leucotrichia (white hairs in the area of vitiligo) and a trichrome pattern (three colours – normal skin colour, hypopigmentation and depigmentation) are good prognostic features. Vitiligo on the face, trunk and proximal limbs is more likely to respond than that on hands and feet. Autologous melanocyte transfer, using a range of techniques including split-skin grafts and blister roof grafts, is sometimes used on dermabraded recipient skin.

The impact of vitiligo differs markedly between populations. In the Indian subcontinent, the effects are more readily discernible than in pale-skinned individuals in northern Europe. Depigmentation is also seen in Hansen's disease (leprosy), which means that individuals with vitiligo are often stigmatised.

Oculocutaneous albinism

Albinism results from a range of genetic abnormalities that lead to reduced melanin biosynthesis in the skin and eyes; the number of melanocytes is normal (in contrast to vitiligo). Albinism is usually inherited as an autosomal recessive trait and there are several different types and presentations.

Type 1 albinism is due to a defect in the tyrosinase gene, whose product is rate-limiting in the production of melanin. Affected individuals have an almost complete absence of pigment in the skin and hair at birth, with consequent pale skin and white hair, and failure of melanin production in the iris and retina. Patients have photophobia, poor vision not correctable with refraction, rotatory nystagmus, and an alternating strabismus associated with abnormalities in the decussation of nerve fibres in the optic tract.

A second form of albinism is due to a defect in the *P* gene, which encodes an ion channel protein in the melanosome. Patients may have gross reduction of melanin in the skin and in the eyes, but may be more mildly affected than type 1 albinos. Establishing the subtype of albinism requires genetic analysis, as there is considerable phenotypic heterogeneity.

Oculocutaneous albinos are at grossly increased risk of sunburn and skin cancer. In equatorial regions, many

die from SCC or, more rarely, melanoma in early adult life. Interestingly, they may develop pigmented melanocytic naevi and freckle in response to sun exposure.

Management

Strict photoprotection (p. 1261), with sun avoidance (including occupational exposure), clothing, hats and sunscreens, is important. Early diagnosis and treatment of skin tumours is essential.

Increased pigmentation

- *Diffuse hyperpigmentation*: most commonly due to hypermelanosis but other pigments may be deposited in the skin, e.g. orange discoloration with carotenaemia and bronze with haemochromatosis (p. 972).
- *Endocrine pigmentation*: may occur in several conditions. Melasma (chloasma) describes discrete patches of facial pigmentation that occur in pregnancy and in some women taking oral contraceptives. The mechanism for this localised increased hormonal sensitivity is unknown. Diffuse pigmentation, sometimes worse in the skin creases, may be a feature of Addison's disease (p. 777), Cushing's syndrome (p. 773), Nelson's syndrome (p. 776) and chronic renal failure due to increased levels of pituitary melanotrophic peptides, including adrenocorticotrophic hormone (ACTH, p. 776).
- *Photoexposed site hyperpigmentation*: occurs in some of the porphyrias and can be drug-induced.
- *Drug-induced pigmentation* (Box 28.38): may be diffuse or localised. It is not always due to hypermelanosis but sometimes is caused by deposition of the drug or a metabolite.
- *Focal hypermelanosis*: seen in lesions such as freckles and lentigines, characterised by focal areas of increased pigmentation.

Establishing the cause is important. Photoprotection may minimise the risk of increasing pigmentation. Topical hydroquinone preparations can be used for skin lightening in some types of hyperpigmentation, although caution is required, particularly in darker skin types.

28.38 Drug-induced pigmentation

Drug	Appearance
Amiodarone	Photo-exposed sites, slate-grey
Arsenic	Diffuse bronze pigmentation Raindrop depigmentation
Bleomycin	Usually flexural, brown
Busulfan	Diffuse brown
Chloroquine	Photo-exposed sites, blue-grey
Clofazimine	Red
Mepacrine	Yellow
Minocycline	Temples, shins, gingiva, sclera, scar sites, slate-grey
Phenothiazines	Photo-exposed sites, slate-grey
Psoralens	Photo-exposed sites, brown

HAIR DISORDERS

These can be subdivided into loss of hair (alopecia, Box 28.39) or excess hair (hirsutism or hypertrichosis), and alopecia into localised/diffuse and scarring/non-scarring. Common examples are described below. Examples of inflammatory scarring (lichen planus, discoid lupus) and non-scarring (tinea capitis, psoriasis, seborrhoeic eczema) alopecia are mentioned elsewhere.

Alopecia areata

The usual presentation of this common autoimmune disorder is as well-defined, localised, non-inflammatory, non-scarring patches of alopecia, usually on the scalp (Fig. 28.39). Pathognomonic 'exclamation mark' hairs are seen (broken hairs, tapering towards the scalp) during active hair loss. A diffuse pattern can uncommonly occur on the scalp. Eyebrows, eyelashes, beard and body hair can be affected. Alopecia totalis describes complete loss of scalp hair, and alopecia universalis is complete loss of all hair. Nail pitting may occur (p. 1298). Spontaneous regrowth is usual for small patches of alopecia but the prognosis is less good for larger patches, more extensive involvement, early onset and an association with atopy. In addition to atopy, alopecia areata is associated with other autoimmune diseases, particularly thyroid disease, and with Down's syndrome.

Androgenetic alopecia

Male-pattern baldness is physiological in men over 20 years old, although it can also occur in teenagers. It is also found in women, particularly post-menopause. Characteristically, this involves bitemporal recession initially and subsequent involvement of the crown ('male pattern'), although it is often diffuse in women.

28.39 Classification and causes of alopecia

Localised	Diffuse
Non-scarring	
Tinea capitis Alopecia areata Androgenetic alopecia Traumatic (trichotillomania, traction, cosmetic) Syphilis	Androgenetic alopecia Telogen effluvium Hypothyroidism Hyperthyroidism Hypopituitarism Diabetes mellitus HIV disease Nutritional (especially iron) deficiency Liver disease Post-partum Alopecia areata Syphilis Drug-induced, e.g. chemotherapy, retinoids
Scarring	
Idiopathic Developmental defects Discoid lupus erythematosus Herpes zoster Pseudopelade Tinea capitis/kerion Morphoea (en coup de sabre)	Discoid lupus erythematosus Radiotherapy Folliculitis decalvans Lichen planopilaris

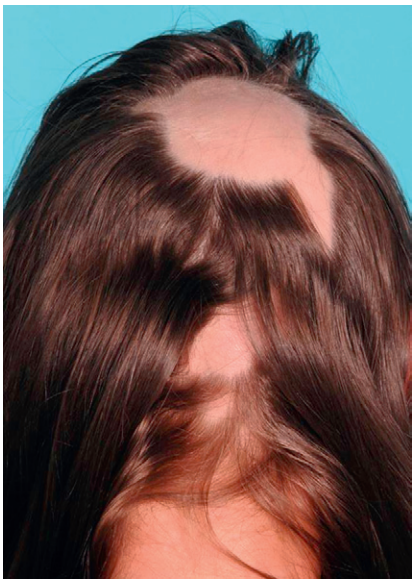

Fig. 28.39 Alopecia areata.

Investigations and management

Important investigations include full blood count, renal and liver function tests, iron studies, thyroid function, autoantibody screen and syphilis serology, as several systemic diseases, particularly iron deficiency and hypothyroidism, can cause diffuse non-scarring alopecia. Hair pull tests may help to establish the ratio of anagen to telogen hairs but require expertise for interpretation. Scrapings and pluckings are sent for mycology if there is localised inflammation. Scalp biopsy and direct immunofluorescence of a scarring alopecia may confirm a diagnosis of lichen planus or discoid lupus erythematosus, but expert interpretation is needed.

The impact of alopecia on quality of life must not be underestimated, and psychological support is required as treatment is difficult. It is important to establish realistic expectations. Underlying conditions must be treated. Alopecia areata may respond to topical or intralesional corticosteroids. Some males with androgenetic alopecia may be helped by systemic finasteride. Topical minoxidil can be used in males and females with androgenetic alopecia but, if an effect is obtained, treatment must be continued and is expensive. In females, anti-androgen therapy, such as cyproterone acetate, can be used. Wigs are often appropriate for extensive alopecia. Scalp surgery and autologous hair transplants are expensive but can be used for androgenetic alopecia.

Hypertrichosis

Hypertrichosis is a generalised or localised increase in hair and may be congenital or acquired. It can be primary or secondary: for example, to drugs such as ciclosporin, minoxidil or diazoxide, malignancy or eating disorders. Laser therapy or eflornithine, which inhibits ornithine decarboxylase and arrests hair growth whilst it is being used, may be helpful. When the hypertrichosis follows a male pattern, it is called hirsutism.

Hirsutism

Hirsutism is the growth of terminal hair in a male pattern in a female (p. 763). The cause of most cases is unknown and, while it may occur in hyperandrogenism, Cushing's syndrome and polycystic ovary syndrome, only a small minority of patients have a demonstrable hormonal abnormality. Psychological distress is often significant and oral contraceptives containing an anti-androgen (e.g. cyproterone acetate), laser therapy or topical eflornithine may be beneficial.

NAIL DISORDERS

The nails can be affected by both local and systemic disease. The nail apparatus consists of the nail matrix and the nail plate, which arises from the matrix and lies on the nail bed (Fig. 28.40). The cells of the matrix and, to a lesser extent the bed, produce the keratinous plate.

Important information may be obtained from nail fold examination, including dilated capillaries and ragged cuticles in connective tissue disease (Fig. 28.41) and the boggy inflammation of paronychia. The latter commonly occurs chronically in individuals undertaking wet work, in those with diabetes or poor peripheral circulation, and subsequent to increased cosmetic nail procedures and vigorous manicuring.

Common nail changes and disorders

Normal variants

Longitudinal ridging and beading of the nail plate occur with age. White transverse patches (striate leuconychia) are often caused by airspaces within the plate.

Effects of trauma

- *Nail biting/picking* is a very common habit. Repetitive proximal nail fold trauma (often thumb nail) results in transverse ridging and central furrowing of the nail.
- *Chronic trauma* from poorly-fitting shoes and sport can cause thickening and disordered growth of the nail (onychogryphosis) and subsequent ingrowing toenails.

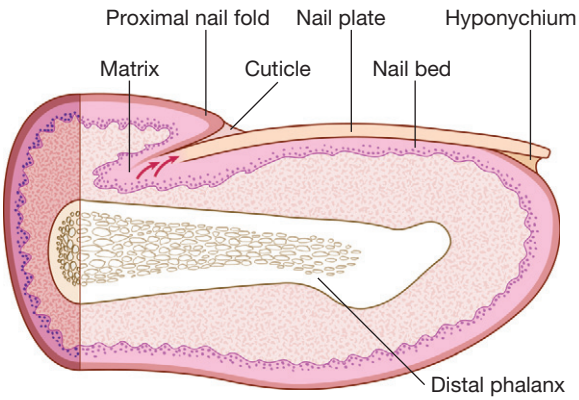

Fig. 28.40 **The nail plate and bed.** Arrows indicate the direction of nail growth.

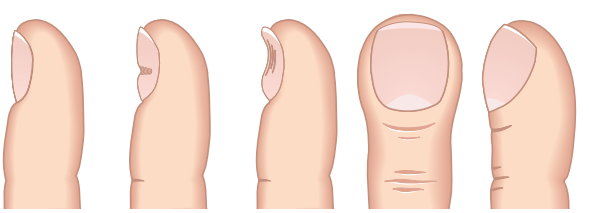
- *Splinter haemorrhages* are fine, linear, dark brown longitudinal streaks in the plate (see Fig. 18.93, p. 627). They are usually subsequent to trauma, especially if distal. Uncommonly, they can occur in nail psoriasis and are a hallmark of infective endocarditis (p. 625).
- *Subungual haematoma* is red, purple or grey–brown discoloration of the nail plate, usually of the big toe (Fig. 28.42). These haematomas are usually due to trauma, although a history of this may not be clear. The main differential is subungual melanoma, although rapid onset, lack of nail-fold involvement and proximal clearing as the nail grows are clues to the diagnosis of haematoma. If there is diagnostic doubt, a biopsy may be needed.

A

B

Fig. 28.41 Dermatomyositis. A Photoaggravation. B Note the prominent periungual involvement. Erythema, dilated and tortuous capillaries in the proximal nail fold, and ragged cuticles are features of connective tissue disease.

Fig. 28.42 Subungual haematoma.



The nails in common skin diseases

- *Dermatophyte infection/onychomycosis*: this is described on page 1280.
- *Psoriasis*: nail involvement is common (see Fig. 28.32B, p. 1287).
- *Eczema*: nails may be shiny due to rubbing skin. Fine pitting can occur. If there is periungual eczema, the nail may become dystrophic, with thickening and transverse ridging. Paronychia is common.
- *Lichen planus*: there may be longitudinal ridging and thinning of the nail, giving a sandpaper texture (trachyonychia), erythematous streaks (erythronychia), subungual hyperkeratosis, pigmentation and, in severe cases, pterygium and a destructive nail dystrophy.
- *Alopecia areata*: nail plate pitting and trachyonychia can occur.

Nail changes in systemic disease

The nails may be affected in many systemic diseases and important examples are detailed below:

- *Beau's lines*: horizontal ridges/indentations in nail plate occur simultaneously in all nails (Fig. 28.43B). They typically follow a systemic illness and are thought to be due to temporary growth arrest of cells in the nail matrix; they subsequently migrate out as the nail grows. Normal nail growth is approximately 0.1 mm/day for fingers and 0.05 mm/day for toes, so the timing of the systemic upset can usually be estimated by the position of the Beau's lines.
- *Koilonychia*: this concave or spoon-shaped nail plate deformity is due to iron deficiency (Fig. 28.43C).
- *Clubbing*: in the early stages, the angle between the proximal nail and nail fold is lost. In its more established form, there may be swelling of the distal digits (Figs 28.43D and E) or toe. Causes include bronchogenic carcinoma, asbestosis (especially with mesothelioma), suppurative or fibrosing lung disease, cyanotic congenital heart disease, infective endocarditis, inflammatory bowel disease, biliary cirrhosis and thyrotoxicosis; rarely, clubbing can be familial or idiopathic.
- *Nail discoloration:* whitening may occur in hypoalbuminaemia. 'Half-and-half' nails (white proximally and red/brown distally) may be found in renal failure. Drugs (e.g. antimalarials) occasionally discolour nails.

A B C D E

Fig. 28.43 The nail in systemic disease. A Normal nail. B Beau's line. C Koilonychia. D and E Digital clubbing.

The nail in congenital disease

Nails can be affected in congenital diseases, such as pachyonychia congenita, a rare, usually autosomal dominant, condition caused by mutations in differentiation-specific keratin genes 6A, 6B, 16 and 17. This results in palmoplantar keratoderma and gross nail discoloration and thickening, due to subungual hyperkeratosis, from birth.

SKIN DISEASE IN GENERAL MEDICINE

Many skin conditions present to other medical specialties. These are listed in Box 28.40 and the most common of those not discussed elsewhere are detailed below.

28.40 Skin problems in general medicine

Primary skin problems	
• Cellulitis	• Leg ulcers
• Vasculitis	• Pressure sores
Skin involvement in multisystem disease	
• Genetic (e.g. neurofibromatosis and tuberous sclerosis)	• Porphyria
	• Sarcoidosis
• Xanthomas	• SLE
• Amyloidosis	• Systemic sclerosis
Non-specific and variable skin reactions to systemic disease	
• Urticaria	• Pyoderma gangrenosum
• Erythema multiforme	• Sweet's syndrome
• Annular erythemas	• Generalised pruritus
• Erythema nodosum	
Skin conditions associated with malignancy	
• Dermatomyositis	• Acanthosis nigricans
• Generalised pruritus	• Superficial thrombophlebitis
Skin problems associated with specific medical disorders	
• Liver: generalised pruritus, pigmentation, spider naevi, palmar erythema, nail clubbing	
• Kidney: generalised pruritus, uraemic frost, pigmentation	
• Diabetes mellitus: necrobiosis lipoidica, diabetic dermopathy	
• Cutaneous Crohn's disease	
Skin problems secondary to treatment of systemic disease	
• Drug eruptions	
Miscellaneous	
• Granuloma annulare	• Morphoea

Conditions involving cutaneous vasculature

Vasculitis

Vasculitis usually presents as palpable purpura (see Fig. 25.42 and p. 1115). Causes include drugs, infection, connective tissue disease, malignancy and Henoch–Schönlein purpura. The diagnosis is confirmed by skin biopsy, with histology and immunofluorescence examination. Investigation should seek systemic involvement (particularly renal). Identification and removal or treatment of the cause is important but often difficult.

Neutrophilic dermatoses

These include pyoderma gangrenosum, Sweet's acute febrile neutrophilic dermatosis and the neutrophilic dermatosis of rheumatoid disease, and are characterised by intense inflammation, mainly consisting of neutrophils, around dermal blood vessels. There can be damage to vessels ('vasculopathy') but usually no frank vasculitis.

Pyoderma gangrenosum

The initial lesion of pyoderma gangrenosum (PG) is usually a painful, tender, inflamed nodule or pustule, which breaks down centrally and rapidly progresses to an ulcer with an indurated, undermined purplish or pustular edge (Fig. 28.44). Lesions may be single or multiple and are classified as ulcerative, pustular, bullous or vegetative. PG usually occurs in adults and, although it may occur in isolation, is usually associated with underlying disease, particularly inflammatory bowel disease, inflammatory arthritis, blood dyscrasias, immunodeficiencies and HIV infection. Investigation should be made with these associations in mind. The diagnosis is largely clinical, as histology is not specific. Analgesia, treatment of secondary bacterial infection and supportive dressings are important. Very potent topical corticosteroids or calcineurin inhibitors may be beneficial. Systemic treatment with tetracyclines, systemic steroids, dapsone, ciclosporin or other immunosuppressants is often required. Once healing has taken place, recurrences are typically only intermittent.

Fig. 28.44 Pyoderma gangrenosum. This young patient had Crohn's disease. Note the cribriform pattern of re-epithelialisation, which is characteristic of this condition.

Pressure sores

Localised, prolonged, pressure-induced ischaemia can lead to the development of pressure sores, which can occur in up to 30% of the hospitalised elderly. They are

associated with considerable morbidity, mortality and expense to health services. The main risk factors are immobility, poor nutrition, local tissue hypoxia – for example, with anaemia, peripheral vascular disease, diabetes, sepsis and skin atrophy – or barrier impairment, such as in eczema.

A localised area of erythema develops at sites of bony prominences (particularly sacrum, greater trochanter, ischial and calcaneal tuberosities, and lateral malleolus). This progresses to a blister and then erosion, which will develop into a deep necrotic ulcer, usually colonised by *Pseudomonas aeruginosa* if pressure is not alleviated.

Prevention is key and involves identification of at-risk patients and regular repositioning and use of pressure-relieving mattresses. Predisposing factors, such as anaemia and poor nutrition, should be corrected. Once established, significant infection must be treated and necrotic tissue debrided. Dressings encourage granulation and surgical intervention may be needed.

Connective tissue disease

Lupus erythematosus

The autoimmune disorder lupus erythematosus (p. 1109) can be subdivided into systemic lupus erythematosus (SLE) and cutaneous lupus, which includes discoid lupus (DLE) and subacute cutaneous lupus erythematosus (SCLE). DLE typically presents as scaly red plaques, with follicular plugging, usually on photo-exposed sites of the face, head and neck, which resolve with scarring and pigmentary change. If the scalp is involved, scarring alopecia occurs (Fig. 28.45). Most patients with DLE do not develop SLE. Patients with SCLE may have extensive cutaneous involvement, usually aggravated by sun exposure, with an annular, polycyclic or papulosquamous eruption. Systemic involvement is uncommon and the prognosis usually good. There is a strong association with antibodies to Ro/SS-A antigen. A diagnosis of cutaneous lupus is confirmed by histopathology and direct immunofluorescence. SLE is a serious multisystem disorder and cutaneous manifestations include photosensitivity with malar (butterfly) rash, Raynaud's phenomenon, chilblains, livedo reticularis and vasculitis. Investigations and management of SLE are outlined elsewhere on page 1111. The possibility of drug-induced lupus should always be considered (see Boxes 25.84, p. 1113; 28.43, p. 1303; and 28.44, p. 1304). Cutaneous lupus may respond to topical corticosteroids or immunosuppressants. Antimalarials and photoprotection are important in the management of cutaneous lupus, and systemic immunosuppression may be required for resistant disease. Paradoxically, low-dose UVA1 phototherapy can sometimes be effective for lupus.

Fig. 28.45 Scarring inflammatory alopecia. This patient had systemic lupus erythematosus and additional cutaneous features of scarring inflammatory discoid lupus erythematosus.

Systemic sclerosis

Systemic sclerosis is an autoimmune multisystem disease that usually presents in middle age and is characterised by progressive cutaneous and connective tissue sclerosis, vascular abnormalities and associated autoantibodies (p. 1112). The earliest feature is usually Raynaud's phenomenon, followed by progressive skin tightening and oedema. Constricted mouth opening and perioral radial furrows, with matted telangiectasiae and pigmentary change, are common. Fixed flexion deformities of the hands, ulceration, calcification, scarring and gangrene of digits may develop. Dilated nail-fold capillaries and ragged cuticles are the norm. Investigation and management are described on page 1113.

Morphoea

Morphoea is a localised cutaneous form of scleroderma that can affect any site at any age. It usually presents as a thickened violaceous plaque, which may become hyper- or hypopigmented. Plaques can become generalised. Linear forms exist and, if in the scalp, there will be scarring hair loss (en coup de sabre). There is no systemic involvement. Topical corticosteroids or immunosuppressants or phototherapy, particularly PUVA or UVA1, can be effective, and systemic immunosuppression may be used for resistant extensive disease.

Dermatomyositis

This is a rare multisystem disease, predominantly affecting skin, muscles and blood vessels (p. 1114). The cause is unknown. There may be an autoimmune mechanism in childhood cases, whereas in adults there is often an underlying malignancy. Dermatomyositis typically presents between 40 and 60 years and is more common in females. In juvenile patients, calcinosis often occurs. The typical cutaneous features are of a violaceous 'heliotrope' erythema periorbitally and involving the upper eyelids. There may be more extensive involvement, with violaceous erythema on the upper trunk and limbs, linear erythematous streaks on the back of hands and fingers, and papules over the knuckles (Gottron's papules). Tortuous dilated nail-fold capillaries, often best seen with a dermatoscope, and ragged cuticles are usually evident. Photoaggravation of the cutaneous features is often prominent (see Fig. 28.41, p. 1298). Tenderness and proximal muscle weakness are indicative of an inflammatory proximal myopathy. Other

systems, such as the respiratory tract, may be involved. Investigations include creatine kinase levels and searching for an underlying malignancy (p. 1115). Treatment usually requires high-dose corticosteroids and/or other immunosuppressants.

Granulomatous disease

Granuloma annulare

This is common and may be reactive, although a trigger is usually not apparent. The hallmark is the presence of dermal granulomas, which are usually palisading and associated with alteration of dermal collagen (necrobiosis). The condition is generally asymptomatic and may present as an isolated dermal lesion with a raised papular annular edge or be more generalised. An association between generalised disease and diabetes has been proposed but not confirmed. Lesions often resolve spontaneously. Intralesional steroids or cryotherapy can be used for localised disease, and UVB or UVA1 phototherapy or PUVA for generalised disease.

Necrobiosis lipoidica

This condition has some histological features in common with granuloma annulare, although necrobiosis predominates. The lesion has a characteristic yellow, waxy, atrophic appearance, often with violaceous edge (Fig. 28.46). Underlying blood vessels are easily seen because of tissue atrophy. Necrobiosis lipoidica typically appears on the shins and is prone to ulceration after trauma. There is a strong association with diabetes: most patients with necrobiosis lipoidica have or develop diabetes, although less than 1% of diabetic patients develop necrobiosis lipoidica. Treatment is difficult and includes potent topical or intralesional steroids, PUVA or UVA1 phototherapy and systemic immunosuppression.

Fig. 28.46 Necrobiosis lipoidica. Atrophic yellow plaques with violaceous edges, on the shins of a patient with diabetes mellitus.

Sarcoidosis

This condition is characterised by the presence of non-caseating granulomas. The cause is unknown, although infectious and genetic factors have been proposed. It is usually a multisystem disease (p. 709), with skin lesions in about one-third of patients. Cutaneous features can occur in isolation and include violaceous infiltrated dermal plaques and nodules, which can affect any site but particularly digits and nose (lupus pernio), more generalised hyper-/hypopigmented or annular papules and plaques, infiltrative changes in scars and erythema nodosum (see Fig. 19.60. p. 710). It is more common and often more severe in black Africans and African–Americans. Investigation and management are described on page 711. Cutaneous disease may respond to topical or intralesional steroids, cryotherapy, UVA1, laser or PDT (p. 1269). Systemic disease usually requires systemic corticosteroids and/or other immunosuppressants. Responses to anti-TNF biological therapies are reported.

Cutaneous Crohn's disease

Cutaneous Crohn's disease (p. 897) is rare but may present as perianal and peristomal infiltrative plaques, lymphoedema, sinuses or fistulae, and oral granulomatous disease. These changes are termed 'metastatic' Crohn's and histology shows non-caseating granulomas. Reactive skin changes can also occur (e.g. erythema nodosum and pyoderma gangrenosum, pp. 1299 and 1303). Treatment is of the underlying disease (p. 902).

Metabolic disease

Porphyrias

The porphyrias (described on p. 458) are a diverse group of diseases, each due to insufficient activity of an enzyme in the porphyrin–haem biosynthetic pathway. Those that cause skin features do so because porphyrins in the skin absorb visible light. The most common skin presentations are photoexposed site blistering and fragility, and pain on daylight exposure.

Photoexposed site blistering and fragility

Acquired porphyria cutanea tarda (PCT) is the most common porphyria to cause these symptoms (and, in most parts of the world, the most common of all the porphyrias). PCT is due to a chronic liver disease (e.g. alcohol, hepatitis C), in combination with liver iron overload. Recognition is important, as the underlying liver disease is usually only diagnosed on investigation of the skin presentation. Typical features are increased skin fragility, blistering erosions, hypertrichosis and milia occurring on light-exposed areas, such as the backs of the hands (Fig. 28.47). Other features may include facial hypertrichosis, hyperpigmentation and morphoea-like changes. Other porphyrias that can cause similar skin features include variegate porphyria and hereditary coproporphyria. It is important not to miss these, as acute neurovisceral attacks (which never occur in PCT) are possible, often triggered by drugs (p. 1303). Pseudoporphyria usually presents like PCT but is most frequently caused by a drug (commonly naproxen; see Box 28.44, p. 1304) or by sunbed use. 'Uraemic porphyria' in renal failure presents like PCT but is caused by raised porphyrins due to impaired elimination rather than an enzyme defect.

Fig. 28.47 Porphyria cutanea tarda. Skin fragility, blistering, scarring, milia and hypertrichosis on the back of hands and fingers in a patient with hepatitis C.

Pain on daylight exposure

Erythropoietic protoporphyria is a rare inherited porphyria but is important to consider. The presentation is usually in early childhood, although the diagnosis is often delayed, in part because physical signs are often minimal despite the prominence of symptoms on sunlight exposure. Erythropoietic protoporphyria is due to ferrochelatase deficiency, which leads to accumulation of lipid-soluble protoporphyrins in the skin. Multiple pigment gallstones, anaemia (usually only problematic if it is misdiagnosed as being caused by iron deficiency) and, rarely, severe liver disease can occur.

Abnormal deposition disorders

Xanthomas

Deposits of fatty material in the skin, subcutaneous fat and tendons may be the first clue to primary or secondary hyperlipidaemia (see p. 453 and Fig. 16.15).

Amyloidosis

Cutaneous amyloid may present as periocular plaques in primary systemic amyloidosis (p. 86) and amyloid associated with multiple myeloma, but is uncommon in systemic amyloidosis secondary to rheumatoid arthritis or other chronic inflammatory diseases. Amyloid infiltration of blood vessels may manifest as 'pinch purpura' following skin trauma. Macular amyloid is more common in darker skin types and appears as pruritic grey/brown macules or patches, usually on the back. Potent topical steroids can be beneficial, although it is often treatment-resistant.

Genetic disorders

Neurofibromatosis

This is described in detail on page 1215.

Tuberous sclerosis

This is an autosomal dominant condition, with two genetic loci identified: *TSC-1* (chromosome 9), encoding hamartin, and *TSC-2* (chromosome 16), encoding tuberin. The hallmark is of hamartomas in many systems. The classic triad of clinical features comprises learning disability, epilepsy and skin lesions but there is marked heterogeneity in clinical features. Skin changes include pale oval (ash leaf) macules that occur in early childhood; yellowish/pink papules in the mid-face (angiofibromas, 'adenoma sebaceum'), occurring in adolescence; periungual and subungual fibromas; and connective tissue naevi (shagreen patches, often on lower back). Gum hyperplasia, retinal phakomas (fibrous overgrowths), renal, lung and heart tumours, cerebral gliomas and calcified basal ganglia may also occur.

Reactive disorders

Erythema multiforme

Erythema multiforme has characteristic clinical and histological features and can be triggered by a variety of factors (Box 28.41); a cause is not always identified. The disease is a reaction pattern and likely to have an immunological basis. Lesions are multiple, erythematous, annular, targetoid 'bull's eyes' (Fig. 28.48) and may blister. Stevens–Johnson syndrome (pp. 1264 and 1302) is a severe form of erythema multiforme with marked

28.41 Provoking factors in erythema multiforme

Infections
• Viral, e.g. herpes simplex, orf, infectious mononucleosis, hepatitis B, HIV • *Mycoplasma* and other bacterial infections
Drugs
• e.g. Sulphonamides, penicillins, barbiturates and carbamazepine
Systemic disease
• Sarcoidosis, malignancy, SLE
Other
• Radiotherapy, pregnancy

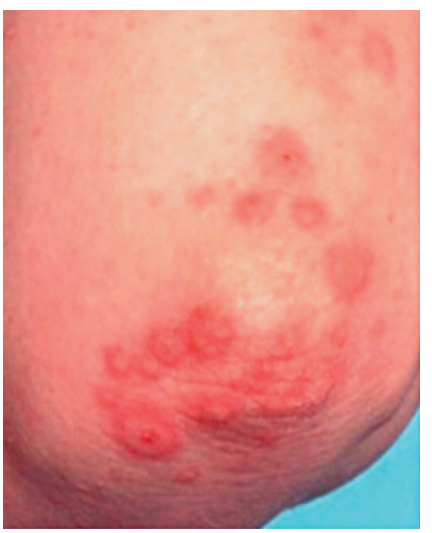


Fig. 28.48 Erythema multiforme in a young woman. Herpes simplex virus infection was the trigger.

blistering, mucosal involvement (mouth, eyes and genitals) and systemic upset.

Identification and removal/treatment of any trigger are essential. Analgesia and topical steroids may provide symptomatic relief. Supportive care is required in Stevens–Johnson syndrome, including ophthalmology input. Systemic corticosteroids may increase risk of infection and a role for intravenous immunoglobulins is controversial.

Erythema nodosum

This is characterised histologically by a septal panniculitis of subcutaneous fat (see Fig. 19.60, p. 710). An identified trigger is often present (Box 28.42). Lesions are typically painful, indurated violaceous nodules on the shins and lower legs. Systemic upset, arthralgias and fever are common. Spontaneous resolution occurs over a month or so, leaving bruise-like marks. Any underlying cause should be identified and removed or treated. Bed rest, leg elevation and oral NSAIDs may offer symptomatic relief. Systemic corticosteroids are uncommonly required and must be avoided in infection. Dapsone and potassium iodide have been effective for stubborn disease.

28.42 Provoking factors in erythema nodosum

Infections

- Bacteria, e.g. streptococci, mycobacteria, *Brucella*, *Mycoplasma*, *Rickettsia*, *Chlamydia*
- Viruses, e.g. hepatitis B and infectious mononucleosis
- Fungi

Drugs

- e.g. Sulphonamides, sulphonylureas, oral contraceptives

Systemic disease

- e.g. Sarcoidosis, inflammatory bowel disease, malignancy

Acquired reactive perforating dermatosis

The hallmark of this condition is transepidermal elimination of dermal material, particularly collagen and elastic tissue. It presents as keratotic papules, particularly in patients with diabetes and chronic renal disease. Treatment with topical steroids, retinoids, PUVA or UVA1 therapy may help. There are other related perforating dermopathies, with characteristic histology.

Annular erythemas

This group of chronic, poorly defined, annular, erythematous and often scaly eruptions can be further subdivided and may be secondary to an identifiable cause. Erythema chronicum migrans can be associated with Lyme disease (*Borrelia burgdorferi*) (p. 334). Erythema marginatum can occur in rheumatic fever (p. 614) or Still's disease (p. 1104). Erythema gyratum repens typically presents as concentric circles of erythema and scale with an advancing edge and is usually associated with underlying malignancy. Erythema annulare centrifugum presents with expanding, scaly, erythematous rings, with central fading. A trigger may not be apparent but possible associations include fungal infection, drugs, autoimmune or endocrine diseases, such as lupus or thyroid disease, and malignancy, particularly haematological. An underlying trigger must be sought and removed/treated. Topical steroids or phototherapy may be helpful for chronic disease.

Acanthosis nigricans

Hyperkeratosis and pigmentation are typical and affected sites have a velvety texture. The flexures, especially axillae and, in dark-skinned people, sides of neck, are involved (pp. 271, 272, 798). There are several types, all associated with insulin resistance. Most often, acanthosis nigricans is found in conjunction with obesity and regresses with weight loss. It can be associated with malignancy, usually adenocarcinoma (particularly gastric), when it is usually more extensive and pruritic, and can involve mucous membranes.

Drug eruptions

Virtually all drugs may have cutaneous adverse effects (Fig. 28.49) and this should be considered in the

Fig. 28.49 Drug eruption. Always think about possible drug causes of any rash. This was doxycycline-induced photosensitivity in a farmer.

28.43 Types of drug eruption

Non-immunological (non-allergic)

All are predictable.

- Striae due to corticosteroids (see Fig. 28.8, p. 1265)
- Asteatosis with statins
- Candidal infections with antibiotics
- Worsening of psoriasis with lithium, β-blockers, antimalarials, NSAIDs
- Urticaria with aspirin due to mast cell degranulation
- Bradykinin-mediated angioedema due to ACE inhibitors
- Doxycycline photosensitivity
- Dapsone haemolysis

Immunological (allergic)

- Immediate IgE-mediated hypersensitivity (type I): penicillin-induced urticaria and anaphylaxis
- Antibody-mediated (type II): penicillin-induced haemolysis
- Immune complex-mediated (type III): drug-induced serum sickness or vasculitis
- Delayed hypersensitivity (type IV): drug-induced erythema multiforme, lichenoid or pemphigus-like reaction; drug-induced lupus, e.g. thiazide

28.44 Clinical patterns of drug eruptions

Reaction pattern	Clinical features	Examples of causative drugs
Exanthematous	Erythema, maculopapular	Antibiotics (especially ampicillin), anticonvulsants, gold, penicillamine, NSAIDs, carbimazole, biological therapies, e.g. adalimumab
Urticaria and angioedema	Sometimes accompanied by angioedema Angioedema alone	Salicylates, opiates, NSAIDs, antibiotics, dextran ACE inhibitors
Lichenoid	Violaceous, lichen planus-like, dyspigmentation	Gold, penicillamine, antimalarials, thiazides, NSAIDs, β-blockers, ACE inhibitors, sulphonamides, lithium, sulphonylurea, proton pump inhibitors, quinine, antituberculous, dyes in colour developers
Purpura and vasculitis	Palpable purpura and necrosis	Allopurinol, antibiotics, ACE inhibitors, NSAIDs, aspirin, anticonvulsants, diuretics, oral contraceptives
Erythema multiforme	Target-like lesions and bullae on extensor aspects of limbs	See Box 28.41, p. 1302
Erythema nodosum	Tender, painful, dusky, erythematous nodules on shins	See Box 28.42, p. 1303
Exfoliative dermatitis	May be erythroderma	Allopurinol, carbamazepine, barbiturates, penicillins, PAS, isoniazid, gold, lithium, penicillamine, ACE inhibitors
Toxic epidermal necrolysis	Rapid evolution, extensive blistering, erythema, necrolysis, mucosal involvement	Anticonvulsants, antibiotics, especially sulphonamides, NSAIDs, terbinafine, sulphonylureas, antiretrovirals, allopurinol
Photosensitivity (p. 1260)	Photo-exposed site rash, may be sunburn-like, exfoliation, lichenoid	Thiazides, amiodarone, quinine, NSAIDs, tetracyclines, fluoroquinolones, phenothiazines, sulphonamides, retinoids, psoralens
Drug-induced lupus	Photosensitivity, discoid lesions, urticarial or erythema multiforme-like. May have positive lupus serology and anti-histone antibodies	Allopurinol, thiazides, ACE inhibitors, PAS, anticonvulsants, β-blockers, gold, hydralazine, minocycline, penicillamine, lithium
Psoriasiform rash	Rash like psoriasis	See Box 28.28 (p. 1286)
DRESS	Facial oedema, fever, extensive rash, lymphadenopathy, eosinophilia and systemic involvement, e.g. hepatitis	Anticonvulsants, trimethoprim, minocycline, allopurinol, dapsone, terbinafine
AGEP/toxic pustuloderma	Rapid onset of sterile, non-follicular pustules on erythematous base	Ampicillin/amoxicillin, erythromycin, quinolones, sulphonamides, terbinafine, diltiazem, hydroxychloroquine
Acneiform eruptions	Rash resembles acne	Lithium, anticonvulsants, oral contraceptives, androgenic or glucocorticoid steroids, antituberculous drugs, EGFR-antagonists, e.g. cetuximab
Pigmentation		See Box 28.38 (p. 1296)
Bullous eruptions	Often at pressure sites and may be other features, e.g. purpura, milia	Barbiturates, penicillamine
Pseudoporphyria	May be indistinguishable from porphyria cutanea tarda clinically	NSAIDS, tetracyclines, retinoids, furosemide, nalidixic acid
Exacerbation of acute hepatic porphyrias		See page 1301 Always check all drugs for safety of use in porphyrias against standard guidelines
Drug-induced immunobullous disease	May be like pemphigoid, pemphigus, dermatomyositis, scleroderma, epidermolysis bullosa acquisita	Penicillamine, ACE inhibitors, vancomycin
Fixed drug eruptions	Round/oval, erythema, oedema ± bullae Same site every time drug is given Pigmentation on resolution	Tetracyclines, sulphonamides, penicillins, quinine, NSAIDs, barbiturates, anticonvulsants
Hair loss	Diffuse	Cytotoxic agents, oral retinoids, anticoagulants, anticonvulsants, antithyroid drugs, lithium, oral contraceptives, infliximab
Hypertrichosis	Excessive hair growth in non-androgenic distribution	Diazoxide, minoxidil, ciclosporin

(ACE = angiotensin-converting enzyme; AGEP = acute generalised exanthematous pustulosis; DRESS = drug rash with eosinophilia and systemic symptoms; EGFR = epidermal growth factor receptor; NSAID = non-steroidal anti-inflammatory drug; PAS = para-aminosalicylic acid)

28.45 Diagnostic clues to drug eruptions

- Past history of reaction to suspected drug
- Introduction of suspected drug a few days to weeks before onset of rash
- Recent prescription of a drug commonly associated with rashes (e.g. penicillin, sulphonamide, thiazide, allopurinol)
- Symmetrical eruption that fits with a well-recognised pattern, caused by a current drug
- Resolution of rash following drug cessation

differential diagnosis of most presentations of skin disease. Drugs can exert their adverse effects via several mechanisms, which can be broadly subdivided into non-immunological and immunological (Box 28.43).

Clinical features

Cutaneous drug reactions typically present in specific patterns (Box 28.44). Non-immunologically mediated reactions can theoretically occur in anyone given sufficient exposure to drug, although idiosyncratic factors, such as genetic predisposition, may render some more susceptible. There is limited information on genetic determinants of drug responses and adverse effects, although advances have been made, e.g. with azathioprine (p. 1268). Immunologically mediated cutaneous drug eruptions typically commence within days to weeks of starting the drug. Detailed history-taking relating to prescribed and non-prescribed medications is essential and there may be other clues (Box 28.45).

Investigations and management

The suspected drug must be stopped. If drug-induced photosensitivity is considered, the patient should be phototested whilst on the drug to confirm the diagnosis; testing should be repeated after drug withdrawal to confirm resolution of photosensitivity (p. 1255). An eosinophilia and abnormalities in liver function tests may occur in adverse drug reactions and, for example, specific IgE to penicillin may be raised in penicillin-induced rash but, otherwise, specific investigations are not available. Rechallenge with drug is not usually undertaken unless the reaction is mild, as this can be risky. Drug withdrawal may not be straightforward and substitute drugs may be required. Antihistamines and/or topical or systemic corticosteroids may provide supportive management, depending on the type of cutaneous reaction. The management of anaphylaxis is described on page 92.

NOTES ON THE INTERNATIONAL SYSTEM OF UNITS (SI UNITS)

Système International (SI) units are a specific subset of the metre–kilogram–second system of units and were agreed upon as the everyday currency for commercial and scientific work in 1960, following a series of international conferences organised by the International Bureau of Weights and Measures. SI units have been adopted widely in clinical laboratories but non-SI units are still used in many countries. For that reason, values in both units are given for common measurements throughout this textbook and commonly used non-SI units are shown in this chapter. However, the SI unit system is recommended.

Examples of basic SI units

Length	metre (m)
Mass	kilogram (kg)
Amount of substance	mole (mol)
Energy	joule (J)
Pressure	pascal (Pa)
Volume	The basic SI unit of volume is the cubic metre (1000 litres). For convenience, however, the litre (L) is used as the unit of volume in laboratory work.

Examples of decimal multiples and submultiples of SI units

Factor	*Name*	*Prefix*
10^{6}	mega-	M
10^{3}	kilo-	k
10^{-1}	deci-	d
10^{-2}	centi-	c
10^{-3}	milli-	m
10^{-6}	micro-	μ
10^{-9}	nano-	n
10^{-12}	pico-	p
10^{-15}	femto-	f

Exceptions to the use of SI units

By convention, blood pressure is excluded from the SI unit system and is measured in mmHg (millimetres of mercury) rather than pascals.

Mass concentrations (e.g. g/L, μg/L) are used in preference to molar concentrations for all protein measurements and for substances which do not have a sufficiently well-defined composition.

Some enzymes and hormones are measured by 'bioassay', in which the activity in the sample is compared with the activity (rather than the mass) of a standard sample that is provided from a central source. For these assays, results are given in standardised 'units', or 'international units', which depend upon the activity in the standard sample and may not be readily converted to mass units.

LABORATORY REFERENCE RANGES IN ADULTS

Reference ranges are largely those used in the Departments of Clinical Biochemistry and Haematology, Lothian Health University Hospitals Division, Edinburgh, UK. Values are shown in both SI units and, where appropriate, non-SI units. Many reference ranges vary between laboratories, depending on the assay method used and on other factors; this is especially the case for enzyme assays. The origin of reference ranges and the interpretation of 'abnormal' results are discussed on pages 4–6. No details are given here of the collection requirements, which may be critical to obtaining a meaningful result. Unless otherwise stated, reference ranges shown apply to adults; values in children may be different.

Many analytes can be measured in either serum (the supernatant of clotted blood) or plasma (the supernatant of anticoagulated blood). A specific requirement for one or the other may depend on a kit manufacturer's recommendations. In other instances, the distinction is critical (e.g. plasma is required for measurement of fibrinogen, since it is largely absent from serum; serum is required for electrophoresis to detect paraproteins because fibrinogen migrates as a discrete band in the zone of interest).

29.1 Urea and electrolytes in venous blood

	Reference range	
Analysis	**SI units**	**Non-SI units**
Sodium	135–145 mmol/L	135–145 meq/L
Potassium*	3.6–5.0 mmol/L	3.6–5.0 meq/L
Chloride	95–107 mmol/L	95–107 meq/L
Urea	2.5–6.6 mmol/L	15–40 mg/dL
Creatinine	60–120 μmol/L	0.68–1.36 mg/dL

*Serum values are, on average, 0.3 mmol/L higher than plasma.

29.2 Analytes in arterial blood

	Reference range	
Analysis	**SI units**	**Non-SI units**
Bicarbonate	21–29 mmol/L	21–29 meq/L
Hydrogen ion	37–45 nmol/L	pH 7.35–7.43
***Pa*CO_2**	4.5–6.0 kPa	34–45 mmHg
***Pa*O_2**	12–15 kPa	90–113 mmHg
Oxygen saturation	> 97%	

29.3 Hormones in venous blood

Hormone	Reference range	
	SI units	Non-SI units
Adrenocorticotrophic hormone (ACTH) (plasma)	1.5–11.2 pmol/L (0700–1000 hrs)	7–51 ng/L
Aldosterone		
Supine (at least 30 mins)	30–440 pmol/L	1.09–15.9 ng/dL
Erect (at least 1 hr)	110–860 pmol/L	3.97–31.0 ng/dL
Cortisol	Dynamic tests are required – see Ch. 20	
Follicle-stimulating hormone (FSH)		
Male	1.0–10.0 U/L	0.2–2.2 ng/mL
Female	3.0–10.0 U/L (early follicular)	0.7–2.2 ng/mL
	> 30 U/L (post-menopausal)	> 6.7 ng/mL
Gastrin (plasma, fasting)	< 120 ng/L	< 120 pg/mL
Growth hormone (GH)	Dynamic tests are usually required – see Ch. 20 < 0.5 μg/L excludes acromegaly (if IGF1 in reference range) > 6 μg/L excludes GH deficiency	–
Insulin	Highly variable and interpretable only in relation to plasma glucose and body habitus	
Luteinising hormone (LH)		
Male	1.0–9.0 U/L	0.11–1.0 μg/L
Female	2.0–9.0 U/L (early follicular)	0.2–1.0 μg/L
	> 20 U/L (post-menopausal)	> 2.2 μg/L
17β-Oestradiol		
Male	< 160 pmol/L	< 43 pg/mL
Female: early follicular	75–140 pmol/L	20–38 pg/mL
post-menopausal	< 150 pmol/L	< 41 pg/mL
Parathyroid hormone (PTH)	1.6–7.5 pmol/L	16–75 pg/mL
Progesterone (in luteal phase in women)		
Consistent with ovulation	> 30 nmol/L	> 9.3 ng/mL
Probable ovulatory cycle	15–30 nmol/L	4.7–9.3 ng/mL
Anovulatory cycle	< 10 nmol/L	< 3 ng/mL
Prolactin (PRL)	25–630 mU/L	–
Renin concentration		
Supine (at least 30 mins)	5–40 mU/L	–
Sitting (at least 15 mins)	5–45 mU/L	–
Erect (at least 1 hr)	16–63 mU/L	–
Testosterone		
Male	10–30 nmol/L	2.9–8.6 ng/mL
Female	0.3–1.9 nmol/L	0.1–0.9 ng/mL
Thyroid-stimulating hormone (TSH)	0.2–4.5 mU/L	–
Thyroxine (free), (free T_4)	9–21 pmol/L	700–1632 pg/dL
Triiodothyronine (free), (free T_3)	2.6–6.2 pmol/L	160–400 pg/dL

Notes

1. A number of hormones are unstable and collection details are critical to obtaining a meaningful result. Refer to local laboratory handbook.
2. Values in the table are only a guideline; hormone levels can often only be meaningfully understood in relation to factors such as sex (e.g. testosterone), age (e.g. FSH in women), pregnancy (e.g. thyroid function tests, prolactin), time of day (e.g. cortisol) or regulatory factors (e.g. insulin and glucose, PTH and $[Ca^{2+}]$).
3. Reference ranges may be critically method-dependent.

(IGF1 = insulin-like growth factor 1)

29.4 Other common analytes in venous blood

Analyte	Reference range	
	SI units	Non-SI units
α_1-antitrypsin	1.1–2.1 g/L	110–210 mg/dL
Alanine aminotransferase (ALT)	10–50 U/L	–
Albumin	35–50 g/L	3.5–5.0 g/dL
Alkaline phosphatase	40–125 U/L	–
Amylase	< 100 U/L	–
Aspartate aminotransferase (AST)	10–45 U/L	–
Bilirubin (total)	3–16 µmol/L	0.18–0.94 mg/dL
Calcium (total)	2.1–2.6 mmol/L	4.2–5.2 meq/L or 8.5–10.5 mg/dL
Carboxy-haemoglobin	0.1–3.0%	–
Caeruloplasmin	0.16–0.47 g/L	16–47 mg/dL
Cholesterol (total)	Ideal level varies according to cardiovascular risk (see cardiovascular risk chart, p. 582), so reference ranges can be misleading. The following values were described by the European Atherosclerosis Society:	
Mild increase	5.2–6.5 mmol/L	200–250 mg/dL
Moderate increase	6.5–7.8 mmol/L	250–300 mg/dL
Severe increase	> 7.8 mmol/L	> 300 mg/dL
HDL-cholesterol	Ideal level varies according to cardiovascular risk, so reference ranges can be misleading. According to the National Cholesterol Education Programme Adult Treatment Panel III (ATPIII), a low HDL-cholesterol is:	
Low	< 1.0 mmol/L	< 40 mg/dL
Complement		
C3	0.73–1.4 g/L	–
C4	0.12–0.3 g/L	–
Total haemolytic complement	0.086–0.410 g/L	–
Copper	10–22 µmol/L	64–140 µg/dL
C-reactive protein (CRP)	< 5 mg/L Highly sensitive CRP assays also exist which measure lower values and may be useful in estimating cardiovascular risk	
Creatine kinase (CK; total)		
Male	55–170 U/L	–
Female	30–135 U/L	–
Creatine kinase MB isoenzyme	< 6% of total CK	–
Ethanol	Not normally detectable	
Marked intoxication	65–87 mmol/L	300–400 mg/dL
Stupor	87–109 mmol/L	400–500 mg/dL
Coma	> 109 mmol/L	> 500 mg/dL

Analyte	Reference range	
	SI units	Non-SI units
Gamma-glutamyl transferase (GGT)	Male 10–55 U/L Female 5–35 U/L	–
Glucose (fasting)	3.6–5.8 mmol/L See p. 808 for definitions of impaired glucose tolerance and diabetes mellitus, and p. 783 for definition of hypoglycaemia	65–104 mg/dL
Glycated haemoglobin (HbA_{1c})	4.0–6.0% 20–42 mmol/mol Hb See p. 808 for diagnosis of diabetes mellitus	–
Immunoglobulins (Ig)		
IgA	0.8–4.5 g/L	–
IgE	0–250 kU/L	–
IgG	6.0–15.0 g/L	–
IgM	0.35–2.90 g/L	–
Lactate	0.6–2.4 mmol/L	5.40–21.6 mg/dL
Lactate dehydrogenase (LDH; total)	125–220 U/L	–
Lead	< 0.5 µmol/L	< 10 µg/dL
Magnesium	0.75–1.0 mmol/L	1.5–2.0 meq/L or 1.82–2.43 mg/dL
Osmolality	280–296 mmol/kg	–
Osmolarity	280–296 mosm/L	–
Phosphate (fasting)	0.8–1.4 mmol/L	2.48–4.34 mg/dL
Protein (total)	60–80 g/L	6–8 g/dL
Triglycerides (fasting)	0.6–1.7 mmol/L	53–150 mg/dL
Troponins	Values consistent with myocardial infarction are crucially dependent upon which troponin is measured (I or T) and on the method employed. Interpret in context of clinical presentation. See p. 535	
Tryptase	0–135 mg/L	–
Urate		
Male	0.12–0.42 mmol/L	2.0–7.0 mg/dL
Female	0.12–0.36 mmol/L	2.0–6.0 mg/dL
Vitamin D, 25(OH)D		
Normal	> 50 nmol/L	> 20 ng/mL
Deficiency	< 14 nmol/L	< 5.6 ng/mL
Inadequate stores	< 25 nmol/L	< 10 ng/mL
Zinc	10–18 µmol/L	65–118 µg/dL

29.5 Common analytes in urine

Analyte	Reference range	
	SI units	Non-SI units
Albumin	Definitions of microalbuminuria are given on p. 476 Proteinuria is defined below	
Calcium (normal diet)	Up to 7.5 mmol/24 hrs	Up to 15 meq/24 hrs or 300 mg/24 hrs
Copper	< 0.6 μmol/24 hrs	< 38 μg/24 hrs
Cortisol	20–180 nmol/24 hrs	7.2–65 μg/24 hrs
Creatinine		
Male	6.3–23 mmol/24 hrs	712–2600 mg/24 hrs
Female	4.1–15 mmol/24 hrs	463–1695 mg/24 hrs
5-hydroxyindole-3-acetic acid (5-HIAA)	10–42 μmol/24 hrs	1.9–8.1 mg/24 hrs
Metadrenalines		
Normetadrenaline	0.4–3.4 μmol/24 hrs	73–620 μg/24 hrs
Metadrenaline	0.3–1.7 μmol/24 hrs	59–335 μg/24 hrs
Oxalate	0.04–0.49 mmol/24 hrs	3.6–44 mg/24 hrs
Phosphate	15–50 mmol/24 hrs	465–1548 mg/24 hrs
Potassium*	25–100 mmol/24 hrs	25–100 meq/24 hrs
Protein	< 0.3 g/L	< 0.03 g/dL
Sodium*	100–200 mmol/24 hrs	100–200 meq/24 hrs
Urate	1.2–3.0 mmol/24 hrs	202–504 mg/24 hrs
Urea	170–600 mmol/24 hrs	10.2–36.0 g/24 hrs
Zinc	3–21 μmol/24 hrs	195–1365 μg/24 hrs

*The urinary output of electrolytes such as sodium and potassium is normally a reflection of dietary intake. This can vary widely. The values quoted are appropriate to a 'Western' diet.

29.6 Analytes in cerebrospinal fluid

Analysis	Reference range	
	SI units	Non–SI units
Cells	< 5×10^6 cells/L (all mononuclear)	< 5 cells/mm^3
Glucose[1]	2.3–4.5 mmol/L	41–81 mg/dL
IgG index[2]	< 0.65	–
Total protein	0.14–0.45 g/L	0.014–0.045 g/dL

[1]Interpret in relation to plasma glucose. Values in CSF are typically approximately two-thirds of plasma levels.
[2]A crude index of increase in IgG attributable to intrathecal synthesis.

29.7 Analytes in faeces

Analyte	Reference range	
	SI units	Non-SI units
Calprotectin	< 50 μg/g	–
Elastase	> 200 μg/g	–

29.8 Haematological values

Analysis	Reference range	
	SI units	Non-SI units
Bleeding time (Ivy)	< 8 mins	–
Blood volume		
Male	65–85 mL/kg	–
Female	60–80 mL/kg	–
Coagulation screen		
Prothrombin time (PT)	10.5–13.5 secs	–
Activated partial thromboplastin time (APTT)	26–36 secs	–
D-dimers		
Interpret in relation to clinical presentation	< 230 ng/mL	–
Erythrocyte sedimentation rate (ESR)	Higher values in older patients are not necessarily abnormal	
Adult male	0–10 mm/hr	–
Adult female	3–15 mm/hr	–
Ferritin		
Male (and post-menopausal female)	20–300 µg/L	20–300 ng/mL
Female (pre-menopausal)	15–200 µg/L	15–200 ng/mL
Fibrinogen	1.5–4.0 g/L	0.15–0.4 g/dL
Folate		
Serum	2.8–20 µg/L	2.8–20 ng/mL
Red cell	120–500 µg/L	120–500 ng/mL
Haemoglobin		
Male	130–180 g/L	13–18 g/dL
Female	115–165 g/L	11.5–16.5 g/dL
Haptoglobin	0.4–2.4 g/L	0.04–0.24 g/dL
Iron		
Male	14–32 µmol/L	78–178 µg/dL
Female	10–28 µmol/L	56–157 µg/dL
Leucocytes (adults)	$4.0–11.0 \times 10^9$/L	$4.0–11.0 \times 10^3$/mm^3
Differential white cell count		
Neutrophil granulocytes	$2.0–7.5 \times 10^9$/L	$2.0–7.5 \times 10^3$/mm^3
Lymphocytes	$1.5–4.0 \times 10^9$/L	$1.5–4.0 \times 10^3$/mm^3
Monocytes	$0.2–0.8 \times 10^9$/L	$0.2–0.8 \times 10^3$/mm^3
Eosinophil granulocytes	$0.04–0.4 \times 10^9$/L	$0.04–0.4 \times 10^3$/mm^3
Basophil granulocytes	$0.01–0.1 \times 10^9$/L	$0.01–0.1 \times 10^3$/mm^3
Mean cell haemoglobin (MCH)	27–32 pg	–
Mean cell volume (MCV)	78–98 fl	–
Packed cell volume (PCV) or haematocrit		
Male	0.40–0.54	–
Female	0.37–0.47	–
Platelets	$150–350 \times 10^9$/L	$150–350 \times 10^3$/mm^3
Red cell count		
Male	$4.5–6.5 \times 10^{12}$/L	$4.5–6.5 \times 10^6$/mm^3
Female	$3.8–5.8 \times 10^{12}$/L	$3.8–5.8 \times 10^6$/mm^3
Red cell lifespan		
Mean	120 days	–
Half-life (^{51}Cr)	25–35 days	–
Reticulocytes (adults)	$25–85 \times 10^9$/L	$25–85 \times 10^3$/mm^3
Transferrin	2.0–4.0 g/L	0.2–0.4 g/dL
Transferrin saturation		
Male	25–56%	–
Female	14–51%	–
Vitamin B_{12}		
Normal	> 210 ng/L	–
Intermediate	180–200 ng/L	–
Low	< 180 ng/L	–

Index

Page numbers followed by an 'f' indicate index entries that relate to a figure; numbers followed by a 'b' indicate entries that relate to a box.

hepatocellular carcinoma, 967, 969f
non-alcoholic fatty liver disease, 926, 944b, 959–961, 960f
prognosis, 944–945, 944b
viral hepatitis, 949b
Cisplatin
bronchial carcinoma, 704
endometrial cancer, 281
gastric cancer, 879b
head and neck tumours, 282
and hypomagnesaemia, 448b
nephrotoxicity, 479–481, 522b
and peripheral neuropathy, 1223b
Citalopram, 244b, 290
Citric acid (Krebs) cycle, 128
Citrobacter spp., 151b
Citrobacter freundii, 303–304
CJD *see* Creutzfeld-Jakob disease
CK *see* Creatine kinase
Cladophialophora bantiana, 382–383
Cladophialophora carrionii, 381
Cladosporium spp., 671
Cladribine, 1041
Clarithromycin
drug interactions, 28b
Helicobacter pylori eradication, 874
leprosy, 350
Mycobacterium avium complex, 406b
pneumonia, 685b
in pregnancy, 154b
Clasp-knife phenomenon, 1145
Clathrin-coated pits, 48
Claude's syndrome, 1148b
Claudication
arm, 602
cauda equina, 1221b
intermittent, 601
Claw foot, 1076
Clearance, 22–23, 23f
CLI (critical limb ischaemia)
Climacteric, 757
Climate change, 102
Clindamycin, 151b
acne vulgaris, 1282
babesiosis, 358
bacterial vaginosis, 417b
gas gangrene, 305
malaria, 356
MRSA, 331
necrotising fasciitis, 305
in pregnancy, 154b
septic arthritis, 1095b
soft tissue infections, 305
Clinical audit, 15, 15b, 15f
Clinical decision making, 7–9
conflict of opinion, 12
end of life, 291–292
ethical analysis, 12–13, 13b
ethical issues, 11–12, 12f
heuristics, 8b
informed consent, 10–11
lack of capacity for, 11
Clinical endpoints, 39
Clinical ethics, 10–11
scenario, 13
see also Ethics
Clinical governance, 14b
Clinical pharmacology, 18–24
Clinical psychologist, 2b
Clinical trials, 32, 32f
CLM *see* Cutaneous larva migrans
CLO *see* Columnar lined (Barrett's) oesophagus
Clobazam, 1184b
Clobetasol, 416b, 418b, 1265b
Clobetasone butyrate, 1265b
eczema, 1285–1286
Clock drawing test, 1233f
Clofazimine
hyperpigmentation from, 1296b
leprosy, 349b, 350
Clomethiazole, effect of old age, 36b
Clomifene, 762, 764
Clomipramine, 244b
narcolepsy, 1187
Clonazepam
epilepsy, 1184b
multiple sclerosis, 1192b
periodic limb movement syndrome, 1188
sleep disorders, 1187
Clonidine
delirium, 203
diarrhoea, 833b
opiate withdrawal, 255
Clonorchiasis, 379b
Clonorchis spp., 163
Clonorchis sinensis, 312b, 378, 379b, 984–986
Clopidogrel
acute coronary syndrome, 594b
angina, 585
unstable, 594b
myocardial infarction, 594b, 599
peripheral arterial disease, 601b
pharmacokinetics, 25b
platelet inhibition, 1050
prophylactic, 599, 1245b, 1245f
stroke prevention, 1245b, 1245f
Clostridia, soft tissue infections, 305b
Clostridium spp., 136f–137f
Clostridium botulinum, 138b, 139, 1210
Clostridium difficile, 137f, 138b, 151b, 304b, 343–344, 344f
diarrhoea, 399
Clostridium novyi, injecting drug users, 299–300
Clostridium perfringens, 308
food poisoning, 342
intravascular haemolysis, 1031
septicaemia, 305
Clostridium tetani, 138b
Clotrimazole, 160b
erythrasma, 1278
genital candidiasis, 417b
Clotting *see* Coagulation
Clozapine
drug interactions, 28b
schizophrenia, 249b
Clubbing, digital, 1298, 1298f
congenital heart disease, 631
lung cancer, 271
Clue cells, 417f
Cluster headache, 1177, 1178b
CMAPs *see* Compound motor action potentials
